PASSENGER HANDLING FUNCTIONS IN AUTONOMOUS PUBLIC TRANSPORTATION

Dávid Földes[1], Csaba Csiszár[2]
[1,2] Budapest University of Technology and Economics (BME), Faculty of Transportation Engineering and Vehicle Engineering (KJK), Department of Transport Technology and Economics (KUKG) Budapest, Hungary

Abstract: Emerging infocommunication and vehicle technologies (e.g. autonomous vehicle) facilitate evolvement of autonomous public transportation in urban areas. It involves launching new service concepts (e.g. telematics-based shared demand responsive transportation), transformation of existing modes and automatization of passenger handling functions. However, there are debates about which processes how to be automatized. The aim is to replace human personnel by machines so as to improve service quality and decrease expenditures. The research questions were, how the functions are to be automatized and what the consequences are on both the machine and the human side. All the passenger handling functions, the existing and altering ones as well as the new functions have been investigated in process and system oriented approach. We have considered the most relevant technological novelties and their application opportunities, and then the required abilities (skills) of travelers. We have revealed correspondences among functions and human abilities. The shifting of intensities of human abilities (cognitive capability) have been estimated. Personnel groups with altering or new functions have been introduced and the functions of the replaced driver have been assigned to the groups or the machine components. Both the gains and the occurrent drawbacks have been assessed. The presented results appoint the research and innovation trends and directly facilitate the developments (e.g. design of smart devices and services as human-machine interface).

Keywords: passenger handling, automatization, autonomization, human abilities, cognitive capability.

1. Introduction

Mobility is to be considered as a complex service, not only providing transportation, infrastructure, etc., where humans are the key elements. Investigation of human components in the passenger transportation system is one of the most challenging tasks as perceptions are strongly heterogeneous, dynamic (evolves in time as an individual goes through different life stages), context dependent and also influenced by the environment. Several smart city and autonomous vehicle projects have already focused on either the city or the vehicle itself but not on the citizens or passengers, who are the end users of the services (Pribyl and Horak, 2015). On the other hand, the role of personnel (drivers, staff) is to be reduced and replaced by machines, where it is required or possible. As these two types of human components are strongly interrelated, introduction of autonomous vehicle (AV) based services requires and implies significant transformation of passenger transportation. The research questions were:

1. which functions and how to be automatized (opportunities)?
2. how does the future traveler's sensations and cogitation change?
3. what kind of modifications are possible in role of personnel?

The automatization in transportation has retrospected for decades. The first autopilot system in flight was introduced in 1912, the first automatic train operation started at 1967 in London. Air transportation has been always foregoer, as the functions and services are especially advanced and automatized (e.g. check-in, baggage sorting system). Nowadays, the manufacturers are developing autonomous road vehicles, which have been already introduced also in everyday operation. Generally, five stages are distinguished in development of AVs which has been identified how the driving tasks are transferred from human to machine. The technological development enables widespread automatization, however several aspects and issues are to be tackled (e.g. safety-security issues, acceptance of the new technologies). The major social impacts of AVs have been described: safer roads (less accidents), travel time reduction, more personalized services, improvement of energy efficiency and parking benefits (Fagnant and Kockelman, 2015).
The future urban mobility system is envisaged by scientific literature as follows: majority of the vehicles are electric, motorized transportation modes are served by autonomous vehicles (Godoy et al., 2015), most of the transportation modes merge into one 'new' integrated, telematics-based, shared mode, ownership of individual motorized vehicles is decreasing, the emphasis is taken on the service instead of the vehicle and sharp boundaries between infrastructure elements are also declining (e.g. AVs drive in buildings arriving as close to the destination as possible). Model about operation of fleet of Shared Autonomous Vehicles (SAV) has been elaborated by Fagnant and Kockelman (2014). According to the model each SAV travels to its final destination only if at least one passenger is carried on the board. The vehicles do not serve defined stop points between origin and destination. The concept of 'Mobility as a Service' (MaaS), which offers convenient door-to-door transportation without the need to own a private vehicle, covers tariff and payment integration, ICT integration and introduction of various mobility packages. An evaluation index about the level of mobility integration has been elaborated in order to compare MaaS systems (Kamargianni et al., 2016).
The future urban transportation modes have been revealed and summarized by Földes and Csiszár (2016). The individual cars are used for the most flexible travel purposes. The other modes (existing conventional public transportation services, demand responsive public transportation, car-sharing, taxi, chauffeur service, car-pooling, ride-

[1] Corresponding author: foldes.david@mail.bme.hu

sourcing) are merging into the new mode (Telematics-based Shared Demand Responsive Transportation - TS-DRT) and the ride-sharing gains more and more importance. A simulation model has been developed by Winter et al (2016) which determines the minimal and optimal fleet size with minimizing the total operational and travel costs for operating a demand responsive, autonomous shuttle service in a campus. The introduction steps of AVs and their effects have been investigated by Davidson and Spinoulas (2015). They found that the increasing share of AVs in the mixed traffic (AVs and manual cars on the road at the same time) causes worse traffic flow parameters at an early stage (Tettamanti et al., 2015), but after achieving homogeneous AV traffic, the parameters are getting much better (Li et al., 2015). According to their vision, share of public transportation and cycling/walking will slightly decrease as a consequence of taking over passengers by new modes based on AVs. The autonomous transportation requires more intensive use of ICT tools and services by passengers (trip planner, electronic information, ticketing, etc.). However, the citizens are different, their requirements and expectations are rather diverse. Bak and Borkowsky (2015) found that users in different regions with very various characteristics (as e.g. wealth, GDP, cultural background) can be represented by surprisingly similar attitudes towards ICTs (e.g. purpose of using an application).
The remainder of the paper is structured as follows. Definition of basic terms are provided in Section 2. The method of investigation of passenger handling functions forms the body of Section 3, where the functions and the required human abilities have been also revealed. Section 4 presents the results, namely the transformed functions and the altered human behavior in the future transportation system. Results are discussed in Section 5. Finally, in Section 6 the conclusions are drawn and the future research directions are summarized.

2. Definition basic terms

We have defined the basic terms:

- **Automated functions** are operated by machine which follows very clearly described, step by step rules. The rules have been programmed into them one by one.
- **Autonomous functions** are operated by machine which is able to make individual decisions using cognitive capabilities and learning abilities. Not all situations have to be mapped in advance, the new situations are perceived, understood and properly managed.
- **Autonomous public transportation**: a system using autonomous technology by vehicle, infrastructure and traveler in order to improve operation and enhance service quality. Most of the components are equipped by sensors, cameras, etc. and communication channels in order to realize V2X cooperation. Technologies either imitate human procedures (e.g. sensing, learning) or realize human-independent new procedures (e.g. localization). The efficiency of operation can be refined and perfected by the new information that is collected by new sensing technologies and was not available before by human sensing. The personnel (e.g. dispatcher, driver, inspector) is eliminated and replaced by machine components in several cases. The mobility service consists of both services on fixed, high capacity arterial routes (mostly based on railways) with regular schedule and flexible, demand responsive services, which may have either feeder or point-to-point role. The latter one is efficient where the demands are low and/or dispersed (International Transport Forum, 2015). The vehicles are in public property. The passenger handling functions are mostly performed without direct human interventions.
- **Passenger handling functions and services**: the functions that are connected to passengers' basic movement and information management before, during and after travel in case of both normal and emergency situations. The functions are realized by either automated (e.g. ticket validation with electronic devices) or autonomous (e.g. providing value added personalized information by recognizing the traveler and learning his/her habits) services. In the first case pre-programmed operation is performed; whereas in the second case the system is able to react to the actual situation using its cognitive capability. One service may cover one or more functions.

3. Method of investigation of passenger handling functions

In order to determine the development potential and effects of automatization on both the machine and the human side, the functions and the human abilities have been investigated in process and system oriented approach. The elaborated method produces quantitative results to compare and prioritize the future developments (Fig. 1.). The main result is the automatization (Computerization) potential value (C_i) on machine side and the Aggregated Ability alteration value (AA_j) on human side. (Computerization word is used as a synonym for automatization in order to create distinct acronyms). They are calculated as difference of future and current indicators and being highlighted by grey colored boxes. C_i expresses the relevance of automatization of the function, where i is the index of function. AA_j expresses how the alteration of the functions influences passengers' required abilities, where j is the index of ability. The higher values indicate higher development potential and more significant alteration. Using the method other important values may be calculated as results of comparison of indicators: automatization level alteration (l_i), human ability indicator alteration (A_{ij}) in the given function, and human ability intensity alteration (a_{ij}) in the given function. The revealed functions are almost the same currently and in the future, however their properties alter (e.g. required human and machine actions). The identified passenger handling functions have been categorized into function groups (Table 1).

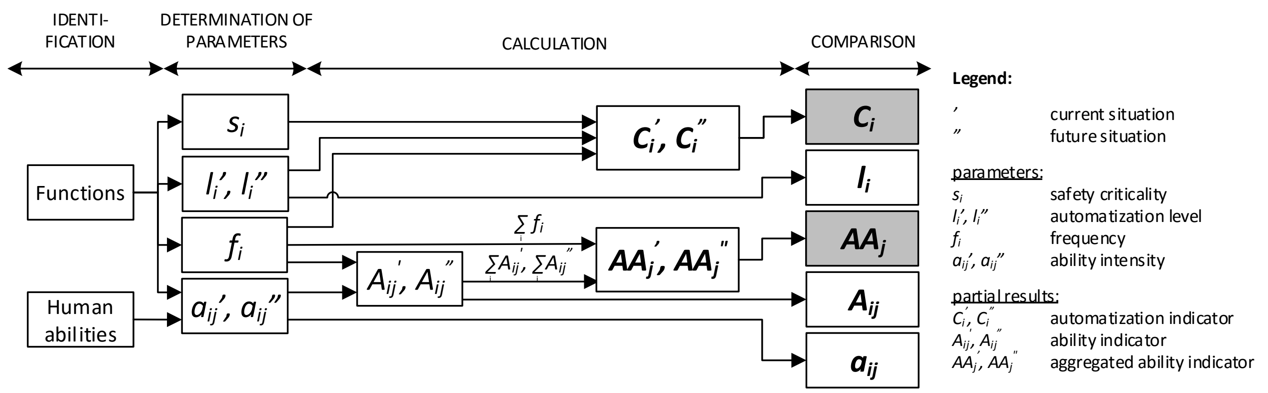

Fig. 1.
Flow-chart of method

Table 1
Functions

function groups nr.	function groups name	functions sign	functions name
1	infotainment	F_{11}	information provision about general conditions and supplementary services
		F_{12}	information provision about current situation
		F_{13}	personalized journey planning and guiding/ navigation
		F_{14}	activity chain planning
		F_{15}	information provision by installed devices (in the stop/station)
		F_{16}	on board information provision by on board devices
		F_{17}	on board complaining/information request
		F_{18}	communication between vehicle-passenger
		F_{19}	entertainment
2	management of entitlement	F_{21}	seat reservation
		F_{22}	payment
		F_{23}	ticketing
		F_{24}	check-in (ticket validation)
		F_{25}	control of entitlement (ticket inspection)

function groups nr.	function groups name	functions sign	functions name
3	safety	F_{31}	avoiding accidents between vehicle and passengers
		F_{32}	handling boarding process (warning, open/ close door)
		F_{33}	handling passengers in diseased conditions
		F_{34}	handling fire cases
		F_{35}	handling traffic collisions - evacuation
		F_{36}	handling vehicle technical failures (broke down)
		F_{37}	handling equipment technical failures
4	security	F_{41}	property protection (individual/common)
		F_{42}	life protection
		F_{43}	emergency call
		F_{44}	safeguard against terrorism
5	management of passenger room/ cabin conditions	F_{51}	management of comfort (e.g. heating, lighting, cleaning)
6	management of feedbacks	F_{61}	complaining
		F_{62}	crowd sourcing
		F_{63}	lost and found
		F_{64}	data collection from/about passenger
		F_{65}	data collection from/about vehicle/infrastructure

3.1 Calculation of indicators on machine side (functions)

Determination of parameters:

- safety criticality (s_i): how much the function should be reliable in safety critical circumstances/situations (Table 2). Same safety criticalities are assumed also in the future.

Table 2
s_i values

value	safety criticality	description
1	not	not safety critical
2	medium	slightly jeopardize human safety/life
3	high	sorely jeopardize human safety/life

- automatization level (l_i): in what degree the function can be automatized, in other words how it is possible to replace the human operations or presence by machine (Table 3). It is a general parameter which does not reflect particular aspects of operators/users. The current (l_i') and the future (l_i'') parameters have been assessed.
- frequency (f_i): average frequency of the function during travels (Table 4). Same frequencies are assumed also in the future.

Calculation of C_i' and C_i'' – Automatization indicators (1): The strong effect of safety criticality is expressed by power function. Calculation method of indicator is similar in both the current (C_i') and future (C_i'') situations. $C_i \in [0..625]$ in case of the introduced values.

$$C_i' = f_i \cdot l_i'^{s_i} \tag{1}$$

Table 3
l_i values

value	automatization level	description
1	low	no machines
2	rather low	slight machine support
3	medium	significant machine support
4	rather high	humans are needed only in safety critical situations
5	high	humans are unnecessary (only supervisors for remote control)

Table 4
f_i values

value	frequency	description
1	very rarely	in case of safety critical situations
2	infrequently	during some travels
3	occasionally	during many travels
4	frequently	during each travel a few times
5	very frequently	during each travel several times

Calculation of differences of indicators (2) or parameters (3) regarding future and current situations (Table 5). Difference between l_i values makes independent analysis possible. C_i is a complex indicator, because frequency and safety criticality are also included. Difference values are to be used for specification of software and hardware requirements during development of the certain functions.

Table 5
Calculation of differences on machine side (functions)

sign	calculation	description
C_i	$C_i^{"} - C_i' = f_i \cdot l_i^{"s_i} - f_i \cdot l_i'^{s_i}$ (2)	relevance of development
l_i	$l_i^{"} - l_i'$ (3)	required or foreseeable development

3.2 Calculation of indicators on human side (passenger)

During development of functions the alterations of required human abilities and cognition are to be investigated and considered as they significantly influence the perceived quality of service. The elaborated analysis method provides results mapping this alteration in a quantitative way. The most relevant human abilities have been identified.

1. eyesight,
2. hearing,
3. speaking,
4. touching,
5. typing,
6. reading,
7. operations by hand,
8. vibration sensing,
9. cognitive capability.

Vibration sensing is an important ability to sense vibration of a device placed in pocket or hand. Cognitive capability is defined as recognition and persistent learning capability. Travelers are able to create new, reliable, value-added information using previous experience, existing knowledge and ambiguous, incomplete secondary information sources. Cognitive capability is rather complex, it includes sensing and processing methods too.
The required abilities are altering as consequence of automatization. We have revealed the ability intensities (as parameters) for the current (a_{ij}') and future (a_{ij}'') situations in case of each function (where j is the index of the ability). Intensity expresses how long the ability is required during the function (Table 6). The low intensity is more convenient for the passenger. AA_j is created by consideration of frequencies and then aggregation of multiplied ability intensities.

Table 6
a_{ij} values

value	ability intensity	description
0	never	unrequired ability
1	rather low	for only a moment
2	low	for a short time
3	medium	cca. half of the time
4	rather high	all time with small pauses (almost continuously)
5	high	all time (continuously)

Calculation of A_{ij}' and A_{ij}'' - Ability indicators (4): frequency influences ability demands during travels, therefore it is considered as a multiplier. Calculation method of indicator is similar in both the current (A_{ij}') and future (A_{ij}'') situations. $A_{ij} \in [0..25]$ in case of the introduced values.

$$A'_{ij} = f_i \cdot a'_{ij} \quad (4)$$

Calculation of AA_j' and AA_j'' - Aggregated Ability indicators (5): as the same ability is required in case of several functions, the demand of this ability can be calculated as a sum of Ability indicators by functions (i), which is divided by the sum of frequencies of all functions. The indicators are calculated for both the current (AA_j') and future (AA_j'') situations. $AA_j \in [0..5]$ in case of the introduced values. The highest the AA_j value is, the more required the ability is.

$$AA'_J = \frac{\sum_i A'_{ij}}{\sum_i f_i} \quad (5)$$

The alteration can be represented by the differences of indicators (6), (7) and parameters (8) regarding future and current situations (Table 7). If the values of differences are negative, the required ability is less than currently, which is advantageous for the traveler.

Table 7
Calculation of differences on human side

sign	calculation		description
AA_j	$AA_j^{"} - AA_j'$	(6)	indicates human sensing and cognitive effort alteration in aggregated way (regarding all functions); it is useful for training and preparation of traveler's senses to autonomous processes
A_{ij}	$A_{ij}^{"} - A_{ij}'$	(7)	indicates what ability how alters at the given function considering all the travels; it is useful for specification of software and hardware requirements during development
a_{ij}	$a_{ij}^{"} - a_{ij}'$	(8)	indicates what ability how alters at the given function; it is useful for specification of software and hardware requirements during development

3.3 Analysis of tasks of personnel

As drivers have passenger handling functions in many cases, their replacement by machine significantly modifies performance of the functions. Therefore, the tasks of personnel have been analyzed and the current driver functions have been identified and assigned to the future personnel groups or the new machine components.

4. Results

The presented results have been calculated by the elaborated method. The used parameters have been determined by assumptions or literature review and were applied for demonstration purposes. More precise determination of the parameters requires further researches (e.g. questionnaire surveys, analysis of human behavior).

4.1 Assessment of functions

The most important properties of functions are summarized in Table 8. Functions with high automatization level alteration $(l_i \geq 2)$ are marked with red numbers. Functions with significant automatization potential $(C_i \geq 100)$ are presented with grey background and bold numbers. They are safety critical and having high automatization level alteration. If both l_i and C_i are high, development requires special attention, as in the case of F_{18}: communication between vehicle-passenger, F_{24}: check-in (ticket validation), F_{31}: avoiding accidents between vehicle and passengers and F_{34}: handling fire cases.

Table 8

4.2. Assessment of human abilities

The role of several abilities is changing as consequence of automatization. Table 9 presents an excerption of the alteration of the required human abilities. The higher the value of cells is, the more the ability is required. Fig. 2. represents the required human abilities (*j = 1-8*) currently and in the future. As cognitive capability (*j*=9) is much more complex than sensing by organs, cognitive capability is not illustrated in the figure. The Aggregated Ability alteration values (AA_j) is used to illustrate the shifting.

Table 9

4.3. Alteration in personnel tasks

The driver functions have been assigned to the different groups (types) of personnel and machines (installed in vehicle or station). This alteration in personnel tasks is represented by 'X' in cells of Table 10. These groups of personnel already nowadays perform several functions, however, their actions are altering as a consequence of modification of function properties and taking over driver functions.

5. Discussion

The analyses pointed out the most relevant development potentials of functions. The first research question, which functions and how to be automatized, is to be answered by results of (2), (3), (7), (8) equations. (2) and (3) assesses the technological opportunities, whereas (7) and (8) provides the required human abilities. The second research question, how the future traveler's sensations and cogitation changes, is to be answered generally by results of (6) and in details by (7) and (8). The third research question, what kind of modifications are possible in role of personnel, is answered by results of Table 10. All the results are interrelated. The most relevant properties of future functions are described considering the results, then the general alteration of human abilities and tasks of future personnel are discussed. Not only the results presented in Table 9, but alteration of all relevant human abilities are discussed in this section too.
Information provision (F_{11}, F_{12}) becomes more location based, personalized, however, the automatization level does not change significantly /$l_{11}=1$/. The location has an impact on e.g. traffic, weather, business ads, coupons, free parking lots, etc. (Rao and Giuli, 2011). The speaking as an ability becomes more important only in case of these functions as consequence of voice-based communication /$a_{3,11}=2$, $a_{3,12}=1$/ and it replaces typing /$a_{3,11}=a_{3,12}=-1$/. Journey planning (F_{13}) and activity chain planning (F_{14}) play more important role as future mobility becomes more pre-planned and personalized (Esztergár-Kiss and Csiszár, 2016). Setting personal characteristics or route expectations requires more time in the first phase, however, later on less time is enough due to cognitive and persistent learning capability of the journey planners. Accordingly, less user cognitive capability is needed /$a_{9,13}=-1$, $a_{9,1}$ $=-2$/. Multimodality between modes or region can be achieved by integration of multiple journey planners (Nykl et al., 2015). The installed information provision (F_{15}) devices provide more information in more automatic way /$l_{15}=2$/, not only about transportation related news, but e.g. about weather, touristic information too. Smart stops are installed as service hubs where travelers receive several information in automatic way. Information about current position, route, next stop, or other location based services are provided via on board devices (F_{16}). The travelers cannot complain to the driver or other personnel directly. The complaining process (F_{17}) occurs mostly via telecommunication devices (e.g. using video call or writing a message). The most significant alteration is foreseeable in the communication between the 'vehicle'

and other participants, especially passengers (F_{18}). The human reactions, mimicry, eye movement, gesticulation play important role in the current traffic. In the future, the vehicle has to indicate its intention unambiguously /$l_{18}=5$, $C_{18}''=625$/. However, the communication comes about via electronic devices. The vehicles recognize each other's, pedestrians' and bikers' location (if they have e.g. smart phone), and can warn all the participants in this way. The entertainment (F_{19}) (browsing on the internet; wireless charging of personal devices) during travel becomes more important, which is also consequence of exemption from driving. Delay-insensitive downloads (DID) enable downloading multimedia content (e.g. audio, video, movies) requested by users (Karagiannis et al., 2011). Role of function seat reservation (F_{21}) becomes more significant. as future mobility is more pre-planned, travelers have to be more conscious. Functions regarding payment, ticketing and check-in (F_{22}, F_{23}, F_{24}) require less direct human acts, however more touching /$a_{4,22}=2$, $a_{4,23}=a_{4,24}=1$/ and typing actions /$a_{5,22}=2$/ (e.g. e-ticketing, using vending machine). Validation of the ticket (F_{24}) becomes more simple (less touching) or entirely automatic /$l_{24}=3$/ (e.g. by tracking user). However, in special cases control of the entitlement (F_{25}) requires human inspectors aided by advanced devices /$l_{25}=2$/.
The CCTV surveillance and advanced sensor technology have important role to prevent safety critical situations. These situations and technical failures should be recognizable by implemented sensors and automatic image processing or remote monitoring by humans. The function of avoiding accidents between vehicle and passengers (F_{31}) is currently the most critical issue in regards of autonomous vehicles /$l_{31}=2$, $C_{31}=490$/. The entire boarding process becomes automatic (door opening/closing and warning), however these systems are rather common (F_{32}) /$l_{32}=1$/. The most safety critical functions (F_{33}, F_{34}, F_{35}, F_{36}, F_{41}, F_{42}) require automatic machine recognition, strict regulations, elaborated intervention plans and fast human actions /$l_{33}=l_{34}=l_{35}=3$, $l_{36}=l_{41}=l_{42}=2$/. The sense of security can be improved by implementation of more static emergency call devices (F_{43}). Avoiding hacking and terrorist attacks require advanced identification of suspicious persons (F_{44}). Management of the passenger room/cabin conditions (F_{51}) becomes completely automatic in the future /$l_{51}=3$/. According to defined rules the machine switches on/off the devices (e.g. heating) based on sensor data. Cleaning processes of the vehicle do not change, however, dirty room is recognized by remote monitoring or passenger complains (feedbacks) via electronic devices. After travel the complaining (F_{61}) mostly does not require personal contact, however, it cannot be eliminated entirely /$l_{61}=2$/. Handling lost belongings (F_{63}) is also changing; travelers should be more aware of its risk and inform the remote monitoring services about the belongings. Data collection from/about passengers (F_{64}) becomes highly automatic if user gives permission. If a passenger provides data, he or she may receive more value-added information. Data collection from/about vehicle/infrastructure (F_{65}) becomes also highly automated.
In the future eyesight still remains significant but its usage intensity slightly decreases. Most relevant reduction can be noticed in operations by hand /$AA_7=-0.49$/ (less direct contact – e.g. during ticket validation). As the significance of smart mobile devices increases, the requirements towards the related human abilities rise. Vibration sensing will be eight times more relevant than nowadays. Significant increasing is expected in touching /$AA_4=+0.39$/ (e.g. during entertainment, boarding), and typing /$AA_5=+0.24$/ (e.g. using personal mobile devices during seat reservation, journey planning, etc.). Whereas sensing abilities alter differently, the required human cognitive capability all in all reduces /$AA_9=-0.22$/, as the machine support is growing. The human thinking (e.g. route planning) is in many cases replaced by machine.
The personal interactions of human personnel groups are particularly needed in case of special passenger groups (e.g. disabled, elderly or technically underdeveloped persons) and situations (e.g. foreign passenger in an unknown city). Therefore, employment of personnel in some functions is more effective than an automated solution (F_{17}, F_{22}, F_{23}, F_{61}, F_{63}). Handling of emergency and security situations (F_{33} – F_{37}, F_{41} – F_{43}) also require human interventions, however, the recognition of these situations can be appreciably automatized. Autonomous functions must be supervised by humans. The attendants' processes are aided by machines, so the number of humans may decline and their operation processes are more efficient (less wrong decisions, faster decision making). The personnel of future public transportation consist of:

- dispatchers: their processes are already currently aided by advanced infocommunication procedures, however some decision cannot be programmed. In the future dispatchers remain as a supervisor.
- supervisors: security attendance and information provision by human presence is important at eventful passenger facilities. Their tasks are broadened with former driver tasks (e.g.: checking cleanness in the vehicle).
- customer service: their role remains significant as several situations require human contact.
- security team: although image recognition systems reliably recognize the critical situations they are unable to interact. Therefore, quick moving human security teams are necessary (e.g. remove abandoned package).
- rescue team: in case of any emergency situation humans can more easily guide the passengers (e.g. during evacuation) and the medical interventions also require personal presence.

6. Conclusions

The main contribution of the research is the elaborated analysis method of passenger handling functions. In this method safety issues, automatization potential, frequency of function usage and human abilities are mapped by parameters. The method is applicable to determine indicators which fairly describe the automatization potential of the functions and the implied alteration of abilities. It has been found that the required eyesight as an ability and the cognitive capability slightly reduce, however, the relevance of vibration sensing, touching and typing significantly increases. In the future travelers receive value-added information and guidance from more sources; some human sensing becomes more intensive, but intensity of cogitation reduces. Less personnel are sufficient and most of them are employed as supervisor. We faced that collection of passenger handling functions require system- and process-oriented approach. Determination of alteration of function caused difficulties as only a few scholar publications related directly to the future transportation and passenger handling functions are available. Our future research focuses on the supplementary operational functions (e.g. parking, cleaning, maintenance), as these functions influence directly the mobility service. The research question is the same, how they to be automatized. Furthermore, we intend to model the entire autonomous public transportation system and its operational processes from several aspects. For instance, one current relevant hot topic is, how do the demands and capacities alter and how the pure traffic situations are to be modelled and simulated.

SUSTAINABLE TRANSPORT DEVELOPMENT STRATEGIES. CASE STUDY: EXTENSION OF THE PEDESTRIAN ZONE IN BELGRADE CENTRAL AREA

Milena Vukmirović[1]
[1] *University of Belgrade – Faculty of Architecture, Belgrade, Serbia*

Abstract: During the seventies, Belgrade mostly has developed in step with other European cities. This particularly refers to the creation of the pedestrian zone in the centre of the city, similar to those that at that period appeared in Paris, Munich and Vienna. The first idea of creating a pedestrian zone in the centre of Belgrade emerged in the early seventies, and was formally defined in the General urban plan from 1972 and later in the Regulatory Plan for the Central Zone of Belgrade from 1977. The fundamental reconstruction of Knez Mihailova Street and the Republic Square was carried out following the urban design project created by architect Branislav Jovin. The works started in May, and the street was open to pedestrians on 20 October 1988. By mid-2010, the majority of planned interventions of this kind have contributed to the formation of the pedestrian zone in the centre of city. Following the recommendations on sustainable urban development and the introduction of a new green hierarchy of urban transport, current development trends favour the further expansion of the pedestrian zone to the banks of the Sava and Danube. Bearing this in mind, the paper would present an overview of past and current efforts to apply the principles of sustainable development in Belgrade, discussed from the aspects of transport policy and concepts for creating a pedestrian-friendly environment.

Keywords: pedestrian zone, sustainable transport, sustainable development, city centre, Belgrade.

1. Introduction

The quality of life and the quality of the environment in cities are notably affected by road transport and traffic. Considering the main problems associated with increasing urban traffic and congestion, the negative impacts on urban quality of life could be emitted in the following domains: visual instruction, noise and vibration, energy consumption, severance, competitiveness, accidents, air pollution, loss of urban “living space”, economic efficiency and equity (European Commission. Environment Directorate-General, 2004). Following the statistics and some predictions, 80% of Europeans live in an urban environment; every year more than 3 million cars are added to the car fleet in Europe and total road traffic kilometres in urban areas will grow by 40% between 1995 and 2030. As the issue is identified, there is a need to find the solution that could be from the one hand increase the road space available for cars, while on the other, the reduction of the car capacity could represent a sustainable, efficient planning solution. The second solution than can contribute in he improvement of the quality of life and quality of the environment in cities.

More increasingly experiencing the negative effects of mobility, cities are opening up to innovative approaches and policies for creating sustainable mobility. Therefore, a large number of cities[2] have active sustainable mobility policies in place as an alternative to cars and also receive the support from EU in promotion and exchange of best practices in areas such as transport infrastructure, norm-setting, congestion and traffic management, public transport services, infrastructure charging, urban planning, safety, security and cooperation with the surrounding regions (European Commision, 2006).

Considering the sustainable mobility, the European Union’s Ministers of Transport adopted a definition[3] “that a sustainable transport system is one that: (1) allows the basic access and development needs of individuals, companies and societies to be met safely and in a manner consistent with human and ecosystem health, and promises equity within and between successive generations; (2) is affordable, operates fairly and efficiently, offers choice of transport mode, and supports a competitive economy, as well as balanced regional development; and (3) limits emissions and waste within the planet’s ability to absorb them, uses renewable resources at or below their rates of generation, and, uses non-renewable resources at or below the rates of development of renewable substitutes while minimizing the impact on land and the generation of noise” (European Union Council of Ministers of Transport, 2001).

Besides the general definition of sustainable transport, EU has adopted a series of documents called “Urban Mobility Package” in order to support measures in the area of urban transport by sharing experiences, show-casing best practices, and fostering cooperation, providing targeted financial support, focusing research and innovation on delivering solutions for urban mobility challenges and involving the Member States and enhance international cooperation (European Commission, 2015). The Package also includes A Concept for Sustainable Urban Mobility Plans (SUMP) that describes the main features of a modern and sustainable urban mobility and transport plan. In this paper special attention of SUMP is given to the element that covers the balanced and integrated development of all modes and on its topic on walking and cycling. This document was also used as an umbrella guideline in defining and developing the main principles for the proposal of the extension of the pedestrian zone in Belgrade central area.

[3] This definition was developed on the basis of the definition from 1997 by the Toronto-based Centre for Sustainable Transportation.

2. European Sustainable Urban Mobility Plan and Integrated Development of All Modes

The European Sustainable Urban Mobility Plan was developed on the basis of the broad exchange between stakeholders and planning experts across the European Union in order to describe the main features of sustainable urban mobility and transport plan. The Plan has defined goals and objectives, a long-term vision and clear implementation plan, an assessment of current and future performance, the balanced and integrated development of all modes, horizontal and vertical integration, participatory approach, monitoring, review and reporting and quality assurance (European Commission, 2013).

As a methodology recommended by the European Union the most of their cities has changed the concepts of urban development by reconstructing the centres and the entire urban transport system. In accordance with that the policy of changing the modes of transport in cities means more space for pedestrians, bicycles and public transport, a reduction of comfort for passenger cars. This situation is perfectly explained in the Manual for Streets (Department for Transport , 2007) as a hierarchy of traffic users with the purpose to assist in design, planning and development control decisions. The hierarchy places pedestrians at the top, followed by cyclists, then public transport, with unaccompanied private car users last (see Fig. 1).

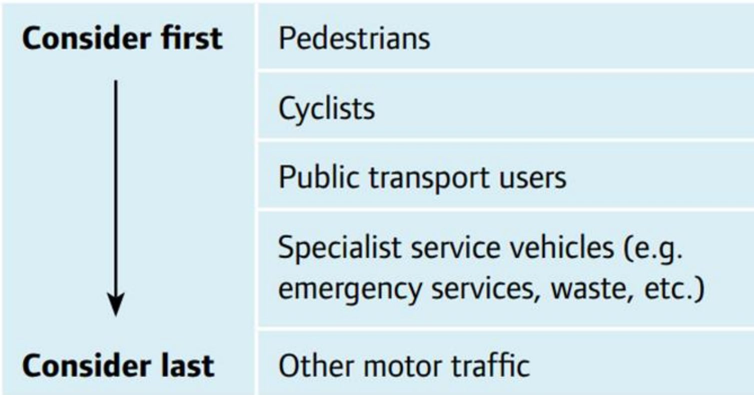

Fig. 1.
The hierarchy of traffic users (Department for Transport, 2007, p. 28)

The principles defined by using the hierarchy "sets objectives that ensure resilience and adaptability in the energy requirements of our transport network, with a focus on delivering societal needs. It pulls together policy proposals that demonstrate a consensus for this type of approach. The combination of cross-modal consensus and sound engineering makes this a powerful tool to achieve the step change needed to deliver a sustainable transport network" (Institution of Mechanical Engineers, 2013). Its creators also consider that it could be used in all governmental departments and businesses when making decisions on their transport choices in terms of both use and planning activities.

Following the principles of SUMP and transport hierarchy the goal is to change the function of transport for longer distances from car to public transport (metro, tram, bus, etc.) while for short distances to encourage the use of walking and bicycles. In addition to this there is a proposal for using the modes of transport based on energy from sustainable sources (electrical buses, electrical cars, etc.). It also proposes the introduction of car sharing system for those who need a short lasting automobile use in the city as well as park and ride for a combination of use od car for travelling out of the city and use of public transport for movement in the city.

The effects of these approaches are visible only if the entire politics in city urban and transport planning is based on the principles of SUMP. As one of it's the most recognisable manifestation is the plan to implement car-free strategies, which can be recognised in many European cities.

2.1. European cities with plans to go car-free

Although it dates back to the seventies, the city plans to go car-free are very actual in recent years. Starting with 2014 several European cities have announced their ambitions to convert parts of their central districts into pedestrian oriented places with less automobile congestion and air pollution. They include Paris, Madrid, Oslo, Milan, Dublin, and Brussels, while Belgrade has also announced its initiatives to extend the pedestrian zone in the centre of the city in mid-2015.

Concerned about the worsening air quality on the centre of the city, the **City of Paris** authorities has decided to keep odd-numbered cars out of central Paris for a single day on 17th March 2014. According to the data collected by Airpartif (2014) on that day, road traffic dropped by 18%, with drops of 13% in the area that surrounds inner Paris and 10% in suburbs. Compared with data from 10th March 2014 it was recorded the reduction levels of pollution by PM-10 within the city by 6%, with levels 10% lower than normal at rush hour on the Beltway. Nitrogen dioxide levels dropped by 10% overall, and by 30% on the Beltway at rush hour (Airparif, 2014). These and similar activities continued during the next two years with a tendency to build new pedestrian zone along the Seine and expand the zone of 30 km/h.

In 2012 the **City of Madrid** has adopted the revised version of General Urban Plan with the aim “to transform much of a car-snarled city centre into a leafy pedestrian's dream” (O'Sullivan F. , 2013). The Plan has foresaw the transformation of 24 major streets of Madrid in that way to remove car lanes, add bike lanes and trees and to put the new hierarchy in place where pedestrians come first, then public transport, then bikes, then cars. It also suggests additional steps to keep inner Madrid car-free, while parking places in central buildings will be strictly limited to encourage people onto public transport.

Dublin city also introduce the urban plan that aims to ban cars from the parts of the city centre until 2017. With these kind of measures the authorities are expecting “to reach a point where one in five people commutes into the core via private car, while the rest coming by transit (55%), bike (15%) or on foot (10%)” (Eric, 2015).

Similar to Dublin, the **City of Oslo** has also announced the plan with the goal to go car-free, banning the private cars in the central district by 2019. The city will enhance its bike infrastructure by building “at least 60 kilometres of bicycle lanes and give a “massive boost” to public transit” (Fouche & Solsvik, 2015). The “total pedestrianization of the historical centre” is the aim of the **City of Milan** local authorities. Even if they do not have a clear timeframe for this action, this could be seen as a continuation of activities started with the introduction of an effective congestion pricing scheme in the core of the city.

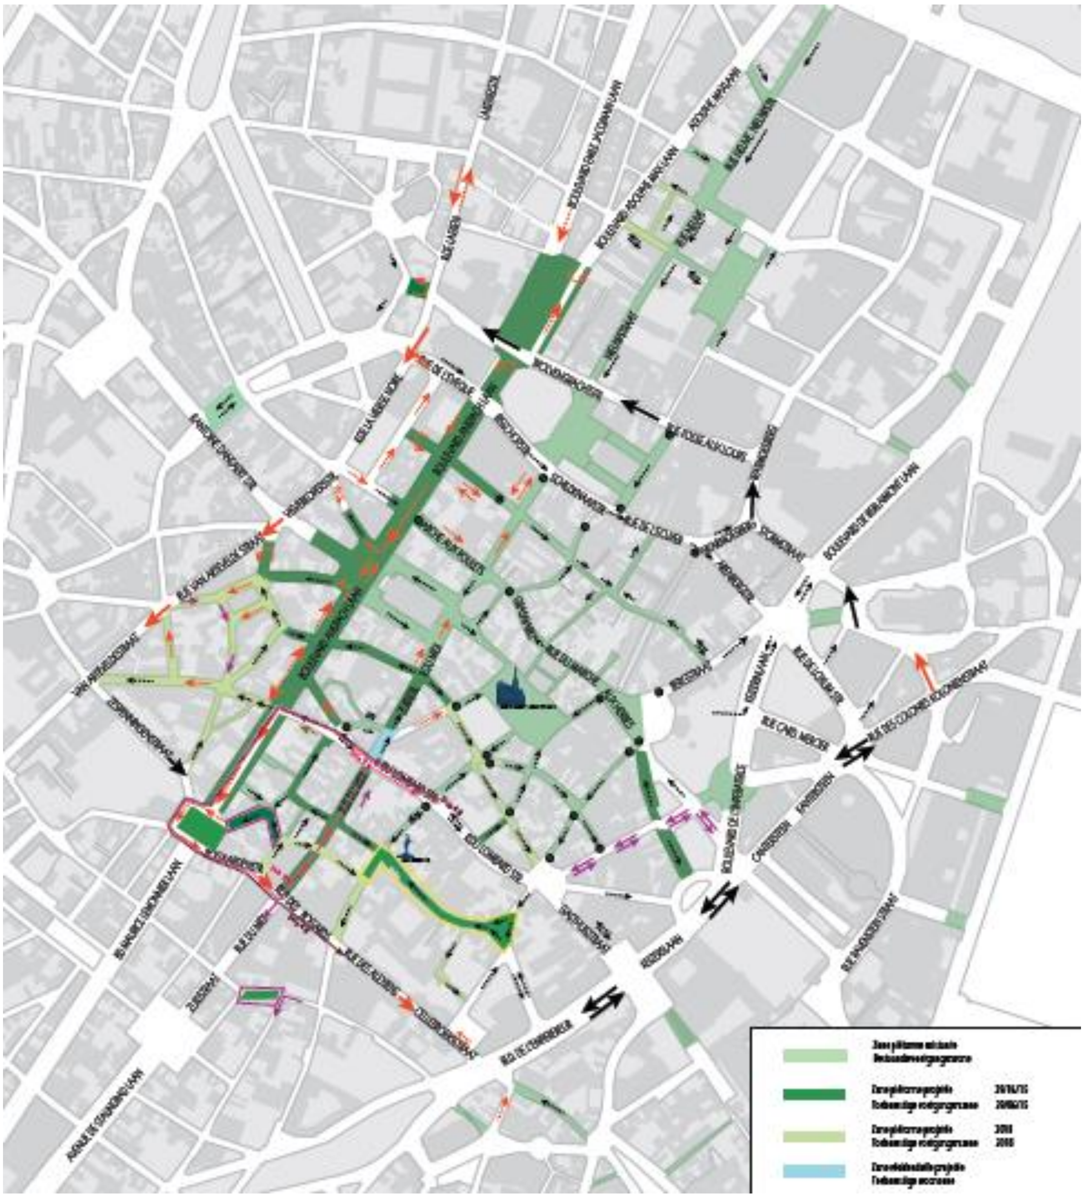

Fig. 2.
Brussels's pedestrian zone (City of Brussels, 2015)

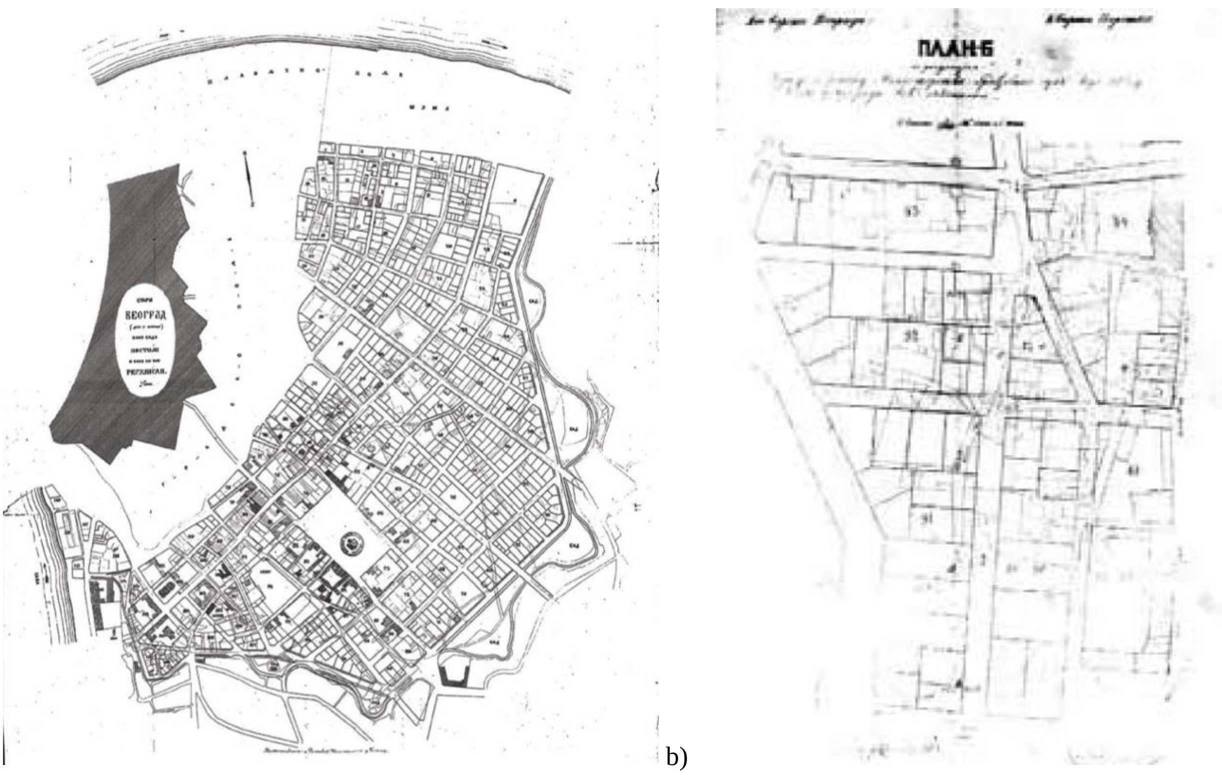
Known as the Europe’s most congested, the **City of Brussels** has a plan to turn the central axis into a pedestrian zone (O'Sullivan F. , 2014). That will contribute to the extension of the existing pedestrian zone almost double (from 28 to 50 hectares, see Fig. 2). The realization of this vision will cause that Brussels will have a pedestrian zone slightly lower than that in Venice. Similar to mentioned European cities, the local authorities of the City of Belgrade are working on the realization of the extension of the pedestrian zone in the city centre, based on the initiatives announced in mid 2015.

3. Extension of the pedestrian zone in Belgrade central area

In the same period when these changes occur in mentioned European cities and by analysing the overview of urban characteristics, open public spaces and quality of life of citizens and bearing in mind the current world trends in the field of urban planning and design, transport, protection and enhancement of natural and environmental surroundings and social development, the City of Belgrade initiated the project Identity_Mobility_Ecology (IME), which was adopted at the meeting of the City Council on April 9, 2015. The Project IME comprises 20 sub-projects whose implementation will enable to establish standards and rulebooks for design of open public spaces, use modern technology for unifying spatial data - GIS, establish new, environmentally acceptable hierarchy of traffic participants, restore facades, improve the city lighting, develop important open public spaces, markets and urban pockets and develop areas of historic and cultural significance. The fourth project titled as "extension of the pedestrian zone of Knez Mihailova street" includes "the implementation of multiple projects in order to further develop the pedestrian zone in the heart of Belgrade, which started in 1980" (Folic and Vukmirovic, 2015).

3.1. Historical background

The year 1867 is marked as the turning point in the history of the modern urban development of Belgrade. It is the year Emilijan Josimovic, the founder of modern Serbian urban planning and the first Serbian urbanist, completed his inventive urban plan of modern European Belgrade, which formed the basis of a survey that he started as an individual enthusiastic researcher. Today we refer to his yearlong work as the first modern urban plan of Belgrade, but it was actually Josimović's book on the reconstruction of Belgrade within the Moat in which he explained his proposal for new urban regulations with a plan in the scale of 1/3000 (see fig. 3a). His work was ordered to transform the oriental town into a European city (Terzic, 1997; Medakovic, 1997; Maksimovic, 1967).



a) b)

Fig. 3.
Emilijan Josimovic: a) Justification of the proposal to regulate that part of the town of Belgrade which lies in the moat using a lithograph plan, scale 1:3000 and b) Regulation of Knez Mihailova Street (Maksimovic, 1967)

According to Blagojevic, "Josimović was a contemporary to the famous European urbanists Haussmann and Cerdà, and his plan followed soon after their famous plans for reconstruction of Paris (1853-71), and Barcelona (1859-70). … He's plan demonstrates the universality of the European planning paradigm of the period, and more precisely of the ring principle which was employed in Vienna, yet it clearly brings out the specific character of Belgrade into its proposals for reconstruction." (Blagojevic, 2009, p. 31). Emilijan Josimović's work is of significant historical importance. The proposals and ideas from his book included, for example, connections between the fortress and the city. He proposed narrow roads realized through three gates, as a three additional passages into the new town. Most crucial for the life of the city is definitely the exit from Delijska (Knez Mihailova Street) to the Terazije (see fig. 3b). This new link emphasized the importance of Knez Mihailova Street, transforming it into a new trade centre.

The new interest for Knez MIhailova Street was aroused in late sixties and beginning of seventies when it came to drafting a new General Urban Plan of Belgrade. The new Belgrade Masterplan 1972 introduces a new, modern concept of transportation planning in the city based on the massive public transport system – metro, as well as planning of the pedestrian zones. This can be characterized as a partial continuation of a European trend of this time, having in mind that the first pedestrian streets in Europe were constructed between 1972 and 1978 (Vukmirović, 2013, p. 469). The conceptual design was made for the pedestrian zone in the city centre, the pedestrian boulevard of New Belgrade and the pedestrian street in Zemun. Belgrade got its first pedestrian street in 1988 on the basis of the regulatory plan of the Central zone of Belgrade from 1977.

Fig. 4.
Knez Mihailova Street - Before and after the transformation into the pedestrian street

The fundamental reconstruction of Knez Mihailova Street and part of Republic Square was carried out according to the project of architect Branislav Jovin. Work started in May, and the street opened to pedestrians on 20 October 1988. According to Ferenčak, converting Knez Mihailova Street into a pedestrian zone was one of the few large urban themes that were brilliantly realized, bearing in mind that Belgrade had not developed enough in the areas of planning and continuity (Ferencak, 2008). The Regulatory Plan for the Central zone of Belgrade from 1977 envisaged the formation of a pedestrian zone, i.e., a network of pedestrian streets, but by 1988 only part of the plan was realized (Vukmirović, 2013, p. 358). Expansion of the Knez Mihailova street pedestrian zone continued in 2008, after which 9 more streets were completely or partially pedestrianized (according to the Plan from 1977). Following this trend, but significantly more ambitiously, in 2015 it continued with the IME project: Identity_Mobility_Environment (Folic and Vukmirovic, 2015). The project envisages the expansion of the Knez Mihailova street pedestrian zone and includes the full implementation of the Plan of 1977, which would make a complete entity with the focus as Knez Mihailova street and continued expansion of the pedestrian streets towards the bank of the Sava on one side and towards Dorćol, that is the bank of the Sava, on the other.

3.2. Contemporary period

Extension of the pedestrian zone of Knez Mihailova Street includes implementation of multiple projects in order to further develop the pedestrian zone in the centre of the city. In this way, the City will develop “a green network” of pedestrian spaces in the city centre, which would interconnect the existing public spaces and spatial units of a broader significance for the urban identity all with the aim to reduce the use of private cars for transport and to create greener, healthier and more pleasant living space. The project will be realised in four phases that are temporarily and spatially defined (see Fig. 5).
First phase of the project covers public spaces with the total area of 35.272m2 (see Fig. 5, blue). Small part of this area is now in the phase of realisation (started in July 2015) and they will be reconstructed on the basis of the initial project for the pedestrian zone of Knez Mihailova street design by arch. Branislav Jovin during the eighties. Other parts of this area need to designed (that is planned to be during the first quarter of the 2016) and realised until the end of 2018. Second phase would be done simultaneously with the first phase. It includes the area of 10.149m2 located on the territory of Kosancicev venac, which is under cultural heritage protection as an ambience ensemble (see Fig. 5, rose). It also needs to be designed following strict conditions of the cultural heritage protection (that is planned to be during the first quarter of the 2016) and realised until June 2017. Third phase of the project includes street network in the area of Savamala district (see Fig. 5, green) with the total area of 4.405m2. It will be conducted within the realisation of Belgrade Waterfront project. Finally, the fourth phase envisages the reconstruction of streets and public spaces along Vasina and Uzun Mirkova Streets with the total area of 39.088m2 (see Fig. 5, purple). This area needs to be designed (that is planned to be during the first quarter of the 2016) and realised until the end of 2019.
As it can be seen, the phases are determined on the basis of the character and status of the territory, which would in the future result in the creation of four distinctive wholes: zone of hospitality (Toplicin venac with associated streets), zone

of history (Kosancicev venac), zone of culture (the path along Vasina i Uzun Mirkova Streets with Students' square and Plateau in front of the Faculty of Philosophy) and trade zone (Knez Mihailova Street).

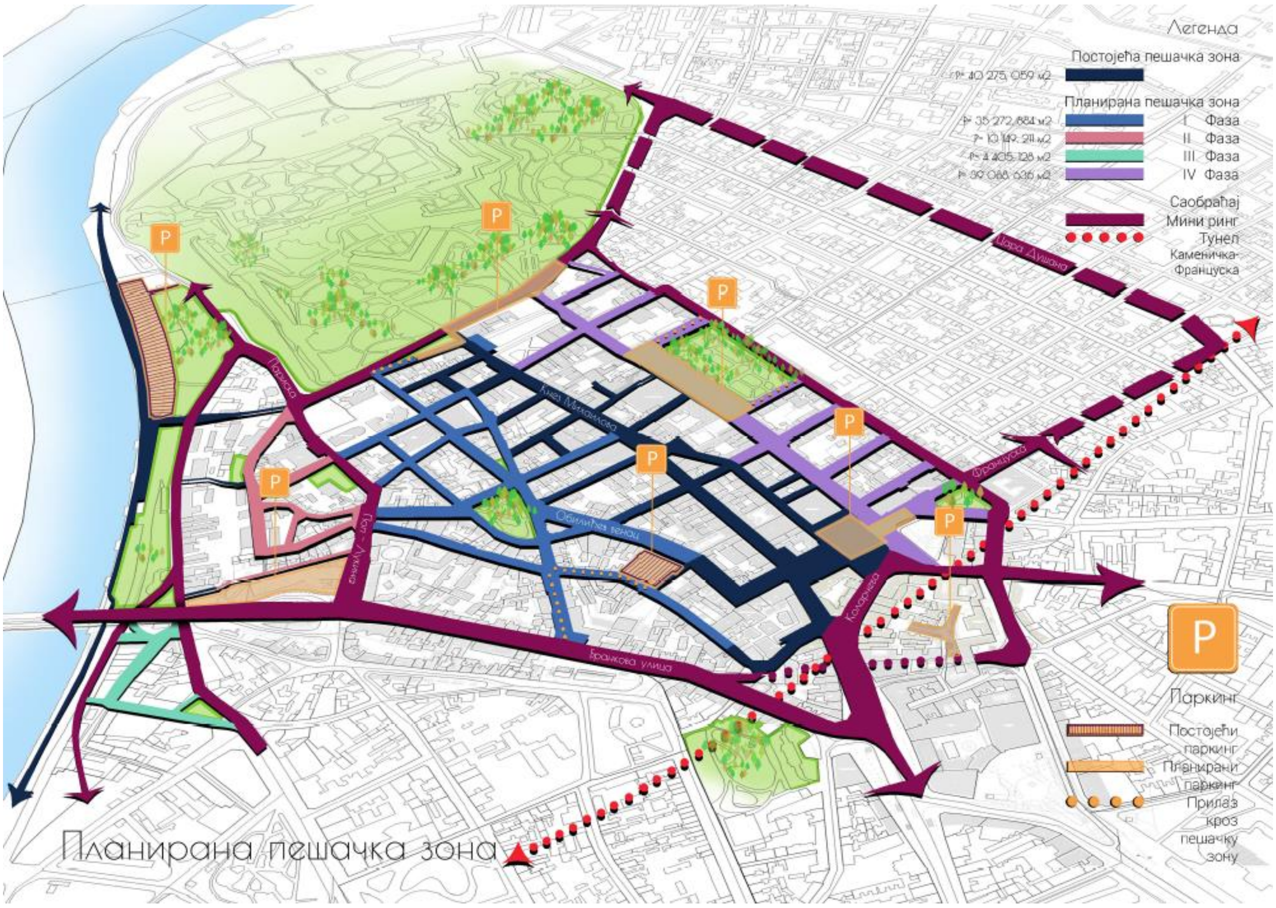


Fig. 5.
Concept of the extension of the pedestrian zone around Knez Mihailova Street. (Projekat IME: Identitet_Mobilnost_Ekologija Grada Beograda, 2015)

For the purposes of verification and further elaboration of this concept, the city authorities conducted two documents - Spatial-ecological valorisation of the future pedestrian zone of Belgrade (Glumac at al. 2015) and Feasibility study of enlargement of pedestrian zone Knez Mihailova Street (CEP 2016). According to the valorisation (Glumac at al. 2015), the extension of the pedestrian zone Knez Mihailova Street is the "most effective way of achieving environmental protection from the consequences of intense traffic, primarily for protection against noise and air pollution with the aim to reduce its level of the central zone of the city". On the other hand, the study (CEP 2016) provided different dimensions and variants of the project implementation. The study included different kind of analyses and produced three possible alternative solutions. The expert team used different methodologies form literature review, good examples of different pedestrian zones as a case studies, direct surveying of residents and car owners, models of intensity of transport, etc. The Study also defined different goals and visions: general conditions of bicycle transport in the centre of the city, logistic inside the area of pedestrian zone, smart functioning of the garbage disposal system, organisation of the public events, development of the GIS database, functioning of the taxis and functioning of the touristic transport. In this way, both documents reflect a general positive attitude with regard to this project and initiative.

3.3. Development of particular public spaces

The first segment of the project – the reconstruction of Vuka Karadzica Street was finished and officially opened in December 2015. It was done in accordance with the project by arch. Branislav Jovin. The project dated form the fist phase of the reconstruction of the street (1986th). The second segment of the project – the reconstruction of the Plateau of the Red Rooster (Crveni Petao) was finished and officially opened in April 2016, while the third segment, Zmaj Jovina Street was reconstructed in August 2016. It was also done in accordance with the project by arch. Branislav Jovin. In May 2016, the same team gave the final proposals for the area of Oblicev venac (see Fig. 6). The reconstruction of this area will start on 3rd September 2016.

Fig. 6.
Concept of the reconstruction of Obilicev venac and associated streets designed by Arch. Sinisa Temerinski i Arch. Branislav Jovin

The second phase of the pedestrian zone extension will cover the areas on the sides of the existing zone. It will be developed in the form of reconstruction and improvement of individual open public spaces and paths with the tendency to establish a connection with the riverbanks of Belgrade – (on Sava and Danube). The team that will deliver the public space design proposals is lead by Prof. Boris Podreka and the interventions will include four segments (see Fig. 7). The first segment covers the path form along the Vasina and Uzun Mirkova Streets with the focal points – public spaces that will be formed on Students' Square and Plateau in front of Faculty of Philosophy. Segment two is belongs to the Toplicin venac with its associated streets. The main public space in this area will be actual Park of Vojvoda Vuk with specially design area for children. The space on the place of the ruined National Library on Kosancicev venac is seen as an historical, memory labyrinth and it belongs to Segment three. The fourth segment is defined by the path along Sremska and Marsala Birjuzova Street, one of the busiest pedestrian connections between Knez Mihailova Street and area Zeleni Venac.

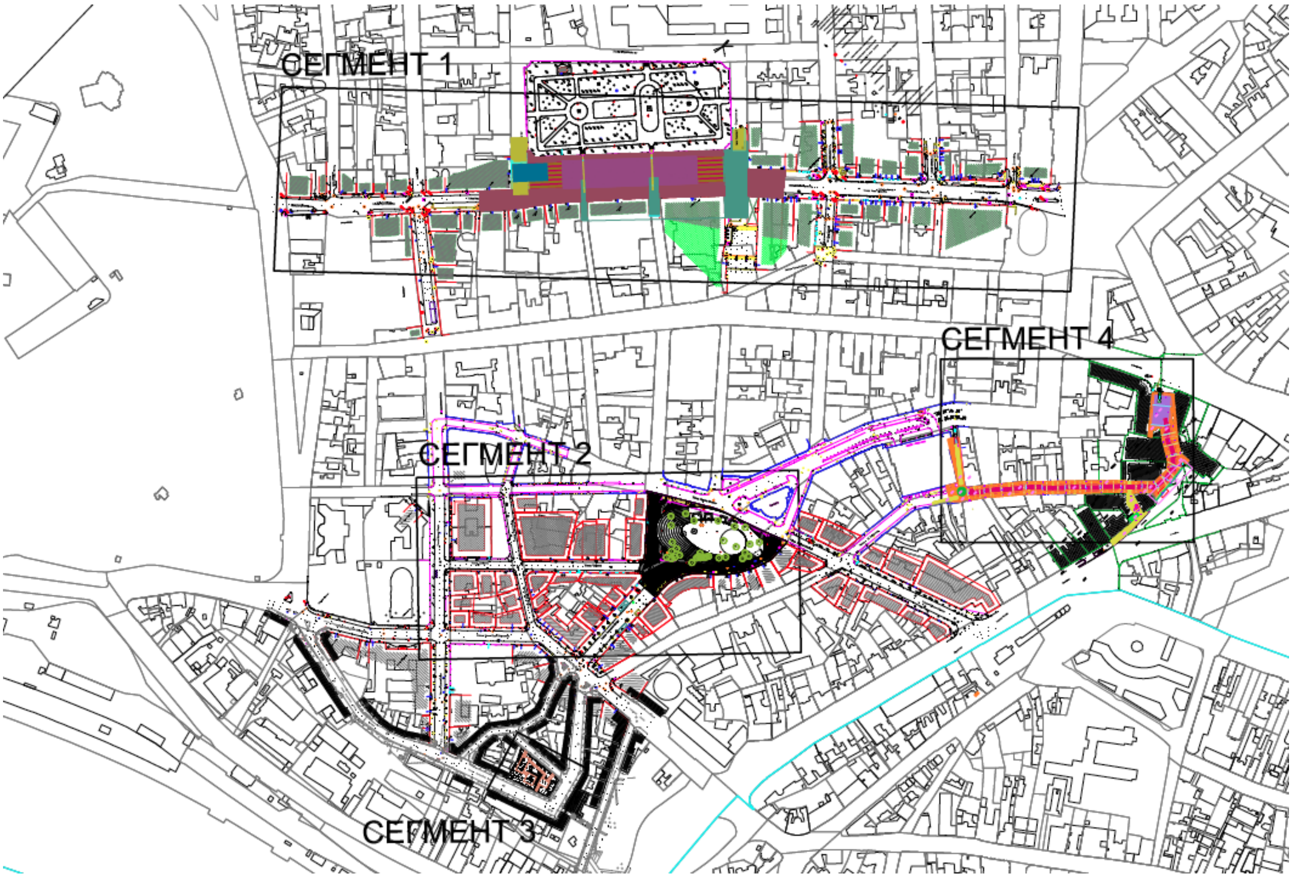

Fig. 7.
Design proposals for the segments. Source: the team lead by Prof Podreka

The functioning of the new pedestrian zone will be possible by introducing a transportation ring (see Fig. 5) for public transport, service and automobile use (most of it will belongs to zone 30km/h). On the other side, the access gates to the pedestrian zone (for public transport and private cars) are planned on the locations of the public transport stops and the planned locations for the new public garages. For the purposes of the movement of old and disable people as well as delivery, the new electric cars that could be moved in circles in the zone will be introduced.

4. Conclusion

Presented initiatives and realisations in order to extend the existing pedestrian zone in the core of the city are completely in line with the actual initiatives and plans of the leading cities in Europe. The guidelines that were proposed by European Union in relation to Sustainable Urban Mobility Plan have proved to be feasible and that achieve the expected results. Although it is considered as ambitious and which implementation will take several years, the project of the extension of the existing pedestrian zone in Belgrade has real potential which is positively evaluated by two studies. However, the expected functioning of pedestrian zone and implementation of the new transport hierarchy is possible only if the entire politics in city urban and transport planning is based on the principles. This can complicate the particular situation in Belgrade, because it still has need for an independent massive transport that was planned in seventies, but the question is what will be its final form.

BENCHMARKING TOOL FOR BIKE SHARING SYSTEMS

Tamás Mátrai[1], Péter Mándoki[2], János Tóth[3]
[1,2,3] BME Department of Transport Technology and Economics, Budapest, Hungary

Abstract: This paper presents the first application of a recently developed benchmarking methodology. Based on the existing practices this article proposes a multi-criteria analysis method for the assessment of PBS systems from user and operator perspectives. System performances differ from user and operator perspective. Best systems show diverse characteristics.

Keywords: bike sharing, benchmark, multi criteria assessment.

1. Introduction

According to UN forecast, the world population in mid-2015 was of about 7.3 billion people and by 2050 will reach 9.7 billion. Along with this urbanization is expected to increase (Buzási and Csete, 2015). One of the main goals of EU transport policy (European Commission, 2011) is to "halve the use of 'conventionally-fuelled' cars in urban transport by 2030; phase them out in cities by 2050". This means that car technology must be improved and clean transport modes must be preferred. EU transport policy also declares the necessity of urban mobility plans. These plans have to facilitate walking and cycling as transport modes. In urban areas the development of the infrastructure of non-motorized transport modes should have priority.
Cycling is one of the fastest developing sustainable transport solutions. With the spread of Public Bike Sharing (PBS) systems it is very important to understand the differences between a wide range of PBS systems. In order to do that we need to gather information about different measures. Active travel measures collected in different projects such as FLOW (Koska et al., 2016). The authors went through the available literature in their previous papers (Mátrai and Tóth, 2016a; Tóth and Mátrai, 2015; Mátrai and Tóth, 2016b), but since then some additional literature review has emerged (Fishman, Washington and Haworth, 2013; Fishman, 2016; Brown et al., 2016), which are comprehensive.
A complete framework has been developed during a doctoral research for analysing, comparing and categorizing public bike sharing systems. The first level of the methodology is gathering data about existing systems. The second level of the methodology compiles a SWOT analysis for each clusters based on the examined systems. The third level is a benchmark tool which supports the evaluation of systems. The fourth level of the methodology is the impact analysis and impact assessment.
This article focuses on the third level: a multi criteria assessment (MCA) for PBS. We summarize the already existing MCA methods in Chapter 2. Based on the existing practices this article proposes a benchmarking method of PBS systems from user and operator perspectives (see Chapter 3). Additionally, a test of the proposed system will be performed through a case study (see Chapter 4). At the last part of this article introduces future research steps and conclusions have been drawn.
The main idea behind this paper comes from the Urban Mobility Index developed by Arthur D. Little (Van Audenhove, Dauby, Korniichuk and Pourbaix, 2014). As the results can be different depending on whether the user's point of view or the operator's point of view is given priority, it is necessary to create two distinct lists. Based on the literature review of different MCA methodologies, the most appropriate has been selected. A shortlist of parameters has to be collected for both viewpoints. Parameter selection is based on expert judgment and results from a questionnaire. Different weighting methods were used and the most appropriate one has been chosen.

2. Literature review

Evaluation methods are used in almost all segments of the economy in the European Union. The European Conference of Ministers of Transport (ECMT, 2004) suggests various analytical procedures to use in transport investment assessment: multi-criteria analysis (MCA); value assessment; cost-benefit analysis (CBA); tariff assessment.
Comparing methods, such as the MCA, assess different competing alternatives, as opposed to method assessing only a single solution relative to absolute values. The most used comparing method is the MCA or benchmarking (Rapcsák, 2007; Gyarmati, 2003; Kukadapwar and Parbat, 2016). There are three main MCA methods that we discuss here, all other methodologies can be categorized under this three: general comparing method; compensatory MCA; outranking MCA (Mándoki, 2005; Magyar et al., 2000).

2.1. Comparing methods

The aim of comparing different alternatives is not always to determine an absolute scale, especially when only limited data are available. In this case a method is necessary which can provide quick and easy to understand results without

[1] Corresponding author: tamas.matrai@mail.bme.hu

weighting. From these methods the most known are the following, which only differ in the presentation methods (Kindler and Papp, 1975, 1977):

- Harris method: the different alternatives are assessed in a four point based scale. The result shown in a table,
- Marting method: the different alternatives are assessed in a four point based scale. The results are presented in a diagram.

The quick results and easy presentation is the advantages of these methods, however they have some limitations. Since they do not use any weighting it can be used only for similarly important criteria. This significantly narrows the field of its scientific application, usually it is used for marketing purposes.

2.2. Outranking methods

As these methods are using a simple weighted average they do not need any complicated methodology or computer programme. The main difference in these are the selection of criteria and their weights. The weights should be defined using as large sample as possible. Two distinct method should be mentioned here, but all the others has similar logic:

- Kesserling method: In this methodology the points in each criterion can be discrete values between 1 and 4 while the weights are between 2 and 10. This method calculate multiplication sum of the weights and points for each alternative, but divide it with the theoretically best alternative. It is immediately providing information not only the ranking of different alternatives, but also about how far are these from the theoretically best one. The scale of the alternatives is between 0 and 1, where 1 is the theoretically best alternative,
- Combinex method: In this method the point in each criterion can be between 30 and 80. The best alternative gets 80, the worst gets 30 while the middle ones calculated based on linear interpolation. There are no restrictions for the weights. The final combinex score of the alternatives are the multiplication sum of the points and the weights. These scores not only show the ranking, but also shows the gap between different alternatives. It is one of the easiest multi-criteria assessment method.

Comparison with these methodologies provide good results with careful preparation. The biggest problem can be in the appropriate selection of weighting factors. If these are not available in advance, they only can be obtained via questionnaires with experts. If these experts are not evaluating the weights in the same way, the results can be uncertain. The results can be manipulated easily if the weights are changed, which can cause confusion in the decision makers if the results are close to each other. In this case this method is not recommended.

2.3. Compensatory methods

In order to simplify the ranking of different alternatives and to provide some procedure there are several methods exist, from which four are presented here, since these are the most used one in the Hungarian literature:

- KI-PA method: In this method the points in each criterion is between 0 to 10. The weights are independent and their sum is equal to 1. This method uses preference and disqualifying factors. The preference (advantage) factor shows how much “A” alternative is better or equal then “B” alternative in percent. The disqualifying factor shows how big is the difference from the best alternative and it only takes into account the largest difference. The comparison is done for each pair, which is the largest deficiency of this method – which was developed by Hungarian authors – since the final ranking is not always obvious,
- ELECTRE: This ranking method is using importance coefficients and the veto thresholds. Veto threshold exists in each criterion. The decision can be made with the help of ranking and veto threshold. This method is different if the aim is to choose, rank or sort. It usually used in the first place in order to create a subset of feasible alternative, then another MCA method is used,
- PROMETHEE - GAIA: This method is based on solely preference factors. It uses progressive ranking, from which a clear ranking can be provided. This method compares the alternatives in each criterion. It also equipped with high level sensitivity analysis and graphical representation,
- AHP (Analytic Hierarchy Process) method (Saaty, 2008): This method using a hierarchical tree method for graphically represent the decision process. The highest level is the aim, under which the criteria and sub-criteria has been written. The alternatives are in the lowest level. The main difference from the above mentioned methods is that AHP uses a common utility function where all the preferences are combined, while the European ones are using alternative pairs for this purpose.

All compensatory methods use some kind of weighting in order to determine the preferences of the evaluator. This method called compensatory, since it provides a possibility for compensation based on the different weights between criteria. The determination of these weights are important since the impact of these on the final results is huge. The weight of a criterion represents the increase in the global score associated to a swing in that criterion between the worst and the best level. The ratio between the weights of two criteria represents the trade-off between these criteria.

There are several different method exists for determining the weights in these assessments. All methods are based on judgments by the decision maker (Oliveira, 2010). The four main types are the following in a structured way:

- Require quantitative judgment: in these methods the decision makers need to understand the difference between each criteria and need to know their possible scale and their desired value: swing weights method, trade-off method,
- Require qualitative judgment: in these methods the decision makers should choose between pairs of alternatives and the system automatically compute the weights based on the answers: MACBETH, AHP

2.4. Urban Mobility Index

In 2010 Arthur D. Little launched its first publication in this topic called "Future of Urban Mobility" in this study the company presented its method call Urban Mobility Index, which assess the performance and maturity of transport and mobility in cities. They analysed 66 cities worldwide. From the research point of view, the importance of this index was its reproducibility, since all the weights and scoring algorithm has been published. Since then the company made a strategic agreement with UITP and they published the refined version of the Index. The number of cities involved reached 84 and are covering all continent. The assessment criteria expanded from 11 to 19.
Besides the easiness of use and the complete openness the calculation process of the index has some flaws. Due to the calculation process the scores are highly dependent on the selected cities. It means that without all the information from all assessed cities the process can be reproduced, but it might give us false results.

3. Methodology

MCA methods are easy to compute and widely used (Esztergár-Kiss and Csiszár, 2016). Based on the literature review in this assessment a compensatory multi-criteria analysis has been selected. The weight definition is based on an expert panel judgment with consensus building method. As the operator and the user perspective is different, two scale has been developed. The other important decision is the usage of scales. Since the authors cannot decide in advance which is better, both absolute and relative value function has been used and the difference analysed. In the relative scale the minimum and maximum point assigned to the worst and the best value of a PBS system in the sample, while in the absolute scale a theoretically worst and best value has been used at each sub-criteria. The point of a given system in given sub-criteria has been calculated with a linear interpolation between these limits (worst and best values).

3.1. Assessment from user perspective

The user perspective represented with 5 main criteria and all together 25 sub-criteria:
1. Coverage (Table 1): This main criterion represents how the system covers the city and the agglomeration. It combines geographic and demographic coverage,
2. Affordability (Table 2): This main criterion shows how affordable to use the system. It uses specific values based on average incomes and public transport fares,
3. Accessibility (Table 3): This criterion represents how easy to access the system. It uses sub-criteria which inform about the opening times and registration processes,
4. Innovation (Table 4): As innovation is an important part of the 4th generation systems, it shows how innovative the system is,
5. Integration and Sustainability (Table 5): Neither integration nor sustainability has enough sub-criteria, but when combined together their weight are equal to the other main criteria.

As the expert panel decided that all 5 main criteria is equally important the weights of each is 0,2 (or 20%).

Table 1
Sub-criteria in the Coverage main criteria

Sub-criteria name	**Weight**	**Worst**	**Best**	**Definition**
City coverage	5%	0	1	Ratio between the service area size and the city size
Agglomeration coverage	5%	0	1	Ratio between the service area size and the agglomeration size
Station density	5%	0	4	Ratio between the number of stations and the city size in km^2
Bike density	5%	0	10	Ratio between then number of bikes and the number of inhabitants in the city (in 1000 people)

Table 2
Sub-criteria in the Affordability main criteria

Sub-criteria name	Weight	Worst	Best	Definition
Specific cost of long term access	5%	0,05	0	Ratio between the cost of annual bike sharing pass and the average monthly income in €
Specific cost of short term access	5%	0,05	0	Ratio between the cost of daily bike sharing pass and the average monthly income in € divided by 20 workdays
Financial attractiveness of long term access	5%	2,5	0	Ratio between the cost of annual bike sharing pass and the monthly public transport pass which covering the entire city
Financial attractiveness of short term access	5%	20	0	Ratio between the cost of daily bike sharing pass and the public transport single ticket

Table 3
Sub-criteria in the Accessibility main criteria

Sub-criteria name	Weight	Worst	Best	Definition
Are there any date when it is closed?	5%	1	0	1 (Yes), it means that the system is closed in some days during a year 0 (No), it means that the system operates all day of the year
Are there any time period of the day when it is closed?	5%	1	0	1 (Yes), it means that the system is closed in some time during an operating day 0 (No), it means that the system operates 24 hours during an operating day
Can the system be used without registration for short term?	5%	0	1	1 (Yes), it means that the system can be used with a single credit card for short term and does not require any registration process in advance 0 (No), it means that a registration process requires in advance, which can be either in person or online
Does it necessary for personally go for registration for long term?	3%	1	0	1 (Yes), it means that either registration is not required or if it is required it can be done online 0 (No), it means that a registration process has to be finished in person in one of the user centres
Station functionality	2%	0%	100%	Ratio between the number of stations where all functions are available and the total number of stations

Table 4
Sub-criteria in the Innovation main criteria

Sub-criteria name	Weight	Worst	Best	Definition
E-bike availability	4%	0	1	Ratio between the number of electric bikes and total number of bikes
Are the docking stations mobile?	4%	0	1	1 (Yes), it means that the stations can be easily moved to another location without any construction 0 (No), it means that the stations cannot be moved to another location without construction activities
Can a helmet be hired?	3%	0	1	1 (Yes), it means that a helmet can be hired from the station 0 (No), it means that the stations cannot be moved to another location without construction activities
Are there an online, real time website to check station occupancies?	1%	0	1	1 (Yes), it means that an online, real time website exists to check station occupancies 0 (No), it means that an online, real time website does not exists to check station occupancies
Is it possible to pre-book a bike online?	4%	0	1	1 (Yes), it means that possible to pre-book a bike online 0 (No), it means that is not possible to pre-book a bike online
Different renting options	4%	0	11	The sum of the different renting options

Table 5
Sub-criteria in the Integration / Sustainability main criteria

Sub-criteria name	Weight	Worst	Best	Definition
PT fare integration	4%	0	1	1 (Yes), it means that bike sharing fare depends on the availability of public transport pass 0 (No), it means that there is no dependency between the public transport and bike sharing fare
User card integration	4%	0	1	1 (Yes), it means that a single user card exists for PT and bike sharing 0 (No), it means that there is no integrated user card exist for public transport and bike sharing
Are there any bonus-malus system available	4%	0	1	1 (Yes), it means that the usage fee depends on some parameters of the system (e.g. rent a bike from a full station is cheaper) 0 (No), it means that the usage fee is constant
Are there any renewable energy source for the stations?	4%	0	1	1 (Yes), it means that a renewable energy source used for the stations (e.g. solar panel) 0 (No), it means that the stations are using conventional energy sources
Are there any e-car used for the redistribution or maintenance?	2%	0	1	1 (Yes), it means that either during the redistribution or maintenance process electric cars have been used 0 (No), it means that no electric car used during the redistribution or maintenance process
Are there any bike used for the redistribution or maintenance?	2%	0	1	1 (Yes), it means that either during the redistribution or maintenance process bikes have been used 0 (No), it means that no bikes used during the redistribution or maintenance process

3.2. Assessment from operator perspective

The operator perspective represented with 5 main criteria and all together 24 sub-criteria:

1. Coverage (Table 1): This main criterion represents how the system covers the city and the agglomeration. It combines geographic and demographic coverage,
2. Affordability (Table 2): This main criterion shows how affordable to use the system. It uses specific values based on average incomes and public transport fares,
3. Usage (Table 6): This main criterion shows how much the system used both with long term and short term access types,
4. Opportunity (Table 7): This criterion provides information about the possibilities of the system. It combines demographic data with general information about the city,
5. Complexity (Table 8): This main criterion describes how complex a system from the operator point of view, how hard is to operate it.

As the expert panel decided that all 5 main criteria is equally important the weights of each main criteria is 0,2 (or 20%). The Coverage and Affordability criteria are the same as in the user perspective.

Table 6
Sub-criteria in the Usage main criteria

Sub-criteria name	Weight	Worst	Best	Definition
Long term user for each bike	4%	0	50	Ratio between the number of new annual pass holders in 2015 and the total number of bikes
Short term user for each bike	4%	0	365	Ratio between the number of daily access pass sold in 2015 and the total number of bikes
Average daily rent for each bike	4%	0	25	Ratio between the number of average daily rent in 2015 and the total number of bikes
Long term users	4%	0	25	Ratio between the number of new annual pass holder in 2015 and the number of inhabitants in the city (1000 ppl)
Short term users	4%	0	400	Ratio between the number of daily access pass sold in 2015 and the number of inhabitants in the city (1000 ppl)

Table 7
Sub-criteria in the Opportunity main criteria

Sub-criteria name	Weight	Worst	Best	Definition
Population	4%	0	10000	Total number of inhabitants in the city (1000 ppl)
Motorization	4%	0	1000	Vehicle ownership; number of cars per 1000 inhabitant, the values are for the country, not specifically for the city
Mode share opportunity	4%	0	55	Ratio between the modal split of public transport and modal split of cycling
Topography	4%	3	1	Topography of the service area categorized in the following three categories: 1 – flat; 2 – easy for cyclist; 3 – hard for cyclist
Helmet legislation	4%	0	100	Helmet legislation in the city for the following categories: 100 – No; 80 – Children only; 50 – Partial rules; Yes – 0

Table 8
Sub-criteria in the Complexity main criteria

Sub-criteria name	Weight	Worst	Best	Definition
Renting modes	4%	1	11	Number of different renting modes including the different mode in the station; at the docks; on the bike and on mobile device
PT fare integration	4%	0	1	1 (Yes), it means that bike sharing fare depends on the availability of public transport pass 0 (No), it means that there is no dependency between the public transport and bike sharing fare
User card integration	3%	0	1	1 (Yes), it means that a single user card exists for PT and bike sharing 0 (No), it means that there is no integrated user card exist for public transport and bike sharing
Are there any bonus-malus system available	3%	0	1	1 (Yes), it means that the usage fee depends on some parameters of the system (e.g. rent a bike from a full station is cheaper) 0 (No), it means that the usage fee is constant
Different usage rate for long and short term	3%	0	1	1 (Yes), it means that the usage fee is the same for short term and long term users 0 (No), it means that the usage fee is different for short term and long term users
Are there any electric bike?	3%	1	0	1 (Yes), it means that the system has some electric bikes 0 (No), it means that the system has no electric bikes

4. Application

As it was described in the previous papers (Mátrai and Tóth, 2016a; b) of the authors, a comprehensive database has been developed as part of a PhD research. From this database a dataset with nine systems has been selected in order to test the benchmarking methodology. The following list contains the main information about these systems, together with some aspect of the selection process:

1. **Mol-Bubi** (Budapest, HU): the first Hungarian system which belongs to the 4th generation. It is a small system with around 100 station and 1200 bikes. It has no e-bikes, but contains several innovative elements such as the on-boar computer, solar panels, GPS. The aim of the system was to promote cycling in Budapest. (http://molbubi.bkk.hu/),
2. **Santander Cycle Hire** (London, UK): it is London's self-service, bike-sharing scheme for short journeys, formerly called as Barclays Cycle Hire. It is a medium sized system with about 800 stations and more than 11 thousand bikes. It was established in 2010 as part of the Mayor’s Transport Strategy. (https://tfl.gov.uk/modes/cycling/santander-cycles),
3. **Vélib** (Paris, FR): it is one of the first bike sharing system which is well-known. It has more than 23 thousand bikes and more than 1800 stations located not only in inner Paris, but also in the suburbs. At least one station located in every 300 meters. It is one of the most known system which using the advertising company business model. (http://en.velib.paris.fr/),
4. **Bicing** (Barcelona, SP): this system especially targeting the local citizens, since it has no English website and the bikes cannot be hired without a personal registration. It has more than 400 station and 6000 bikes from which 150 is electric. (https://www.bicing.cat/),
5. **BiciMAD** (Madrid, SP): it is the first system which equipped only with electric bikes. The 165 stations and more than 200 bikes covering Barcelona inner city. It has a different pricing policy than the usual bike sharing systems, since the first 30 minutes is not free. (http://www.bicimad.com/),
6. **Citibike** (New York City, US): it is the largest system in the US. It is launched in 2013 with around 6000 bikes and 500 stations, but it is undergoing a large expansion in 2016 to reach 10 thousand bikes. It covers Queens, Manhattan, Brooklyn and Jersey City. (https://www.citibikenyc.com/),
7. **Capital BikeShare** (Washington DC, US): it works in the capital of the USA as well as Arlington, Alexandria and Montgomery County. It has more than 3000 bikes and 350 stations. It was the first bike share system in North America, which started in 2008 with 10 station and 120 bikes. The system itself is jointly owned by the participating jurisdictions and operated by a service provider. (https://www.capitalbikeshare.com/),
8. **Bixi** (Montreal, CA): this is the system with around 5200 bikes and 460 stations. The service area covers Montreal, Longueuil and Westmount. The system operator went bankrupt in 2014, but with the help of the municipality the system stayed in place. Since then it has successful expansion around the globe. (http://montreal.bixi.com/en),
9. **EcoBici** (Mexico City, ME): the system is in place in Mexico City, where the climate supposed to not the best for cyclist. It is created both for the citizens and tourists and started in 2010 with 84 stations and 1200 bikes. Currently it operates with 6000 bikes and 450 stations. Here the first 45 minutes is free. (https://www.ecobici.df.gob.mx/en/)

All systems can be categorized into the 4th generation according to the methodology described in the previous papers (Mátrai and Tóth, 2016a; b) of the authors. Except for the continental European ones, all other systems publish their usage statistics according to their open data policy and legal background.
The first radar chart (Fig. 1.) shows the weighted point in each main criteria from the user perspective and the second (Fig. 2.) from the operator perspective. This is the detailed results of the assessment.

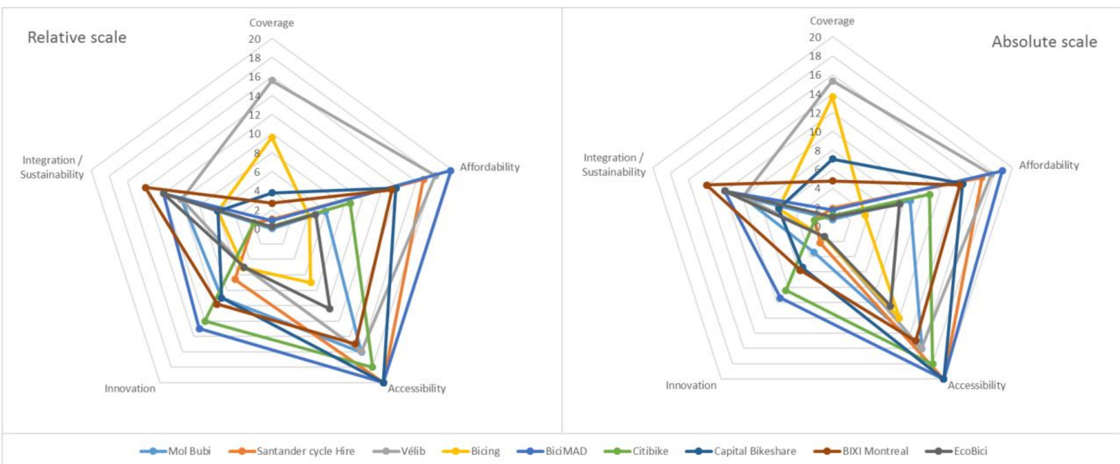

Fig. 1.
Radar chart of bike sharing system from user perspective using relative or absolute scale

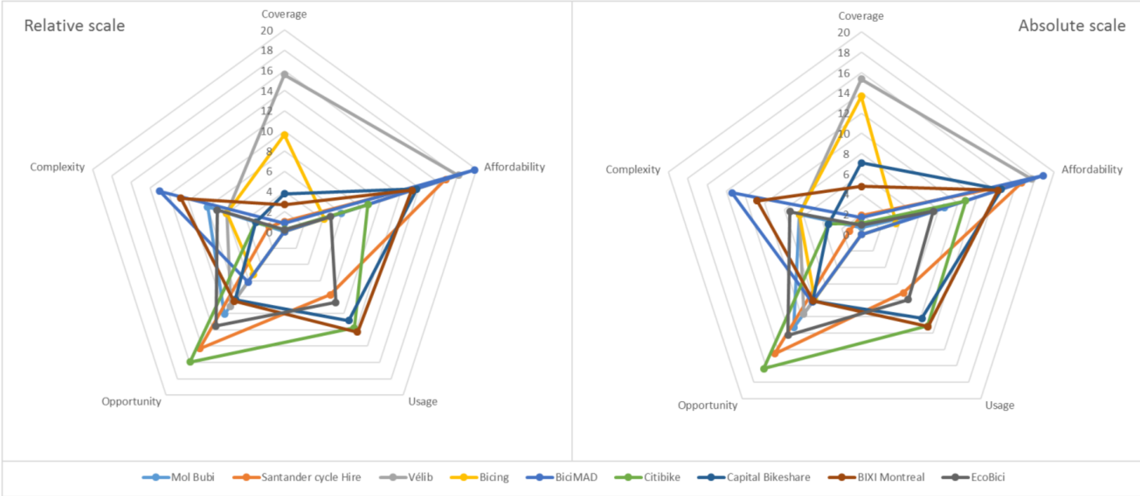

Fig. 2.
Radar chart of bike sharing system from operator perspective using relative or absolute scale

Fig. 3. shows the total points of each system visually and this is the sum of the previous charts. The vertical scale represents the total weighted points. 100 points can be reached in a relative scale if a system is the best in all sub-criteria, while in an absolute scale if a system reach the theoretical maximum in each sub-criteria.

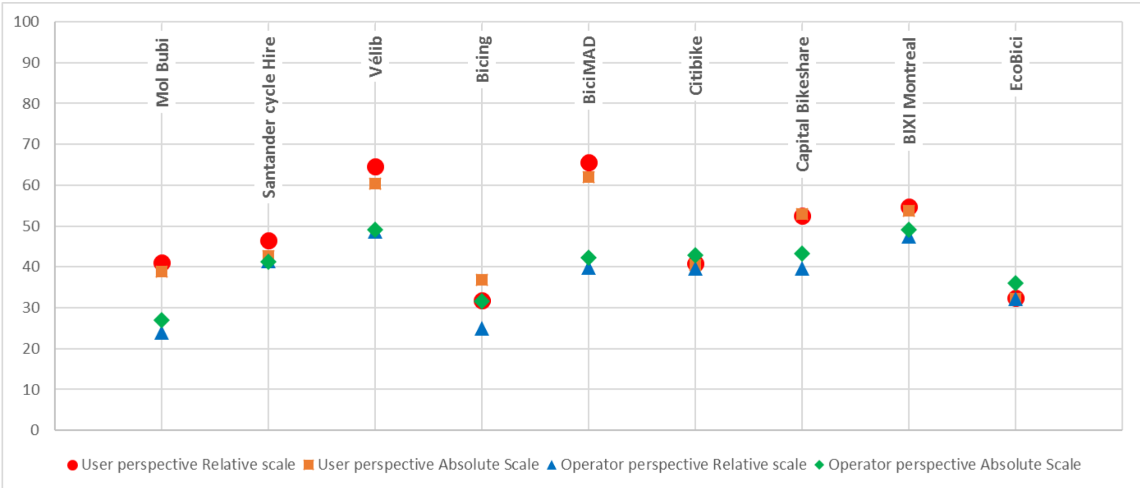

Fig. 3.
Comparison of system total points from different viewpoint and with different scale

Table 9 shows the ranking of the analysed systems from different perspectives. From user perspective the first five systems are the same in both scales, while in operator perspective this is only the case for the first two. Vélib and BIXI Montreal are in the top three in both perspectives.

Table 9
Ranking of the systems under investigation from different perspective and scale

User perspective		
#	Relative scale	Absolute scale
1	BiciMAD	BiciMAD
2	Vélib	Vélib
3	BIXI Montreal	BIXI Montreal
4	Capital Bikeshare	Capital Bikeshare
5	Santander cycle Hire	Santander cycle Hire
6	Mol Bubi	Citibike
7	Citibike	Mol Bubi
8	EcoBici	Bicing
9	Bicing	EcoBici

Operator perspective		
#	Relative scale	Absolute scale
1	Vélib	Vélib
2	BIXI Montreal	BIXI Montreal
3	Santander cycle Hire	Capital Bikeshare
4	BiciMAD	Citibike
5	Capital Bikeshare	BiciMAD
6	Citibike	Santander cycle Hire
7	EcoBici	EcoBici
8	Bicing	Bicing
9	Mol Bubi	Mol Bubi

5. Conclusion

Large amount of data has been collected from several PBS systems (nearly 80 systems, i.e. around 10% of the already existing set of around 800 systems), from which 9 has been selected for the application of our methodology. During the selection process we considered geographical representation, city size, transport behaviour differences, innovativeness in order to draw an appropriate sample. A methodology has been developed taking into account the literature review. The methodology has been applied to the selected systems and some general conclusions have been drawn.

It can be stated that system performance usually differs depending on user and operator perspectives, although some systems got similar points (such as EcoBici, Santander cycle Hire, Citibike). Points from user perspective are usually higher or the same in the relative scale.

Comparing the relative and absolute scales, the best performing systems are the same, which can be the result of that the theoretical maximum values are usually close to the best system's value.

The best systems show diverse characteristics. They got high points in different main criteria, which means they have different advantages and shortcomings. In the same time, they have similar total scores. None of the systems got total score close to the maximum 100 points, which was one of the prerequisites of the methodology development. The main opportunities and shortcomings are easily identifiable.

It has to be mentioned that this methodology, as it is normally the case, has certain limitations. Sample size has strong influence on the results if the relative scale is used. In the same time, using the absolute scale can be misleading if the theoretical maximum value calculations are wrong.

The advantage of the presented methodology is that it does not contain any sub-criteria which require expert judgement, in other words all sub-criteria are defined in a quantitative way. The financial and economic impacts are not used in this method, since cost-benefit analysis is a more elaborated solution for this purpose that, on the other hand, requires significantly more information from the PBS system. Usage statistics represent a very small part of the evaluation, since the authors believe that this way the method is easier to apply for both existing and planned systems. Usage statistics tend to be too optimistic (Kelly et al., 2015; Mátrai, 2013).

As always, the work is far from being completed. We identified the following topics for future research:

- Extend the sample for all 80 systems in the database,
- Add new sub-criteria,
- Develop questionnaires for users and operators in order to collect data to define weights for sub-criteria,
- Apply sensitivity tests on the methodology.

All the above mentioned research ideas may add important finding for the fine tuning of the methodology.

CHILD-FRIENDLY MOBILITY - A GUIDELINE PUBLISHED BY THE AUSTRIAN RESEARCH ASSOCIATION FOR ROADS, RAILWAYS AND TRANSPORT (FSV)

Helmut Lemmerer[1], Thomas Macoun[2], Manuela Winder[3]
[1,2,3] Research Center of Transport Planning and Traffic Engineering - Vienna University of Technology, Vienna, Austria

Abstract: The guideline “Child-friendly Mobility” aims at designing public space in a child-friendly manner. It is effective for both urban and rural settlements and refers to the daily mobility of children aged between zero to fourteen. Children have needs and skills different from adults and their special needs should be taken into account. This will lead to a paradigm change in the transport planning process: it has to deal not only with the engineering of the transport space, but also the design of the living space for children. Participation of children themselves will play an important role in this new traffic planning approach.

Keywords: child-friendly mobility, transport planning, traffic safety, participation.

1. Introduction

In the recent decades, living and development conditions for children have largely changed. The increase of road traffic and its consequence led to a rise of risks from road traffic, air and noise pollution, lack of public space and leading to less physical activities of children, which affect the healthy child development at each stage of the childhood. Transport planners have to consider the requirements of all road users: creating a child-friendly environment poses new challenges for transport planners. This guideline serves to the child-friendly design of public space and is applicable for both urban and rural settlements. It refers to the daily mobility of children between zero and fourteen year-old. The guideline considers the entire world of experience and mobility of children. A number of international and national reports, conventions and action plans claim the design of an environment suitable for children, e.g.: children’s environment and health action plan for Europe (CEHAPE) (WHO, 2004), protecting children’s health in a changing environment (WHO, 2010), convention on the rights of the child (CRC) (UN, 1989), Austrian children's health and environment action plan (BMLFUW & BMGFJ, 2007), Austrian implementation report on healthy environments for children (BMLFUW & BMG, 2010), Austrian children and youth health strategy (BMG, 2012) and the Austrian action plan on physical activity (BMLVS & BMG, 2013).

2. Special needs of children

Independent and safe mobility is an important prerequisite for the healthy physical, mental and psychological development of children. The public space has to become more attractive for children. Accordingly, the design of public spaces has to be aimed to ensure safe road use and with the fact that children can move and play on their own without parental control.

The development of certain abilities of children differs greatly between age groups and individuals. Thus, children are a very heterogeneous group and must not be regarded as small adults since they differ in their thinking, perceiving and acting.

An appropriate transport planning action regarding children's requirements considers the developmental conditions for the participating children. Children's danger awareness is gradually developed based on their own experiences, e.g. watching accidents and explanatory notes of caregivers. By the age of about twelve children are able to anticipate risks and to take preventive actions. In addition, their estimation of distance, direction, and speed and their ability to empathize with other road users are learned step by step. Their field of view is smaller than adults by about a third and is not fully developed until the age of twelve. Thus, children's perception of lateral approaching danger is limited. They need more time to classify their visual and acoustic experience and they are more focused towards individual aspects than the overall impression of a situation.

2.1. Different age groups have different demands of the public space

Early childhood: Up to 3 years
The toddler age is a time of experimentation and experiencing. The child is interested in everything that comes from the outside world. Principal residence of the child is the living area or external sites e.g. playschool. In addition to walking, children start to move with tricycles, sit in the bike trailer or child seat in the car or use public transport accompanied by adults. The guidelines mainly refer to this age group by the needs of parents and caregivers.

[1] Corresponding author: helmut.lemmerer@tuwien.ac.at

Pre-schoolers: 4 to 5 years
The ability to move independently improves. New motion sequences are learned e.g. riding a bike. First cognitive, social and emotional skills are developed. Parents accompany the children in their trips and attendants stay within sight. They mainly play at specially intended places e.g. playgrounds, in yards or gardens.
Children of primary school age: 6 to 10 years
The desire for more open space increases. The children are interested in everything, to get active themselves and they are very eager for knowledge. Unaccompanied, children cover more and more trips (school, residential area). After passing the cycling proficiency test by the age of 10 years, they have the license to bike unaccompanied on the roadside in Austria.
Children in adolescence: 11 to 14 years
The radius of action of the young people increases and expands beyond the close to home area. With increasing age, adolescents take over spaces in the entire local area. At the same time, they stay in delimited areas in order to retreat. They prefer to walk, to cycle or to use public transport independently.
The possibility of independent mobility depends on the mobility network sector and the parental control.
Different mobility patterns by gender
In addition to the age, the usage of public space differs by gender. Research shows that boys have larger action areas than girls and they cover longer distances on foot or by bike. In general, boys have more accidents and they take over open space by active games. Girls are more interested in social games less aimed at competition. Particularly girls require safe refuges.

3. Considering needs of children as a prerequisite for a child-friendly transport planning

3.1. Independent mobility and child-friendly areas of activity

As soon as children have the opportunity to cover their daily trips by foot or bicycle, they often experience that the usage of their areas of activity is largely limited due to the risks of road traffic. However, this trend leads to a further increase of road traffic (e.g. parent taxis) and to an additional endangering of children who cover their trips by active modes.

3.2. Traffic safety

A large percentage of accidents involving children do not occur on routes to school as these are protected by crossing guards or traffic police. The large amount of road traffic and its high speed leads to stress in children and parents. As a result, parents prohibit unaccompanied stay and playing outdoors and/or drive children by car to various events and locations. Through that, children result in a lack of important experiences that strengthen their self-responsibility and self-confidence. All these skills are important mandatory requirements of an accident-free mobility. In addition, a high level of car availability results in the continuing decline of road skills of the children since they hardly learn to get around unaccompanied and thereby to correctly assess the road risks. Inexperienced and motoric untrained children have a higher injury risk than children with developed motor skills.

3.3. Participation

Present planning decisions affect the social, economic and ecological future of the children in the next decades. Participation is the involvement of children in decision-making processes of which they are affected, either directly or indirectly. Children should have the opportunity to discuss and to co-design. This is because at the age of four to six years, children can argue their view if the discussion is related to their direct neighborhood. By the age of seven children are able to get an overview of their immediate area of life and to take deliberative decisions. Children can be involved in almost all design tasks, ranging from the development of urban and rural transport concepts, up to public space design as well as the design of bus stops. It matters that the planning subject is as realistic and specific as possible with a direct relationship to their world of experience.

3.4. Planning actions

In addition, street design has to consider the needs of children. The overall planning goal is to achieve an advanced livability for children in public spaces and in urban areas. The quality of life depends on the use, density and zoning map and on the available free space. Following an overall consideration of the settlement area, it is thus possible to promote the respective means of transport according to their importance for children. In any case, high priority is given to traffic on foot, cycle traffic and public transport instead of the private motor vehicle.

3.5. Network Planning and spatial network

The entirety of all streets and places form a spatial network. The development of a general scheme and the assessment of a street require an overall design concept. Consistent with this approach further planning is supposed to be carried out. Where there is no overall design concept a current situation analysis is required. The spatial network has to consider the characteristics and the optimum applications of the various means of transport. Main street axes related to motor vehicle transport are possible. In addition, a stronger networking and mixing of the road space usage is essential for the purpose of street design beyond pedestrian zones.

3.6. Consideration of action spaces of children in planning process

Barriers such as heavy trafficked roads or tram/railway lines result in the remoteness of activities (separation effect, fragmentation). Due to barriers, the distance to school gets longer, shops and residences of friends can only be reached accompanied by adults (Fig. 1.).

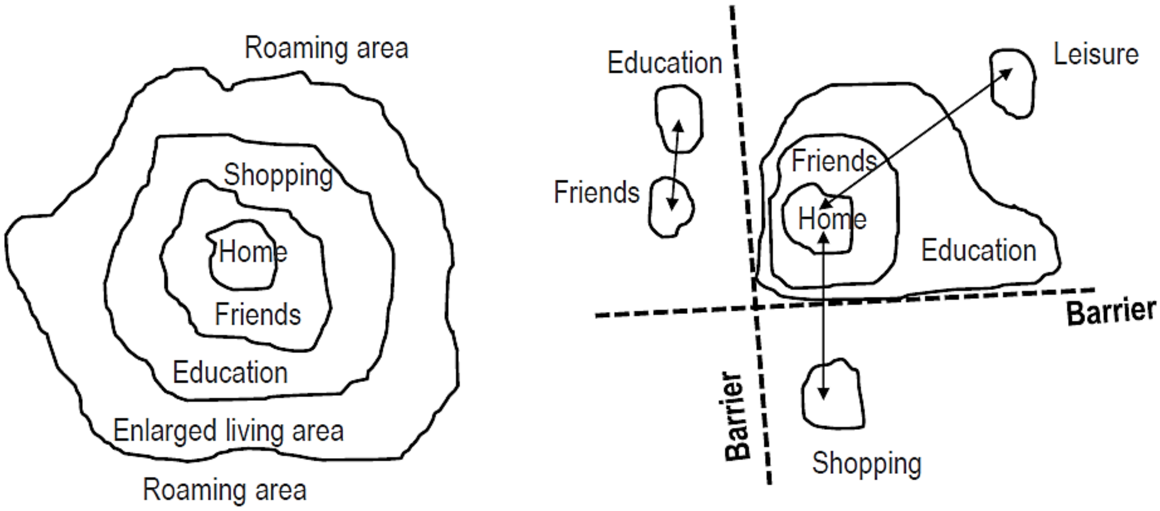

Fig. 1.
Model of occupation of the living area in concentric circles
Source: Busch (1995), own figure

Action spaces should be located in the immediate living area and not separated by e.g. risky road spaces. If necessary, the crossing of the road network has to be designed in a secure child-friendly manner. Action spaces of different age groups have to be considered in the planning action by providing respective extended zones (e.g. seven-year-old children are in need of an action space of at least 0.7 km²). Action spaces of children increase rapidly by age and achieve 3 km2 and more for ten year olds. Current traffic related measures are limited to traffic-calmed zones in living areas. A child-friendly planning approach however has to integrate urban functions such as education, leisure, green areas and shopping destinations. Therefore, indicators such as spatial density, location and accessibility, centralization and urbanity have to be examined.

4. Facilities of public space as a living and mobility space

The qualification and quantification of children's demands on the street space are the basis of the planning process. The demand derives from the needs of the adolescents. Little children up to primary school age require a secure routing in the course of their trip chain around the playground or the shopping area. The public space is supposed to be planned diverse in order to encourage children to establish a creative, self-directed utilization.

- Playground design by spacious and attractive playing areas,
- Green vegetation on public spaces (trees, hedges, shrubs, etc.),
- Spatially associated playing areas through safe pathways (attractive for both pedestrian and bicycle traffic),
- Easily accessible, safe crossing aids,
- Reduced motorized traffic in residential areas: setting up pedestrian areas, promotion of car-free neighborhoods (e.g. residential streets) to largely car-free residential areas and districts. Avoidance of truck traffic,
- Reduce speed of motorized traffic: Implementation of pedestrian areas. Widespread 30 km/h speed zones. Speed limit on major roads frequently used by children,
- Stronger focus of public transport on the needs of older children: Easy readable and comprehensible network, reduced ticket pricing, transport links to points of interests of children,
- Mobility management/mobility education: raise awareness for the needs and abilities of children (FGSV, 2012)

5. Conclusion

Independent and safe mobility is an important prerequisite for a healthy physical, mental and psychological development of children. Therefore, the design of public spaces has to consider both safe road use and the fact that children can move and play by themselves in the public space without parental control. Planning actions of road systems have be aligned to the needs of all road users particularly with regard to children. The implementation of a child-friendly environment raises new challenges for the traffic planning and management. In other words, a paradigm change must take place away from engineering transport space towards designing a child-friendly living space.

Acknowledgment

This paper is based on the guideline child-friendly mobility (RVS 03.04.13) prepared by the working committee urban traffic of Austrian research association for roads, railways and transport (FSV).

SESSION 10: ROAD TRAFFIC AND TRANSPORT RESEARCH - MODELING AND OPTIMIZATION

ESTIMATION OF CAR OWNERSHIP IN TURKEY USING ARTIFICIAL BEE COLONY ALGORITHM

Ersin Korkmaz[1], Erdem Doğan [2], Ali Payıdar Akgüngör [3]
[1,2,3] Civil Engineering Dept., Engineering Faculty, Kırıkkale University, Kırıkkale, Turkey

Abstract: This study proposes Artificial Bee Colony (ABC) models to estimate the number of cars in Turkey. In other words, car ownership is defined the number of cars per 1000 people. In the models development, population (P), per capita Gross Domestic Product (GDP) as dollars and fuel prices as Petrol, Diesel and Lpg were selected as model parameters. Two different ABC models were developed using the data covering from 2004 to 2015. According to fuel type, the coefficients of models were determined for each fuel type. Therefore, the sum of number of cars for each fuel type presented car ownership in Turkey. Developed models' results were statistically compared to observed values in terms of root mean square errors (RMSE), mean absolute percentage errors (MAPE) and coefficient of determination (R^2). The results of the ABC models showed that they were suitable to estimate the number of cars. To investigate the performance of ABC models for future estimations, a ten-year period from 2016 to 2025 was considered. Thus, future values of population were obtained from the projection of Turkish Statistical Institute (TSI) and the projections of other parameters, per capita GDP and fuel price, were executed according to current growth curve. The results obtained from future estimations reveal the suitability of ABC approach for determination of car ownership.

Keywords: car ownership, Artificial Bee Colony (ABC), Turkey.

1. Introduction

Especially, due to the rapid development of Turkey's economy in the last decade people's welfare and purchasing power are increasing. This increment affects car ownership as other socio-economic situations, and the number of cars is rising rapidly day by day. It is a fact that the rising of the number of cars has both positive and negative effects on people life. First of all, the private car is a component of modern life and is viewed as a symbol illustrating the people's status. Therefore, individuals in developed and developing countries desire to own their cars and benefit advantages of them. When individuals have their own cars, they are able to go wherever they want without the constraints of public transport timetables and the limitations of distance or time associated with walking and cycling. However, owing a car comes with some costs. Especially, while purchasing, taxes and maintenance costs of cars are directly related to individuals, other effects as increments in energy consumption, traffic congestions and air pollutions etc. and reductions in incomes of public transports are related to society and governments. In addition to these, car ownership data is used as a parameter by car manufacturers and oil companies to determine their strategies on products that are not yet on the market.

Due to the importance and effects of car ownership on society and economy, it has been intensely studied over many years by researchers. The first studies of this subject began in 1930s and have been developing since then. The very early research about the car ownership was started with (Wolff, 1938). A lot of researches, (Tanner, 1958, 1975; Mogridge, 1989 etc.) have studied on car ownership and have developed different forecasting models. Earlier models of car ownership were related to aggregate data and generally cross-sectional data, time series data etc. However, in recent decades researches have tended to centre on the development of disaggregate models. Because of developments in socio-economics conditions, individual's propensity and accessibility to own a vehicle have increased rapidly in especially developing countries. Pooled time-series data and panel data etc. were used by some researchers as (MVA Consultancy, 1996 and Hanly and Dargay, 2000). Jong *et al.* (2004) studied about car ownership and classified this subject in nine types. They are aggregate time series models, aggregate cohort models, aggregate car market models, heuristic simulation models, static disaggregate ownership models, indirect utility models of car ownership and car use, static disaggregate car-type choice models, panel models and pseudo-panel models and dynamic car transactions models. Nine types models were compared in terms of sixteen criteria, ranging from the treatment of supply, through level of aggregation and data requirements, to the treatment of scrappage. As a result, it was showed that the most preferred model type would vary from context to context. Whelan (2007) studied on modelling car ownership in Britain and he applied their models using a methodology known as prototypical sampling. After successfully validated models, they were used to forecast for future by taking into account changes to the socio-demographic characteristics of Britain. Clark (2009) attempted to predict the level of household car ownership as a function of the characteristics of the household and the individuals that make up the household. He showed that results of study were in line with those from previous research but performed a potential to predict the higher levels of household car ownership with greater accuracy than other similar studies. Some researchers from Turkey have studied about car ownership and they have applied different approaches to estimate car ownership. Ogut (2006) utilized Fuzzy Regression for modeling car ownership in Turkey. He determined the urbanization rate, average family size, gross national product per capita, average car cost, gasoline price and total length of roads as independent variables. He showed that using fuzzy method could be more practical than other methods. Codur and Tortum (2006) applied neural networks for modelling car ownership in Turkey. They selected four independent parameters which are GDP, petrol price, car price and road

[1] Corresponding author: ersin_korkmaz1@hotmail.com

lengths. The results of this study showed that Artificial Neural Network was more successful and reliable than other classical models in terms of nonlinear reflection ability.
Artificial Bee Colony (ABC) algorithm is one of these different approaches and the purpose of this study is to examine whether ABC is effective and useful to accurately estimate car ownership in Turkey. Two different ABC models were proposed based on population (P), per capita Gross Domestic Product (GDP) as dollars and fuel prices as Petrol, Diesel and Lpg. The performance of ABC models was evaluated by means of the root mean square error (RMSE), the mean percentage absolute error (MAPE) and the coefficient of determination (R^2) for both test and train data. Analysis results showed that all proposed car ownership models could be used for indicator of socio-economic studies and relationship between car ownership and development.

2. Details Experimental

2.1. Artificial Bee Colony Algorithm

Many of the real-world optimization problems are too complex and they may not be solved by developing mathematical formulas. When being tried to solve such a problem by using conventional methods, the solution may take too long time and results may not be located at desired solutions although it may take long time. In this case while searching for problem solution, intuitive (heuristic) methods have been developed and tried to reach the best results. Heuristic methods to solve a problem are known as the methods described to decide on the best solution from a variety of movements.
Artificial Bee Colony Algorithm is one of Artificial Intelligent and popular swarm based optimization algorithms. It is a stochastic global optimization method inspired by the foraging behavior of a honey bee swarm. Karaboga (2005) introduced firstly this algorithm in 2005 and applied in several fields to solve different problems up to date. In other words, ABC is an optimization algorithm created by following the example of their unique intelligent behavior of bees and by inspiring the method which bees use to search foods.
There are task-sharing in a bee colony collecting honey in their natural habitat. One of the most important things to ensure the continuation of the life of the bee colonies are foraging. There are some important factors in this process as the resources collected in the hive and feed sources can be found in the environment so on. The search process starting together with being removed hive by bees, it will initially continue with arbitrary food research. As a result of the reduction in the amount of food in found source, bees begin to forage or turn to other sources according to information received from other bees. That the information of found sources are transmitted to each other and sources as pollen and water so on. are brought to hive by bees are the activities carried out in the process.
As the minimal model of foraging behavior of honey bees, the colony of artificial bees in ABC are divided into three groups. They are employed bees associated with specific food sources, onlooker bees watching the dance of employed bees within the hive to choose a food source and scout bees searching for food sources randomly. At the beginning of algorithm, the food sources are investigated by scout bees and after that, it begins to be collected the nectar from these the sources. Thus, both found sources are used and information of sources are shared to onlooker by bees returning to employed from scout. While occurring convergence to point of solution with the move of onlooker bees to rich researches, new solution points are investigated by scout bees returning from employed bees in depleted sources. This situation continues in the cycle process until the optimal point is found. Food sources in algorithm refers to possible solutions of problems being tried to be optimized. The amount of nectar of a source refers to the quality value of the solution expressed by welding. Thus, the process of searching for good food sources can be considered as the process of finding the optimal solution.
Algorithm operation is carried out in four basic steps. They are as below:

- Determining of the initial values of sources.

Properly functioning of algorithm is related to the creation of the initial source correctly. Randomly determining the sources corresponding resolutions which involve all search space is the main concern. Initial resources are randomly generated in the lower and upper limits of each parameter. Mathematical expression of this step;

$$ {}_{i}^{0}x_j = {}^{min}x_j + rand(0,1)\left({}^{max}x_j - {}^{min}x_j\right) \tag{1} $$

where ${}_{i}^{0}x_j$ is created source, j = 1, …D and i = 1, …SN. D is the number of variables and SN is determined number of sources. ${}^{max}x_j \ ve \ {}^{min}x_j$ refer to lower and upper limits of each parameter.

- Direction of employed bees to sources.

One of the assumptions of this algorithm is that the number the number of employed bees is the same as the number of the food sources. There are seeking of new sources in neighborhood of first sources which employed bees have directed. Mathematical expression of neighborliness research;

$$ v_{ij} = x_{ij} + \emptyset_{ij}\left(x_{ij} - x_{kj}\right) \tag{2} $$

where x_{ij} is existing food source, v_{ij} is new resources sought in the neighborhood of the available resource and $\emptyset_{ij}$ is a random number varying between -1 and 1. There are limits for v_{ij} and in case of violation of these limits it is postponed to the limit again. Limit expression of v_{ij};

$$v_{ij} = \begin{cases} x_j^{min}, v_{ij} < x_j^{min} \\ v_{ij}, x_j^{min} \leq v_{ij} \leq x_j^{max} \\ x_j^{max}, v_{ij} > x_j^{max} \end{cases} \tag{3}$$

- Calculating selecting probabilities of food sources for onlooker bees.

According to information provided by the employed bees, source that has the highest fitness value will be selected by onlooker bees. The expression of each source's fitness function;

$$p_i = \frac{fitness_i}{\sum_{j=1}^{SN} fitness_i}$$

(Error! No text of specified style in document.)

where $fitness_i$ is the fitness value of i. and p_i is probability of selection.

$$fitness_i = \begin{cases} 1/(1+f_i), f_i \geq 0 \\ 1 + abs\,(f_i), f_i < 0 \end{cases} \tag{5}$$

where f_i is cost value of v_{ij}.

- Giving the decision of exclusion of the use of existing resources.

If there are depleted sources, they are abandoned and replaced with a new solution by scout bees. Otherwise, stopping criterion is checked without using replacing.

2.2. Development of ABC models

To develop ABC models, necessary data were obtained from Turkish Statistical Institute (TSI, 2015). Two different mathematical models, namely linear and power forms, given in Eqs. [6-7] respectively, proposed to estimate car ownership in Turkey.

Linear Form;

$$Co = w_1 * x_1 + w_2 * x_2 + w_3 * x_3 + w_4 \tag{6}$$

Power Form;

$$Co = w_1 * x_1^{w_2} * x_2^{w_3} * x_3^{w_4} \tag{7}$$

in which x_1 is the number of population, x_2 is per capita Gross Domestic Product (GDP) as Dollars and x_3 is fuel prices as Petrol, Diesel and Lpg. W_i is the corresponding weighting factors.
The coefficients of the models given in Table 1 are obtained by using ABC.

Table 1
The coefficient of models

Linear			Power		
Petrol	**Diesel**	**LPG**	**Petrol**	**Diesel**	**LPG**
w1=-0,053	w1=0,302	w1=0,281	w1=9,96E+15	w1=3,21E-28	w1=1,74E-36
w2=-45,009	w2=-144,695	w2=36,160	w2=-1,172	w2=4,964	w2=5,155
w3=-196784	w3=67993,920	w3=146526,400	w3=-0,031	w3=-1,633	w3=0,380
w4=8353598	w4=-19428816,540	w4=-18489778,100	w4=-0,245	w4=2,108	w4=0,402

According to fuel type, the coefficients of models were determined for each fuel type. Therefore, the sum of number of cars for each fuel type presented car ownership in Turkey. Since car ownership is defined the number of cars per 1000 people, the sum of number of cars for each fuel type is calculated as the number of cars per 1000 people.

3. Results and Discussion

The performances of models were evaluated in terms of error criteria which are RMSE, MAPE and R^2 defined in Eqs. 8-10.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(D_{Observed} - D_{estimated})^2} \tag{8}$$

$$MAPE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{Co_{Observed} - Co_{estimated}}{Co_{Observed}}\right| * 100 \tag{9}$$

$$R^2 = 1 - \left[\frac{\sum_{i=1}^{n}(Co_{Observed} - Co_{estimated})^2}{\sum_{i=1}^{n}(Co_{Observed} - Co_{mean})}\right] \tag{10}$$

The performances of models for each fuel type were separately evaluated in terms of error criteria. The comparison results are illustrated in Table 2**.** As seen from Table 2, linear model illustrated better performance than power model for each fuel type. Especially, there are significant differences in terms of RMSE, MAPE and R^2 in diesel type. Linear model performed considerable values in MAPE and R^2 for each fuel type. They are 1.00, 9.35 and 3.11 for MAPE and also 0.9849, 0.9833 and 0.9979 for R^2, respectively. Car ownership values for per 1000 people have been calculated according to proposed models and are showed their results in Fig 1. The performance of the linear model are better than that of other model when the relationship between model estimates and observed data has been investigated. Fig 2 graphically illustrated this relation. As understood from Fig. 2, observed values and estimated values of linear model are in agreement and R^2 of this relationship is 0.9849.

Table 2
The Statistic of Data for Comparison

	Linear			Power		
	Petrol	**Diesel**	**LPG**	**Petrol**	**Diesel**	**LPG**
RMSE	51 739	125 965	67 055	50 342	21 6664	195 608
MAPE	1.00	9.35	3.11	1.18	24.91	8.16
R^2	0.9849	0.9833	0.9979	0.9858	0.9514	0.9747

Relationship between observed and estimated values

4. Future estimates of car ownership for Turkey

Due to better performance of the linear model, it is selected to estimate the number of cars in the future. Thus, car ownership can be forecasted according to developed scenarios. In this section of the study, a scenario is considered to estimate car ownership until 2025. According to the projection of TSI, the population of the country will be around 85 million in 2025. The projections of other parameters, GDP and fuel price, were executed according to current growth curve. The average GDP and fuel price growth rate were taken as 5%. They will be around $14 941 for per capita GDP, TL 7.88 for petrol, TL 6.98 for diesel and TL 3.76 for LPG in 2025. The reader is referred to Table 3 for data on population and other parameters data used in this scenario. ABC Linear model estimates are tabulated in Table 4. The study results show that car ownership value steadily will increase in Turkey and will reach a value of 150.

Table 3
Population and other parameters' predictions

Year	**Future Estimates**				
	Population	**Per Capita GDP (Dollars)**	**Petrol (TL)**	**Diesel (TL)**	**LPG (TL)**
2016	78 965 645	9 631	4.66	4.13	2.23
2017	79 766 012	10 113	4.94	4.38	2.36
2018	80 551 266	10 619	5.24	4.64	2.50
2019	81 321 569	11 150	5.55	4.92	2.65
2020	82 076 788	11 707	5.89	5.22	2.81
2021	82 816 250	12 292	6.24	5.53	2.98
2022	83 540 076	12 907	6.62	5.86	3.16
2023	84 247 088	13 552	7.01	6.22	3.35
2024	84 936 010	14 230	7.43	6.59	3.55
2025	85 536 010	14 942	7.88	6.98	3.76

Table 4
Linear model car ownership estimates

Year	Car Ownership
2016	132
2017	135
2018	137
2019	140
2020	142
2021	144
2022	146
2023	148
2024	149
2025	150

5. Conclusion

This study presents an application of the ABC algorithm to estimate car ownership in Turkey for the next decade. ABC car ownership prediction models are developed by using a twelve-year historical data covering the years between 2004 and 2015. In the model development, two mathematical forms which are linear and power are determined. The population, per capita Gross Domestic Product as dollars and fuel prices as Petrol, Diesel and Lpg are considered as model parameters. A comparative study is performed among developed car ownership models and observed data. The all ABC models results are a good agreement with observed data. Especially, linear model is coherent with observed data. Therefore, linear model can be used for future estimates.
All developed models are statistically compared in terms of error criteria, such as RMSE, MAPE and R^2 for each fuel type. The results show that the performance of linear model is better than that of power in terms of RMSE and MAPE and R^2. Especially there are significant differences in terms of RMSE, MAPE and R^2 in diesel type.
In order to evaluate the future performance of the developed ABC linear model a scenario is considered. This scenario covers ten years' period from 2016 to 2025. According to the scenario, the population, per capita GDP, petrol, diesel and LPG price in Turkey will reach nearly 85 million and also $14 941, TL 7.88, TL 6.98 and TL 3.76 in 2025, respectively. The forecasting results show that car ownership value steadily will increase in Turkey and will reach a value of 150. The mean of this is an approximately 15% increase in car ownership between 2015 and 2025.
The performance of a model may increase with increasing the number of the model parameters and model forms. For further studies, other parameters which are effected on car ownership could be employed to improve the performance of the models.

ASSESSING THE POSSIBILITIES OF REDUCING THE TRANSPORT COMPANY COSTS

Vieroslav Molnár[1], Katarína Pačutová[2]
[1,2] Technical University of Kosice, Kosice, Slovakia

Abstract: Article deals with economic evaluation and reduction of transport company costs. Costs reduction can be achieved by reducing fuel consumption in trucks and by choosing appropriate vehicle for packages transport of cargo to the company premises. Three types of vehicles are used for the research purpose. Fuel consumption and toll prices are considered essential indicators for choosing appropriate vehicle for delivering packages from 4 towns in East Slovakia to the specific destination.

Keywords: reducing, fuel consumption, costs, road freight transport.

1. Introduction

If the transport company wants to compete on the market it has to continuously face increased requirements and implement measures that optimize the company's operation which would lead to lower costs (Tomková et al., 2015). Costs of the company can influence profits of the transport company in the most significant way (Nedeliakova et al., 2016). The opportunity to succeed in the market full of competitors is given to that carrier who is able to work efficiently with available funds, thus efficiently operating their vehicle fleet (Ficzere et al., 2014). The customer can be given a lower cost while maintaining the quality of performed services and maintaining a reasonable profit for the transport by the carrier that is able to provide a sufficient number of performances with the vehicle fleet for the monitored period (Strohmandl, 2014). In road transport, small carriers often incorrectly determine the costs for transport and set the price for provided services accordingly (Fedorko and Čujan, 2014). Carriers often calculate incomplete costs or focus solely on price given for a realized unit of performance (Szendrő and Török, 2014). Thus set costs do not provide economically correct results by every transport (Poliak and Konečný, 2015). Fuel costs make up one of the highest cost items in goods transport. Since this is a variable cost, it is directly proportional to the realized performance and the higher the performance the higher the fuel consumption is (Cvengoš, 2013). Several authors are dedicated to possibilities of a reduction in consumption of trucks in terms of reducing the cost. Kment (Kment, 2010) deals with optimizing the fuel consumption of vehicles from the position of a vehicle producer, and further discusses the possibilities of the carrier. Jankovič (Jankovič, 2011) analyses in detail the historical development of fuel costs and national excise, road tolls and charges in the same relation. Gnap (Gnap, 2014) introduces a method of approach to the calculation of the impact of tolls on toll rates, focusing on carload shipments. Poliak (Poliak, 2010) introduces the issue of determining the share of tolls on the cost of transportation for unit cargo.
The aim of this paper is to highlight one of the options for reducing the cost of the company transport by reducing the fuel consumption in trucks and by choosing appropriate vehicle for packages transport of cargo to the company premises.

2. Material and Methods

For the research purposes, a company which is engaged in international road haulage was selected. The company owns 7 trucks with capacity up to 12 tons. The company´s customers are mostly in the industrial park in Kechnec and in towns Michalovce, Košice, and Prešov. Customers include smaller private companies and parcel delivery companies as Kühne Nagel, DHL, Schenker, Norbert Transport, etc. Fig.1 offers an overview of vehicles used in the company according to manufacturer mark, the amount of euro pallets, the volume of the load and capacity of the tank as well as EURO category. Three types of vehicles were used for the purpose of assessing the possibilities of reducing the transport company costs - namely Renault Master, DAF LF and Iveco Euro Cargo + render depicted in Fig. 1.

3. Reducing the Transport Company Cost

Costs reduction can be achieved by reduction of fuel consumption in trucks and by choosing appropriate vehicle for packages transport of cargo to the company premises.

3.1. Reduction of Fuel Consumption in Trucks

There are several ways for the company to reduce the fuel consumption in trucks. One way is to reduce the technical speed of the vehicle. The lower the speed the lower the fuel consumption in trucks. Technical speed was monitored mainly on motorways and expressways over the period of five years to determine the satisfactory and optimal technical speed that fulfills the required consumption.

3.2. Choosing Appropriate Vehicle for Packages Transport

The appropriate type of vehicle was chosen for collection of packages from Košice, industrial park Kechnec, from cities Prešov and Michalovce to company premises in Majerovce. Three vehicles were considered when choosing the appropriate type- Renault Master vehicle, DAF LF and Iveco Euro Cargo + render. The criteria for the right vehicle were the vehicle consumption and the price of toll fees. Examined indicators that were discussed during transport from Kosice, Kechnec, Michalovce and Prešov have similar values. Geographic location, the driver´s driving style, the distribution of goods in the vehicle area, the scale of packages or weight of packages affected the fuel consumption. The weight of packages depended on the city the package came from. Usually, the same packages were distributed and therefore the fuel consumption often reached a similar level.

4. Results and Discussion

4.1. Reduction of Fuel Consumption in Trucks

The achieved results over the period of five years divided into months for vehicles Renault Master DAF LF and Iveco Cargo + render are depicted in Fig. 4 - Fig. 6 and confirm the contemplated assumption about the reduction of consumption when reducing technical speed.

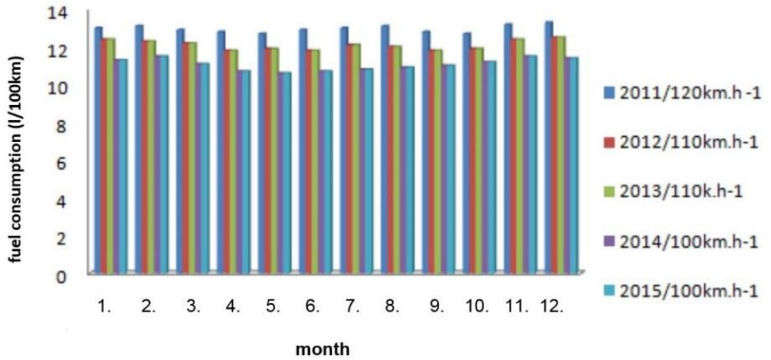

Fig. 4.
Fuel consumption 2011 – 2015 (Renault Master)

Fuel Consumption 2011 – 2015 (DAF LF)
Source: Authors

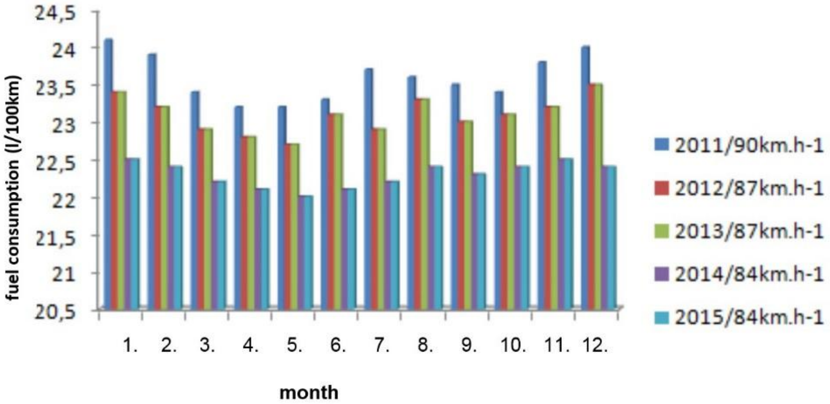

Fig. 6.
Fuel consumption 2011-2015 (Iveco Euro Cargo + render)
Source: Authors

In 2011 Renault Master vehicles were going on the motorways and expressways 120 km per hour. DAF LF with Iveco Euro Cargo + render vehicles were doing 90 km per hour. These speed values resulted in the highest fuel consumption values. In 2012 technical speed of vehicles was lowered in Renault Master to 110 km per hour. DAF LF and Iveco Euro Cargo + render lowered their speed to 87 km per hour. In 2013 the vehicles were going the same speed as in 2012. In 2014 the speed for Renault Master vehicles lowered to 100 km per hour. DAF LF with Iveco Euro Cargo + render vehicles lowered their speed to 84 km per hour. The same applies for the year 2015 when it was confirmed that this speed is satisfactory for driving on motorways and expressways. By lowering the technical speed less fuel was consumed which resulted in lower company costs.

4.2. Choosing Appropriate Vehicle for Packages Transport

Renault Master vehicle had the highest fuel consumption when transporting from Michalovce and the lowest when transporting from Prešov. Iveco Euro Cargo + render vehicle reached the highest consumption when transporting from Kechnec. DAF LF vehicle had the highest consumption when transporting from Košice. Fig. 7 depicts that difference in consumption while transporting packages was almost the same in all vehicles.

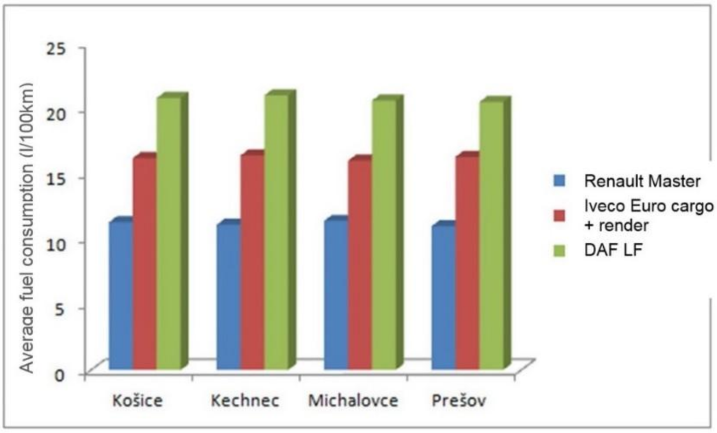

Fig. 7.
Average fuel consumption structure for packages transport
Source: Authors

The reason why toll fees were relatively similar despite the fact that the routes were of different lengths is that not all the sections of the routes were subjected to charges. Toll price was determined according to the emission classes of vehicles and the class. Solo vehicles belong to emission class EURO V, VI, and EEV class truck 3.5 tons - 12 tons. Toll charges do not apply to Renault Master and Iveco Euro Cargo + render. The highest price of tolls for DAF LF truck up to 12 tons was on a route from Kechnec mostly because the truck was driving through the toll sections. The lowest price of tolls was from the town Michalovce. For Renault Master vehicles and Iveco Cargo + render, there were no tolls on a two-way road from Kosice, Kechnec, Prešov, and Michalovce. The calculations showed that toll fees were at their highest on a route from Majerovce to Kechnec. The main reason for this was the highest price for the number of traveled sections as well as the highest number of package transports from an industrial park in Kechnec. For Renault Master and Iveco Euro Cargo + render vehicles, no toll fees applied. DAF LF vehicle paid 1.993,5 € in 2015. No toll fees applied to Renault Master and Iveco Euro Cargo + render on a route from Majerovce to Kosice, but DAF LF vehicle paid 727,04 €. 0 € were paid for Renault Master and Iveco Euro Cargo + render vehicles on a route from Majerovce to Presov, but DAF LF vehicle paid 512,04 €. The lowest prices were paid on a route from Majerovce to Michalovce. Renault Master and Iveco Euro Cargo + render vehicles paid 0 € and DAF LF vehicle only 32,3 €.

4.3. Final Evaluation

Fig. 8 depicts how 3,934.51 € will be saved in a year by exchanging Iveco Euro Cargo + render vehicle for Renault Master. The average price for fuel was 1,135 € per liter in 2015. 4,465.7 € were saved by choosing Renault Master vehicle for package transport in 2015. 7,402,91 liters of fuel would be saved if Renault Master vehicle transported the packages with lower volume instead of DAF LF vehicle. This would mean that a sum of 8,402.3 € is saved in 2015 taking into account an average price for fuel. A total sum of 3,936.6 € and 3,468.4 liters of fuel would be saved by exchanging Iveco Euro Cargo + render vehicle with DAF LF vehicle.

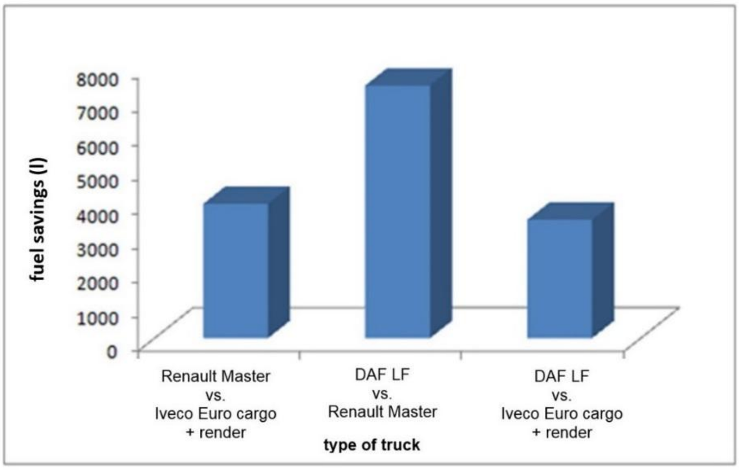

Fig. 8.
Fuel savings
Source: Authors

Fig. 9 depicts the toll price savings. Toll prices are not applicable to Renault Master vehicle. 3,264.9 € would be saved in 2015 by exchanging DAF LF with Iveco Euro Cargo + render vehicle. If the number of goods was smaller and a loading area of the Renault Master vehicle would be sufficient the company would save 3,264.9 € on toll fees *(Toll price savings).*

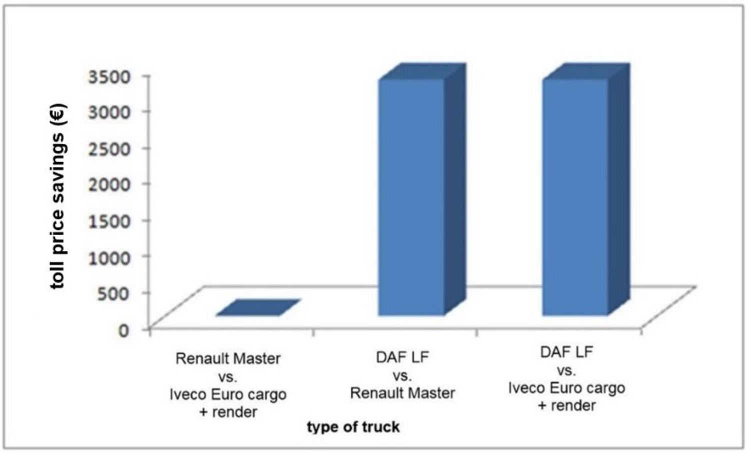

Fig. 9.
Toll price savings
Source: Authors

Fig.10 depicts total savings of fuel and toll fees. 4,465.7 € would be saved in 2015 if Iveco Euro Cargo + render is replaced by Renault Master. 7,201.6 € would be saved in 2015 if DAF LF is replaced by Iveco Euro Cargo + render. If it was possible to transport a required amount of goods by Renault Master instead of DAF LF it would save 11,667.2 € on fuel and toll fees.

5. Conclusion

All the companies that do business want to achieve the best results in order to maximize their profits. The company costs belong to those items that influence the company's profit in the most significant way. Therefore companies use many methods to achieve the lowest costs. One way how to lower the costs is called cost reduction which can be achieved by reducing the fuel consumption in trucks and by choosing appropriate vehicle for packages transport of cargo to the company premises. The achieved results confirm that monitoring and optimizing the possibilities of lowering transport costs is important.

THE IMPACT OF VARIOUS ORGANISATIONAL MEASURES ON THE LOGISTICS COSTS OF COMPANIES IN THE AUTOMATIVE INDUSTRY

Sebastjan Škerlič[1], Robert Muha[2]
[1,2] University of Ljubljana, Faculty of Maritime Studies and Transportation, Pot pomorščakov 4, SI-6320 Portorož, Slovenia

Abstract: The use of systems for controlling logistics costs is not the only activity that guarantees lower logistics costs in companies. There are also various organisational measures within the company, such as the centralisation of logistics and establishing a system for encouraging innovation, which can have a significant impact on the effectiveness of cost management within the company's logistics department. To this end, a survey was conducted on a sample of 30 Slovenian companies that are suppliers to the international automotive industry. The goal of the study is to analyse the impact of the implementation of these measures on the level of logistics costs in the automotive companies. The results of the study are an important starting point in the development of modern methods for controlling logistics costs. They represent an important contribution to ensuring the development of the economics of transport, warehousing and other logistics costs in manufacturing companies operating in the automotive industry.

Keywords: logistics costs, centralisation of logistics, innovations, automotive industry.

1. Introduction

The small size of the Slovenian market drives companies in the Slovenian automotive industry to seek business opportunities outside local frameworks. Once they find themselves in an international environment, they face unrelenting competition in terms of providing high quality products and services. In addition, they are increasingly confronted with demands for a systematic reduction of costs. Up until now, companies have mitigated the effects of cost reductions by achieving greater productivity and better quality and with continuous product improvement. However, the fact is that many suppliers have reached the stage where significant cost reductions cannot be achieved by improving productivity and quality (Singh et al., 2005). Cost reduction in the supply chain is an even more sensitive issue, because it leads to poor-quality logistics services.

Logistics costs account for most of the costs in a company's supply chain. They also cover a significant share in the cost structure of the company as a whole. There are significant differences in the level of logistics costs between companies from different industries, despite several scientific studies indicating that their share in the total sales revenue of a company amounts to at least five percent. When defining logistics costs, it is important to consider the integrity of these costs as they occur in different business areas. The authors referenced in this paper (Stock and Lambert, 2001; Zeng and Rossetti, 2003; Christopher, 2005; Fugate et al., 2010; Engblom et al., 2012) classify logistics costs as a percentage of revenues from sales of goods and identify at least six individual cost components: transportation, warehousing, inventory management, administration, packaging and indirect logistics costs.

Therefore, in the highly competitive environment of the automotive industry, efficient logistics costs controlling plays an important role, because it ensures that the supply of all subjects that are part of the supply chain runs smoothly. Apart from the use of various logistics cost controlling systems, companies can make use of various organisational measures such as the centralisation of logistics and setting up a system to encourage innovation, in order to optimise the processes in the supply chain.

A centralised approach to organizing logistics means that companies have a separate department uniting all the logistics activities that were previously dealt with by different departments (e.g. sales, purchasing, manufacturing, etc.), under the same management. The commitment to the constant development of products, services and processes requires companies to focus on the process of encouraging innovation. Setting up a mechanism to encourage innovation company-wide can lead to the long-term creation of ideas and initiatives to control logistics costs.

The purpose of this study is to analyse the impact of the implementation of the centralisation of logistics operations and the establishment of a system aimed at encouraging innovation on the level of logistics costs. The results of the study represent an important contribution to ensuring the development of the economics of transport, warehousing and other logistics costs in manufacturing companies operating in the automotive industry.

In the second chapter, an overview of the international automotive industry and the processes currently taking place on the route between automotive manufacturers and suppliers is presented. The third chapter consists of a statistical analysis, followed by a discussion in the final chapter.

2. Participation in the international automotive industry

Over time, the automotive industry reached a level of development that sets an example for other industry sectors in terms of process management and strengthening relationships in the supply chain. Taking part in this industry has many advantages, but also entails certain responsibilities, as demands for the optimisation of business processes are passed from the end-customers down the supply chain. The importance of this industry lies largely in its connection to the domestic and international economy and its complex value chain. The automotive industry is one of the world's largest

[1] Corresponding author: sebastjan.skerlic@fpp.uni-lj.si

job creators, employing more than two million people, which accounts for approximately 5.5% of all jobs in EU-27 countries (ACEA, 2016).
The majority of new vehicles come from the assembly lines in sophisticated and highly structured processes. Manufacturing 60 million vehicles requires around 9 million employees, who are directly involved in the manufacture of vehicles and their parts. It is estimated that every job position provided directly by a particular car manufacturer (e.g. BMW, AUDI, FORD, TOYOTA and others) supports at least 5 indirect jobs in the community. From this perspective, the automotive industry contributes at least 50 million jobs worldwide, since manufacturing vehicles requires the use of various goods and services from different industrial sectors. Among the most important are steel, iron, aluminium, plastic, glass, carpets, textiles, computer chips, car tyres and other goods (OICA, 2016). Figure 1 shows the total sales of vehicles of the past ten years. Following a period marked by the international financial crisis in 2008 and 2009, which saw a decrease in sales, there was a 25% increase in 2015, compared to the period before the crisis. Thus, participation in the international automotive industry represents many business opportunities and challenges for Slovenian suppliers.

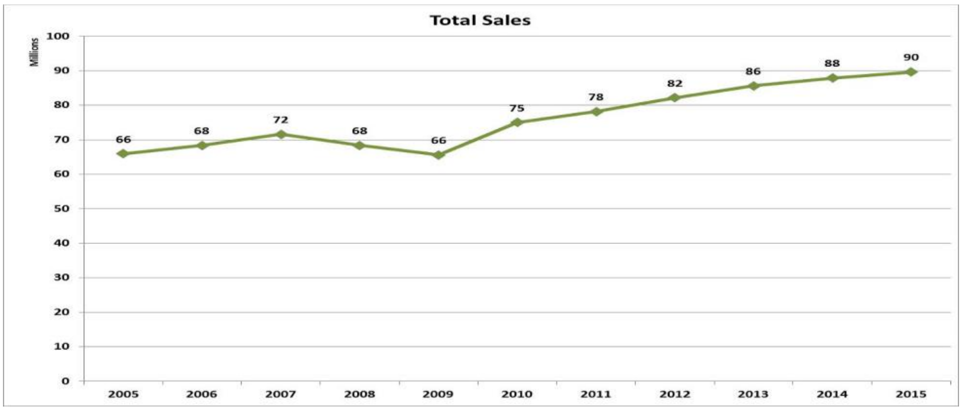

Fig. 1.
The number of vehicles sold from 2005 to 2015 in million EUR

A look at the production of motor vehicles worldwide between 2000 and 2014 (Figure 2) reveals a marked increase in production in China. As early as in 2000, 4% of the total world motor vehicle production was concentrated in China, while in 2014, this share rose to 27%.

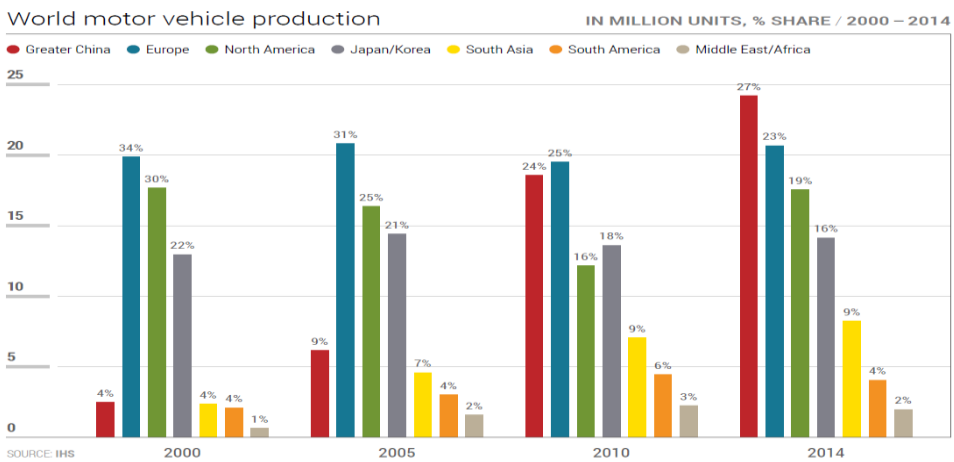

Fig. 2.
World motor vehicle production by country from 2000 to 2014
Source: ACEA, 2016

The global automotive sector is constantly evolving. Fierce competition pushes companies to excel in the various fronts, including cost, design, functionality, manufacturing and quality (Park and Simpson, 2005). In addition to expectations regarding quality management, first tier suppliers in the automotive industry in particular are subject to strategic requirements, which are indirectly related to implementing and strengthening the concept of lean manufacturing (Singh et al., 2005):

- continuous pressure to reduce costs,
- increasing innovation,

- achieving high production capacities,
- achieving ecological and environmental standards,
- achieving high safety standards,
- close proximity to production facilities,
- integrating a 3PL (Third Party Logistics Provider),
- greater integration in post-sales activities and
- effective computerisation of business processes.

The need for continuous cost reduction is seen as a competitive necessity worldwide (Womack et al., 1990). It is quite common for automotive manufacturers to demand that their suppliers reduce the costs of components by 2.5 to 5.0% annually. In most cases, this demand is non-negotiable, which means that suppliers are under extreme pressure to achieve an acceptable level of costs as demanded by the manufacturers. Thus far, suppliers have been succeeding at meeting this demand primarily by achieving greater productivity, better quality and continuously improving their products. Singh et al. (2005) indicate that many suppliers have reached the stage where significant cost reductions are no longer achievable by improving productivity and quality. This is confirmed by a study by Roland Berger (2014), as it points out possible friction in the relationship between automotive manufacturers and suppliers. Figure 3 shows the current and future efforts by automotive manufacturers (VW, BMW, Daimler, PSA and Renault-Nissan) to reduce costs and the effects on relationships with suppliers.

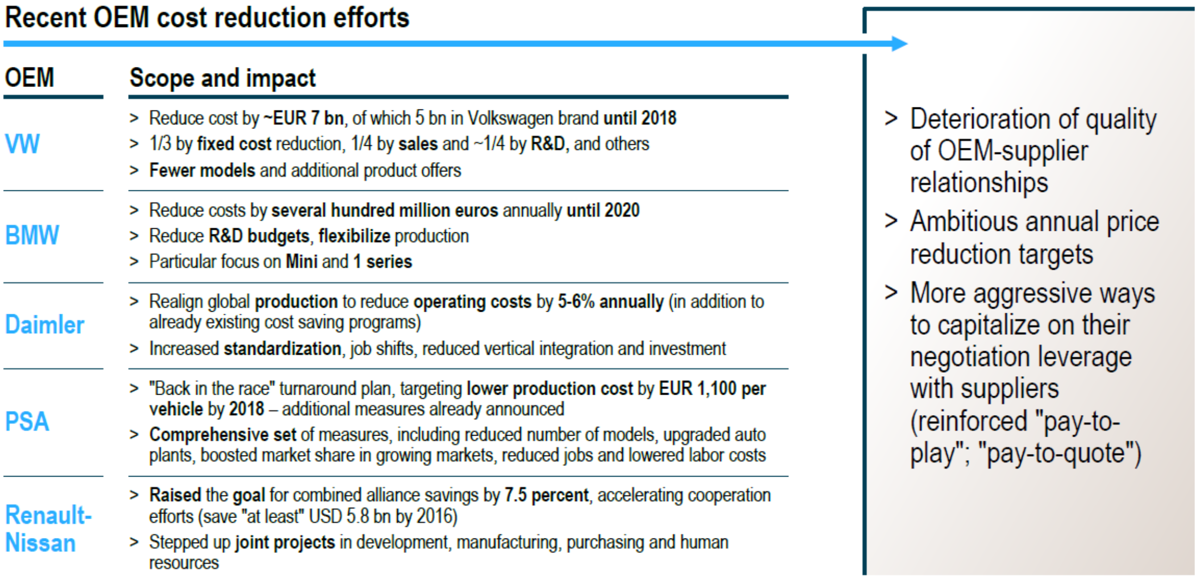

Fig. 3.
The demands for cost reduction by automotive manufacturers towards suppliers
Source: (Roland Berger, 2014)

When examining the cost structure of a vehicle, Figure 4 indicates that the cost of materials purchased is 53%. Ambitious annual targets of automotive manufacturers to reduce prices with suppliers derive from the above fact. Labour costs are surprisingly low, but if we take into account the personnel costs in the entire supply chain of a company (including on the suppliers' side), the entire value chain in the automotive industry reveals a different picture (Figure 5).

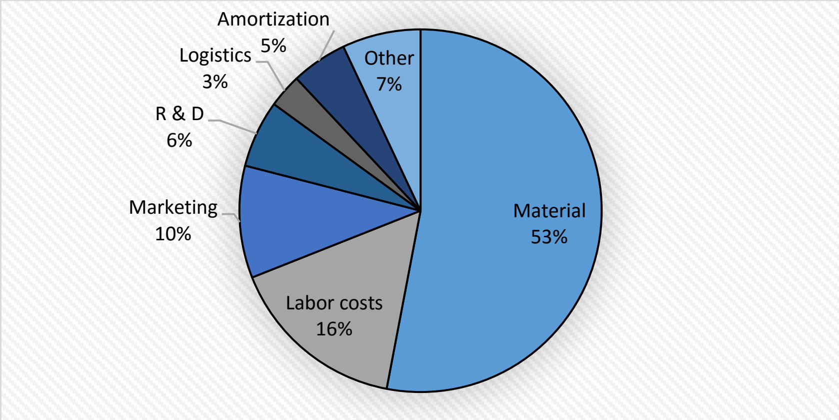

Fig. 4.
The cost structure of a vehicle
Source: Primc, 2011

In this case, labour costs amount to 70% of the entire value chain, while the costs of materials are reduced to 10%. Figure 5 also shows the potential savings that could be achieved, if automotive manufacturers were to reduce their vertical integration and thereby give a larger share to suppliers from countries where labour is cheaper (Primc, 2011).

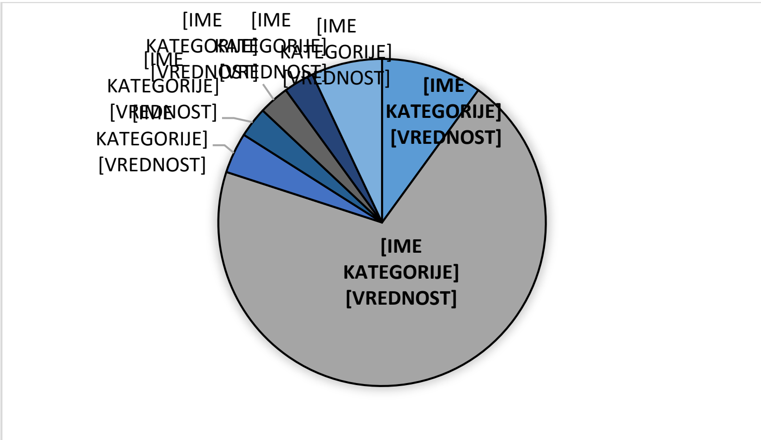

Fig. 5.
The cost structure of the entire value chain
Source: Primc, 2011

In light of the facts presented above, it becomes more clear why there has been an increase in the production of vehicles in countries with cheaper labour that also offer access to a cheaper base of local suppliers. It is precisely these facts that enable automotive manufacturers to have a more aggressive approach in exploiting their negotiating power towards suppliers, mainly in Europe.

3. Results

The survey was conducted on a sample of 30 Slovenian companies that are suppliers to the international automotive industry and lasted between February and May 2015. The share of logistic costs in company revenue was an ordinal variable measured on a four-point scale (1 = < 5%; 2 = 5– 9%; 3 = 10-20%; 4 = >20%). The centralisation of logistics services and innovation encouragement were dichotomous variables. The difference in logistic costs between categories of dichotomous variables was examined by Mann-Whitney U test. The level of statistical significance was set to α = 0.05 (one-tailed) when factors influencing lower logistic costs were examined as the direction of associations was presupposed. Statistical analysis was performed in IBM SPSS 22.0.
Table 1 shows the results of testing differences in logistic costs between categories of dichotomised variables such as centralisation of logistics and innovation encouragement. Companies encouraging innovation have statistically significantly (p = 0.023) lower logistic costs (Me = 1, i.e. < 5 %) than companies not encouraging innovation (Me = 3; i.e. 10-20%). Companies with centralised logistics seem to have similar logistic costs to those with decentralised logistics.

Table 1
Median value of the share of logistic costs by centralisation of logistics and innovation encouragement and results of Mann-Whitney U test

Factor in the company	n	Me	U	p
Centralization of logistics				
Yes	17	1.0	64.5	0.109
No	10	1.5		
Innovation encouragement				
Yes	23	1.0	30.0	**0.023**
No	5	3.0		

Note: * n = number of companies; Me = median value of logistic costs rate
(1 = < 5%; 2 = 5– 9%; 3 = 10-20%; 4 = >20%).

4. Discussion and conclusion

The analysis of the results shows that innovation has the greatest impact on the level of logistics costs. Companies that have implemented a system for encouraging innovation have lower logistics costs in comparison with companies that do not have such a system in place. As expected, innovations have the biggest influence on logistics costs, because of the specific nature of logistics operations that require seeking the best cost solutions in terms of streamlining transport, warehousing, operational and other logistics costs. The continuous development of information technology (advanced programs and decisions-making tools), work instruments (RFID, Barcode, etc.), means of transport (efficient and economical vehicles) and the logistics network (new road, rail, air, sea connections and distribution centres) enables a wide selection of innovative and modern logistics solutions, which can result in lower total logistics costs.
The results of the study represent an important contribution to ensuring effective systems for controlling logistics costs and a set of important guidelines for a better organisation of logistics systems in manufacturing companies operating in the automotive industry.

OPTIMAL ROUTE DESIGN FOR SHARED PARA TRANSIT SERVICE IN PATNA, INDIA

Vijaya Bandyopadhyaya[1], Ranja Bandyopadhyaya[2]
[1] *Chandragupta Institute of Management, India*
[2] *National Institute of Technology, Patna, India*

Abstract: In most small cities in India, para transits form the basic mode of shared transport that people use for their daily commuting. These para transits include autos (motorized three wheelers) and taxis or cabs. These small transit systems usually carry about 5 to 6 passengers and ply on fixed short routes ranging from 3 to 8 kms. With increase in population and travel demand, there has been a huge increase in the number of para transit vehicles, particularly autos in recent years and optimal scheduling of para transit is essential. The current work suggests a dynamic framework for optimal scheduling of para-transit operations considering the randomness in arrival of passengers. It assumes a stochastic queuing model for scheduling of para transit operations such that the waiting times are minimized and the cost of operations is realized with an optimal level of profit.

Keywords: para transit, optimal scheduling, queuing.

1. Introduction

In most small cities in India, shared para-transits form the basic mode of transport for people for their daily commuting. These para-transits include shared autos (motorized three wheelers) and shared taxis or cabs. These small transit systems usually carry about 5 to 6 passengers and ply on fixed short routes ranging from 3 to 8 kms. They follow a fixed route of operation. With increase of population and travel demand, more number of these para-transit vehicles ply on the roads resulting in increased congestion in the links.

The para transit operations are demand based and do not follow a definite schedule of start and stoppages. The scheduling of para transit is a complex problem involving minimization of user waiting time, minimization of user travel time, deciding the optimal stopping locations in the network, and maximization of profit for the vehicle drivers.

Very few existing works focus on routing and scheduling of para transit operations. A few researchers have worked on scheduling of public transit systems, especially bus systems, as elucidated below.

Peng and Huang (2000) developed a web-based transit information system design using GIS to integrate web serving. GIS processing, network analysis and database management. The design is interactive and users can interact with information on transit routes, schedules and trip itinerary planning. They proposed a path finding algorithm for transit network to handle special characteristics like time-dependent services, common bus lines on same street and non symmetric routing with respect to an origin destination pair.

Shafahi and Khani (2010) studies the transit network scheduling problem and aims to minimize the waiting time at transfer stations. They propose a mixed integer programming model for departure times of vehicles for minimizing transfer times and a genetic algorithm that can help in case of larger networks. A case study of the Mashhad City bus network is given to explain and evaluate the model and genetic algorithm.

Hadas and Ceder (2010) proposes a dynamic programming model to improve transit service reliability by proper coordination of public transit vehicles for optimally reducing transfer time. The results obtained from the optimization model are validated using simulation.

Ceder (2011) studies the public transport vehicle scheduling problem and considers relation between characteristics of a trip and the vehicle type required for each so that the cost is minimized. A heuristic algorithm is developed based on the deficit function theory. The case of the Egged bus company in Israel is used to explain the algorithm for network route design, timetable development and vehicle scheduling and crew scheduling.

The above studies have used optimization techniques for scheduling public transit systems. However, the scheduling of para transit systems needs to be dynamic and stochastic queuing models can be used to understand the system. Some researchers have used queuing models, both deterministic and stochastic, to estimate delays for different types of transport systems including roads, railways and airways as explained below.

Hendrickson et al (1981) models schedule delay in a deterministic setting based on user equilibrium concepts and deterministic queuing theory to minimize total user delay. They considered the arrival time of users at a bottleneck in morning hours in cases of on-time arrival and late arrival. They used numerical examples to illustrate the queuing scenario and determine the delay and system optimal flows. They also identified related research issues.

Turnquist & Daskin (1982) proposed queuing models for estimating delay to rail cars in passing through yards, both while waiting for classification and also during connection to an appropriate outbound train, to obtain the mean and variance of delay times. The models are then used in an example application to draw inferences regarding the effectiveness of alternative strategies for dispatching trains between yards.

Hansen (2002) showed how runway delay externalities can be explained using a deterministic queuing model. The author estimated the delay impact of each arrival flight on every other arriving flights at Los Angeles International Airport to suggest variable pricing of runway use at the airport.

[1] Corresponding author: vijaya@cimp.ac.in

Hansen et al (2009) used both deterministic and stochastic queuing models to understand queuing behaviour at airports and predict delays over a wide range of congestion levels.
The objective of the work is to suggest a dynamic framework for optimal scheduling of para-transit operations considering the randomness in arrival of passengers.
The next section describes the methodology adopted for the study. Section 3.0 illustrates the methodology with an example. Section 4.0 gives the summary and conclusions of the work.

2. Methodology

As mentioned earlier, most research in the past have focused on optimal scheduling and routing of transit systems, usually bus transit systems. Scheduling of para transit systems will be different from bus transit systems as the nature of the two systems is very different. The bus transit system has buses of much higher capacity. The buses usually have designated start time at pre defined intervals, usually defined by the demand during that hour, and designated stoppages. The start time does not dynamically change on a day based on the demand. Usually for para-transit systems like autos no formal schedules exist for start and stop and scheduling is dynamic and demand based. Vehicles start only when they are full. The arrival of passengers at a stop is a random event. It is difficult to optimize the schedules of autos so that the waiting times can be minimized. The application of queuing theory seems relevant in this context.
In this article, the applicability of queuing model for scheduling para transit systems is explained with the help of an example of autos starting from a key point of the city of Patna in the state of Bihar, India. The detailed approach of the methodology used is illustrated in Fig. 1.

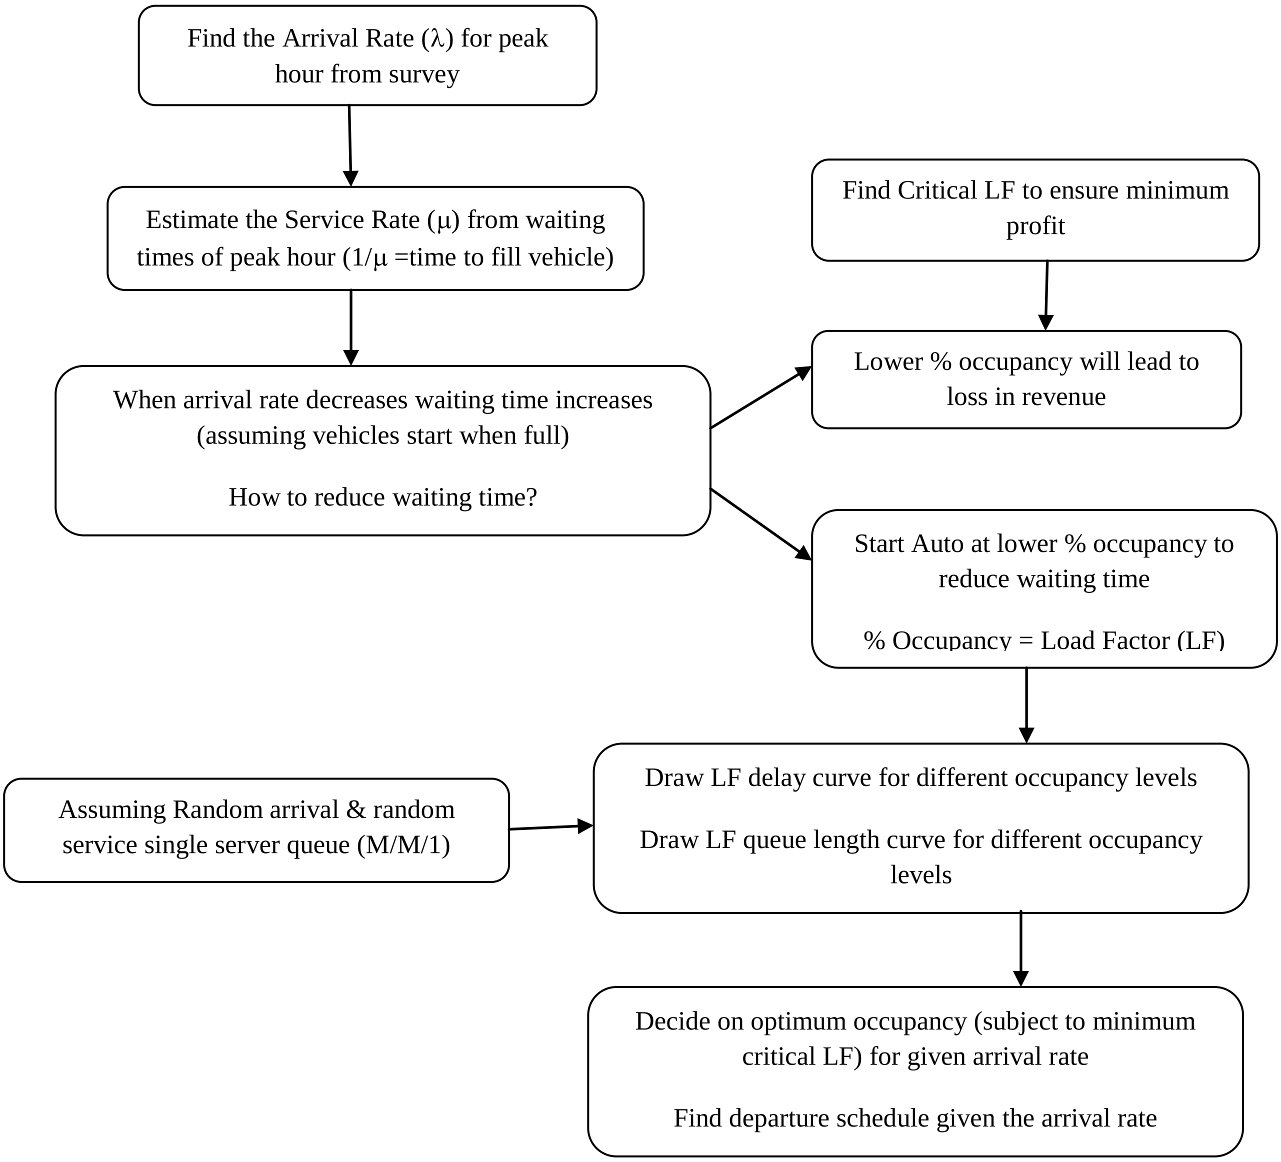

Fig. 1.
Methodology of overall work

The passenger arrival is random and the transit vehicles start when they are full. In order to take both these constraints in the scheduling model better, the problem can be viewed as a queuing model where passengers (customers) come to the starting point (the server) and wait till they are served i.e. they get into an auto and the auto departs for the required destination. It is assumed here that there are enough number of autos and availability is not a problem. Also, the autos wait at the starting point and get filled up one at a time. The service time is the time the passenger waits in the auto, or the time taken by the auto to get filled. This is linked to the arrival rate as the time taken by auto to get filled is a function of arrival rate. Thus the service time rate is also random. The transit vehicle operation can be viewed as a single server system.

The M/M/1 queuing model, the classic stochastic queuing model, may be applied in this situation. M refers to a memoryless (or Markovian) distribution, that is, to the exponential distribution (Ravindran, Phillips, & Solberg, 1987). Therefore, the M/M/1 queue is a model with exponentially distributed interarrival times, which implies that the arrivals are Poisson distributed, service times are exponentially distributed and there is a single server. It may also be assumed that the queue discipline is *first come, first serve* (FCFS). The capacity of the system and size of the source population can be assumed to be infinite. The arrival rates of passengers are independent of each other and can be assumed to follow a Poisson distribution. It may be obtained from the number of passengers arriving at a starting point during a rush hour or otherwise estimated from the number of autos leaving a node for a given destination, assuming 6 passengers are there in the auto. The service rate may be estimated from the average time intervals between departures.

The arrival rate (λ) of passengers at a given start point during the peak hours may be found from survey. The service rate (μ) may be estimated from the waiting times during peak hours, where $1/\mu$ is the time required to fill a vehicle.

If the average waiting time of a passenger at a given start point is known, it can be assumed that the arrival rate is Poisson distributed, Probability of i customers coming at a given hour may be found out. Also probability of i customers in queue can be found out. The mean waiting time in the queue can be estimated. Also the mean utilization of server and mean throughput rate can be estimated. The time for start of a para-transit can also be estimated.

From the above model 3 situations can arise

1. $\lambda = \mu$ which indicates optimum utilization. This means that user waiting time is minimum and the transit vehicles run at full capacity ensuring maximum profit for transit operators. The passenger arrival is equal to the optimum achievable service rate. The supply and demand are in equilibrium. This is easy to conceptualize.
2. $\lambda > \mu$ which indicates that the demand cannot be met in the system.
3. $\lambda < \mu$ which indicates that the system is not functioning optimally. The passenger arrival is less than the optimum achievable service rate. Due to decrease of arrival rate the waiting times of passengers increase as the time to get auto filled increases. Also the transit vehicle owners loose the revenue or run at a loss if the auto runs partially filled to minimize user waiting time. The transit vehicle scheduling in such case is a challenging scenario.

The suggested methodology for scheduling considers the case when $\lambda < \mu$. This can be done considering two objectives:

1. Reduce waiting time of passengers in the transit-vehicle
2. Ensure no loss due to vehicle not getting filled to capacity

The load factor, also the percentage occupancy of the auto, is shown in equation 1.

$$\rho = \frac{\lambda}{\mu} \tag{1}$$

Where λ is the arrival rate and μ is the service rate.

The service rate has to be greater than or equal to the arrival rate ($\lambda/\mu<1$) for the passengers to be served during the rush hour. However, as the arrival rate decreases the waiting time increases for passengers. The autos need to start at lower occupancy rates to reduce waiting times. However, this will lead to loss in revenue. An optimum load factor needs to be estimated that will minimize waiting times while also ensuring a minimum profit. The optimal number of passengers in an auto may be found from the vehicle operating cost, minimum desired profit and fare per passenger as shown in equation 2. A critical load factor is determined from the optimal number of passengers and vehicle capacity as shown in equation 3.

Initially we need to find the load capacity utilization (LF) can be estimated from equations below.

$$N_{Popt} = \frac{Total\ vehicle\ operating\ cost + Minimum\ desired\ profit}{Fare\ per\ passenger} \tag{2}$$

$$LF = \frac{N_{Popt}}{Vehicle\ Capacity} \tag{3}$$

Considering no loss criteria, transit vehicle should start when the transit vehicle is filled to load capacity utilization.

Assuming random arrival and random service single server queue (M/M/1) the delays and queue lengths are found for different occupancy levels. The length of the queue (Lq) can be obtained using equation 4 and waiting time in the queue can be obtained from equation 5.

$$L_q = \frac{\rho^2}{1-\rho} \tag{4}$$

$$W_q = \frac{L_q}{\lambda} \tag{5}$$

The delay versus load factors and queue length versus load factors are plotted to find the optimal load factor. The cut-off points are decided above which the delay and queue length increases exponentially, as explained later. The two load factors, one from cost and other from waiting times (delay) are compared to decide on the optimum critical load factor. This may be then used to decide the optimum occupancy level for a given arrival rate. The departure schedules can then be decided that will take care of arrival rates of passengers at a given hour while minimizing the waiting times and also ensuring a minimum profit for the auto drivers.

3. Illustration of Methodology

The concept is explained with the help of a small case study. For the autos of a given route from a given starting point (Gandhi Maidan), the arrival rates of passengers have been estimated as 4.4 per minute i.e. λ = 4.4 per minute from survey, and the service time is estimated to be 4.63 minute from waiting time survey.

Table **1** shows the waiting times in queue in minutes for different load factors.

Table 1
Waiting time & Queue lengths for different load factors

Load Factor	Waiting time in queue (Wq)	Ln(Wq)	Length of queue (Lq)	ln(Lq)
0.5	0.11	-2.17	0.50	-0.69
0.55	0.15	-1.88	0.67	-0.40
0.6	0.20	-1.59	0.90	-0.11
0.65	0.27	-1.29	1.21	0.19
0.7	0.37	-0.99	1.63	0.49
0.75	0.51	-0.67	2.25	0.81
0.8	0.73	-0.32	3.20	1.16
0.85	**1.09**	0.09	**4.82**	1.57
0.9	1.84	0.61	8.10	2.09
0.95	4.10	1.41	18.05	2.89
1	2.27E+14	33.06	1E+15	34.54

Fig. 2. shows the waiting times (in natural log scale) for various load factors.

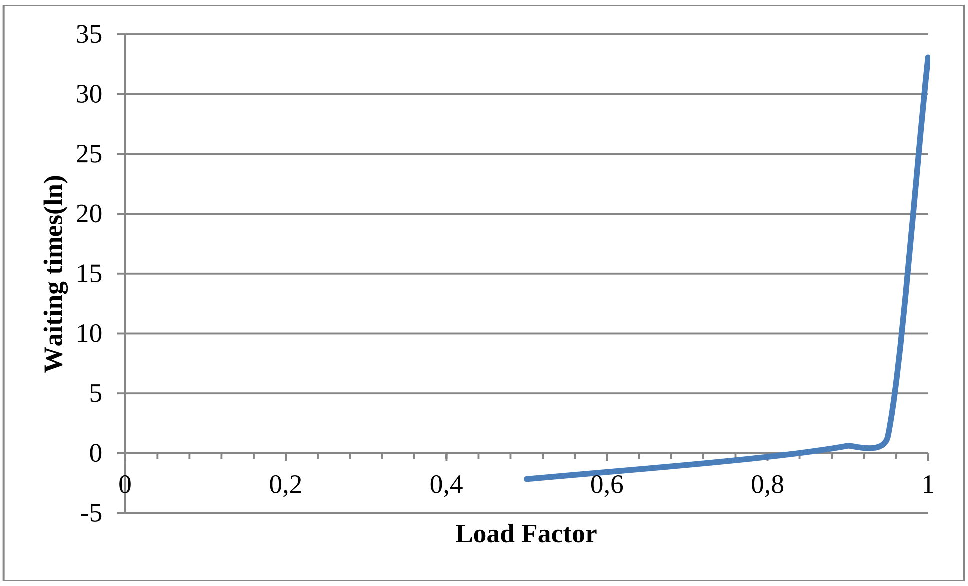

Fig. 2.
Waiting Time for different load factors

Fig. 2. shows the length of queue (in natural log scale) for various load factors.

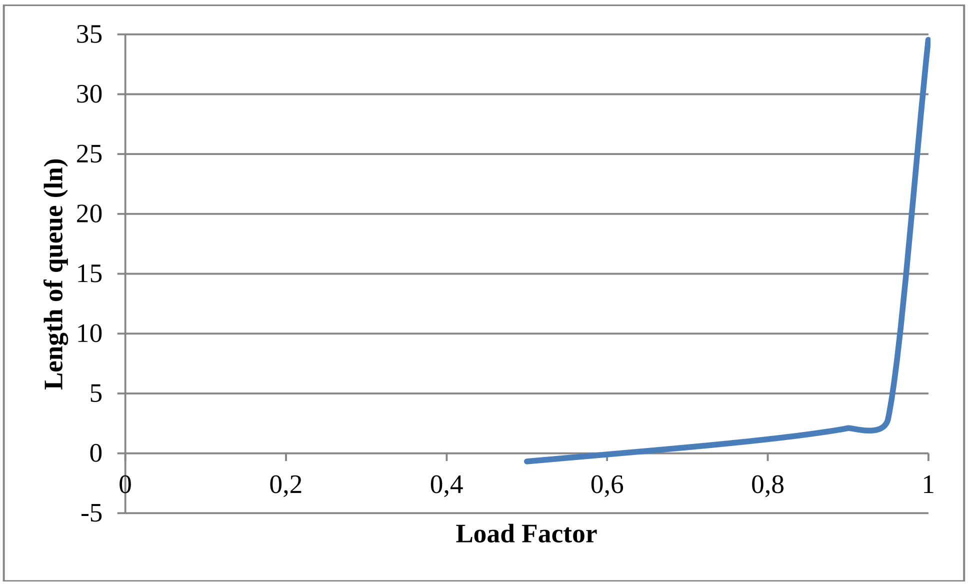

Fig. 3.
Queue lengths for different load factors

The observed load factor is 0.95. It may be observed from the above two figures that the waiting time and queue length increases exponentially above a load factor of 0.95. However, it may also be observed that above a load factor of 0.85, the queue length becomes more than double and waiting time is also almost double. So, the load factor 0.85, at which queue length is 4.82, can be taken as the critical load factor. So, looking at the waiting times, it may be recommended that autos start when 5 passengers arrive.
The cost of the trip can also be used to determine the optimal number of passengers required to start an auto. The cost of running an auto per km is can be estimated as Rs.3.5, using IRC method (IRC, 2009). So for a 8 km trip, the total cost is Rs.28. The fare per passenger is Rs.8 for the same distance. So assuming a 20% profit margin, the optimal number of passengers may be estimated from equation 2 as 4.2. So, if autos start with 5 passengers, they can make a profit of 39%.

4. Summary and Conclusions

Scheduling of para transit systems like autos in India is a difficult problem, different from other types of transit systems like buses. The scheduling of para transits is a dynamic process that can be modelled using the stochastic queuing model M/M/1. The scheduling may be done using a queuing model when arrival rates of passengers, service rates and transit costs can be estimated by survey method. The aim is to minimize waiting times of passengers while ensuring a minimum desired profit for the auto drivers. The case study of autos in Patna, Bihar, India is used to illustrate the suggested methodology.

ANALYSIS AND ASSESSMENT OF THE TRANSPORT VOLUME BY ROAD VEHICLES IN THE ADRIATIC-IONIAN REGION

Ivan Ivković[1], Dragan Sekulić[2], Dušan Mladenović[3]
[1,2,3] University of Belgrade-Faculty of Transport and Traffic Engineering, Belgrade, Serbia

Abstract: The paper presents the results of research that have been reached in the framework of the implementation of activities in work package "Assessment of the Adriatic port system and its integration with hinterland" of the EA Sea-Way project. Analysis and assessment of the transport volumes by passenger and freight road vehicles was carried out for the six countries in the Adriatic-Ionian Macro-Region: Albania, Croatia, Greece, Italy, Montenegro and Slovenia. Methodological approach included the specifics of the area at the national level and changes in transport demands on road infrastructure during the period from 2005 to 2030. Assessment and quantification of changes in transport volumes was carried out for the short-term (five-year) and the medium-term period (ten-year).

Keywords: road vehicles, transport volume, road network, assessment.

1. Introduction

The main objective of the EA Sea-Way project is development of new cross border, sustainable and integrated transport services and the significant improvement of physical infrastructures related to those new services. This should lead to improve the accessibility and the mobility of passengers across the Adriatic-Ionian area and its hinterland. Since the EA Sea-Way project brings together all modes of transport, analysis of road transport indicators is an essential part of the activities. The traffic volume expressed in motor vehicle kilometres (passengers veh-km or freight veh-km) or transport volumes expressed as passenger-kilometres (PKM) or tonne-kilometres (TKM) can be presented as indicators of sustainable transport from the standpoint of providing economic and consumer benefits (Litman, 2016). On the other hand, the dominance of this transport mode in relation to others and more pronounced negative impact of road transport on the environment puts them into indicators that do not have a prefix "sustainable" (Dobranskyte-Niskota et al., 2007). For these reasons, their monitoring, analysis and assessment are becoming increasingly important. Analysis and assessment of realized traffic and transport volumes must be able to adequately provide decision makers with informative signals on the multiplicity of issues involved. (May et al., 2008; Castillo and Pitfield, 2010; Torok, 2013). Therefore, these indicators are irreplaceable data on which decisions are taken in order to create a sustainable transport system using different transport models. Bearing in mind the above mentioned, in this paper was carried out an analysis and assessment of transport volumes in the six countries of the Adriatic-Ionian Macro-Region: Albania, Croatia, Greece, Italy, Montenegro and Slovenia. The results of research are input data for the complete and successful implementation of sustainable development of passenger transport models for the Adriatic basin, capacity building and further pilot actions.

2. Methodological approach

Fig. 1 shows the methodological approach that was used in the analysis and assessment of the transport volume by road vehicles in the Adriatic-Ionian Macro-Region.

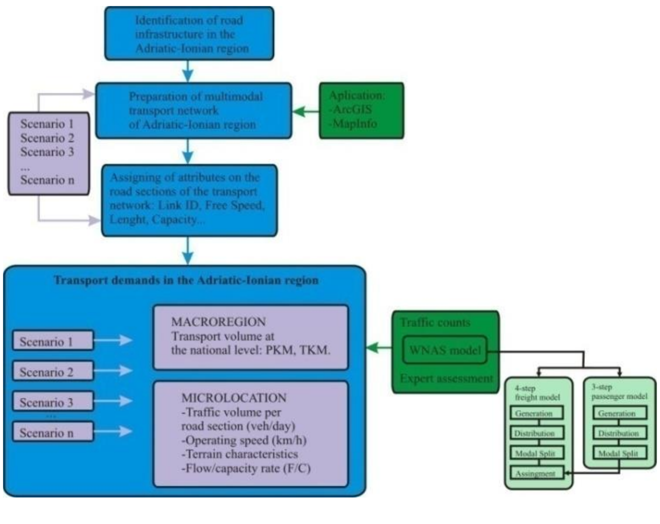

Fig. 1.
Methodological approach for analysis and assessment of the transport volume by road vehicles

In the first step, methodological approach includes the identification of road infrastructure which is the subject of research. Fig. 2 shows the road network of the Adriatic-Ionian Macro-Region

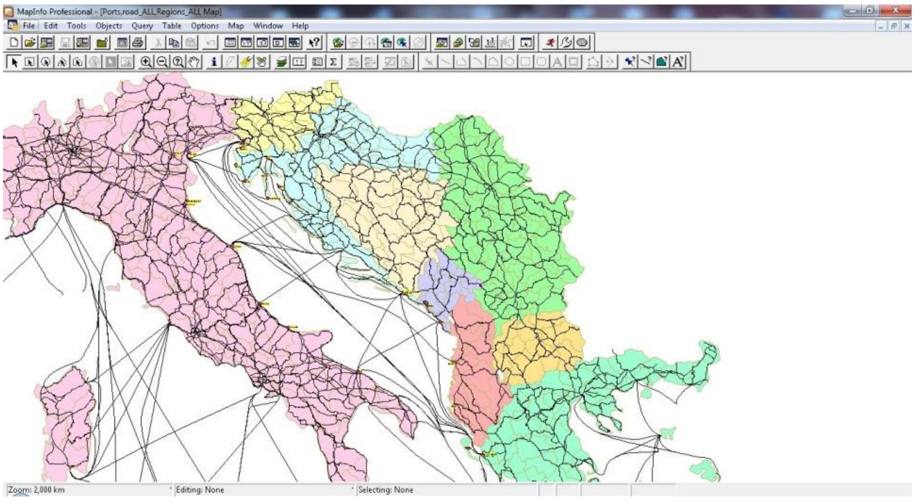

Fig. 2.
Road network of the Adriatic-Ionian Macro-Region

The National Road Network in Albania is about 18,000 km long including 3,636 km of National Roads, 10,500 km of interurban roads, and the rest of 4,000 km is under the jurisdiction of autonomous units, enterprises or companies. The primary road network is about 1,138 km with nine main connections which made up the basis of the network. The secondary network is 1,998 km long.

In Croatia, two major road corridors extend from the capital city Zagreb. The first main corridor (highway A1) provides directions to the west and south west, i.e. through Karlovac to the Croatian coast with the value of the average annual daily traffic (AADT) of approximately 30,000 veh/day (average for the period 2010-2013). The corridor includes the arterial that bypasses Bosiljevo, namely, to Rijeka (highway A6) with AADT value of around 12,000 veh/day and to Zadar, Šibenik and Split (continued highway A1) with AADT value of around 13,000 veh/day. The second main corridor spreads from Zagreb across Nova Gradiška, Slavonski Brod (highway A3) to the Lipovac border crossing with AADT values of around 20,000 veh/day, 13,500 veh/day, 10,500 veh/day, 6,000 veh/day, respectively.

Greece’s road network covers 117,000 kilometres in total (mainland and islands). Total road network includes motorways, highways, and main or national roads, secondary or regional roads, and all other roads in a country. A motorway is a road designed and built for motor traffic that separates the traffic flowing in opposite directions. The main road axes are: Athens- Thessaloniki (E75); Athens-Corinth (E94); Corinth-Patras (E65); Corinth-Tripoli-Kalamata (E65); Patras-Pyrgos-Olympia (E55); Thessaloniki-Kavala-Alexandroupoli (E90); Igoumenitsa-Alexandroupoli (Egnatia Odos Motorway); Chania-Agios Nikolaos (Crete E75).

Traffic corridors with the dominant values of the traffic flow spread on Italian territory at around 7000 km of highways divided into 35 road sections. Ports within Adriatic-Ionian Macro-Region that are analyzed in the EA Sea-Way project (Trieste, Chioggia, Ravenna, Ancona, Termoli and Bari) are located near or lie on certain highways. The port of Trieste is located on the highway A4 Torino-Trieste whose length is 524 km with an AADT value of over 100,000 veh/day. The port of Chioggia is located near the highway A13 Bologna-Padova with an AADT value of around 60,000 veh/day and A57 that passes around Venice with similar characteristics as the highway A4. In addition to the port of Ravenna at a distance of approximately 30 km stretches highway A14 Bologna-Taranto with a total length of 743 km and with an AADT value of around 45,000 veh/day. Close to the A14 road section are also located ports of Ancona, Termoli and Bari.

In Montenegro, they are six road corridors where 5 corridors extend from the capital city Podgorica: The first main corridor extends northwards towards Kolašin with an average AADT value of about 5,700 veh/day. The second main corridor extends northwest to Nikšić with an average AADT value of about 6,500 veh/day. The third main corridor extends westward to the Cetinje with an average AADT value of about 8,000 veh/day. The fourth main corridor extends southwest to the port of Bar over Mišići, with an average AADT value of approximately 8,300 veh/day. The sixth corridor extends over Adriatic coast from Herceg Novi to Ulcinj with an average AADT value of about 7,000 veh/day. Geographical position of the port of Bar places port of Bar close to the main node of coridor from Adriatic coast and corridor extends southwest to the port of Bar over Mišići.

In Slovenia, four major road corridors extend from the capital city Ljubljana. The first main corridor (highway A2) extends northwest towards Jasenice over Kranj and Bled with an average AADT value of about 30,000 veh/day. The second main corridor (highway A1) extends northeast to Maribor over Celje with an average AADT value of about 38,000 veh/day. The third main corridor (highway A2) extends southeast to the Novo Mesto with an average AADT value of about 25,000 veh/day. The fourth main corridor (highway A1) extends southwest to the port of Koper over Postojna, with an average AADT value of approximately 38,000 veh/day.

In the second step, the preparation of road network was conducted. This includes the allocation of attributes on the individual road sections: length, number of lanes in one direction, operating speed, design speed, hourly capacity, etc. Based on statistical data, the current state of realized transport volumes by vehicle categories (passenger cars, buses and trucks) was obtained in the period from 2005 to 2012 for the above mentioned six countries. The assessment of transport volumes in 2020 and 2030 was based on the WNAS (WorldNet Assignment) model. WNAS model is composed of two sub-models: three-step passenger model and four-step freight models. WNAS model takes into account a number of influential factors to the actual transport volumes on the road network: traffic-geographical position of the region, socio-economic and socio-political characteristics, deployment of activities, the characteristics of the transport network, the parameters of passengers and freight flows. Quantification of changes in transport volumes is carried out according to two scenarios: an optimistic scenario which involves increasing of transport volumes for 10% in relation to the real scenario and the pessimistic scenario which involves decreasing of transport volumes for 10% in relation to the real scenario. The real scenario represents the realized (assessed) transport volumes for 2020 and the 2030 in the countries of the Adriatic-Ionian Macro-Region obtained by using WNAS model.

3. Results and analysis

Table 1 shows the realized and assessed transport volumes of passenger cars, buses and trucks on the road network of the Adriatic-Ionian Macro-Region.

Table 1
Realised and forecasted transport volumes of different vehicle categories in Adriatic–Ionian Macro-Region (1000 x milion PKM/TKM-realistic scenario)

The declining trend in realised transport volume of passenger vehicles (passenger cars and buses in 2011), and trucks (2012) stagnation (buses 2012) or a slight growth (passenger cars for the year 2012 and trucks in 2011) in the case of Croatia are in line with the trend of actual transport volume on road sections in the port area Rovinj, Pula, Krk, Mali Lošinj, Rab, Split and Dubrovnik (Ivkovic, 2015) observed within EASEA-WAY project. Therefore the changes at the state level can be characterized as relevant for assessing the growth or decline of traffic in the future (short-term or medium-term period) in the Adriatic-Ionian Macro-Region. Major discrepancies are evident during the summer months of 2011 and 2012, which was expected given the fact that the data in Table 1 refer to the full-year period of observation. From Table 1 it can be seen that in the short term (up to 2020) according to the results of the model, expected growth in passenger kilometres is 21.17% for passenger cars and 5.95% for buses compared to 2010. In relation to trucks, it is expected for 2020 tonne kilometres growth of 66.29% compared to 2010 (Table 1). In 2030, the expected growth in transport volume based on model approximation is 70.82% (passenger cars), 35.93% (buses) and 109.57% (trucks).In the pessimistic scenario (Table 2) the characteristic growth rates have the following values: for passenger cars relative to 2010, short term/long term: 21.17%/53.74%; for buses 5.95%/22.33%; for trucks 49.66%/86.61%; while the optimistic scenario equivalent values are: for cars 48.09%/87.90%;, for buses 29.50%/49.52%; for trucks 82.92%/130.52%. It should be noted that the provided changes are related to changes in traffic volume in regions of Croatian ports (Rovinj, Pula, Krk, Mali Lošinj, Rab i Dubrovnik) expressed in tonne kilometres or passenger-kilometres.

Table 3 shows the changes of the transport volume in relation to the year 2010 in Italy for the three scenarios.

Table 3
Changes of the transport volumes in relation to the year 2010 in Italy (1000 x million PKM/TKM/%)

120.90	118.79	18.28	16.21	108.8116	106.9139	6.45	4.59	132.992	130.6725	30.10	27.84
Trucks											
Realistic scenario				Pessimistic scenario				Optimistic scenario			
2020	2030	change 10/20	change 10/30	2020	2030	change 10/20	change 10/30	2020	2030	change 10/20	change 10/30
Model	Model	%	%	Model	Model	%	%	Model	Model	%	%
229.30	248.10	30.45	41.15	206.37	223.29	17.41	27.03	252.23	272.91	43.50	55.26

The declining trend in actual transport volume of passenger vehicles (passenger cars and trucks in 2011 and 2012), or stagnation (buses 2011 and 2012) in the case of Italy are in line with the trend of actual transport volume on road sections in the port area (Trieste, Chioggia, Ravena, Anconna, Termoli and Bari) observed within EASEA-WAY project. As opposed to Croatia, there is no significant deviations in the third quarter of 2011 and 2012, which was expected given the fact that the third quarter includes two months out of the season (Ivković, 2015) while data of transport volumes from Table 1 relating to the one year period observations. Therefore the changes at the state level can be characterized as relevant for assessing the growth or decline of traffic in the future (short-term or medium-term period) in the Adriatic-Ionian Macro-Region. From Table 1 it can be seen that in the short term (up to 2020) according to the results of the model, expected growth in passenger kilometres is 3.27% for passenger cars and 6.45% for buses compared to 2010. In relation to trucks, it is expected for 2020 tonne kilometres growth of 30.45% compared to 2010. In 2030, the expected growth in transport volume based on model approximation is 23.90% (passenger cars), 16.21% (buses) and 41.15% (trucks).In the pessimistic scenario (Table 3) the characteristic growth rates have the following values: for passenger cars relative to 2010, short term/long term: 3.27%/11.51%; for buses 6.45%/4.59%; for trucks 17.41%/27.03%; while the optimistic scenario equivalent values are: for cars 26.22%/36.29%; for buses 30.10%/27.84%; for trucks 43.50%/55.26%. It should be noted that the provided changes are related to changes in traffic volume in regions of Italian ports expressed in tonne kilometres or passenger-kilometres.

Tables 4, 5, 6 and 7 show the changes of the transport volume in relation to the year 2010 in the whole territory of countries: Slovenia, Montenegro, Albania and Greece. As it was mentioned above, for Croatia and Italy in terms of the relevance of data for the whole territory of entire countries, it is sufficient to provide analysis of the rate of increase or decrease of the transport volumes for different scenarios by tables.

4. Conclusions

Based on the presented results and analysis, the conclusions of this research are as follows:

- Distribution of transport volumes at the level of the Adriatic-Ionian Macro-Region is extremely heterogeneous. By far the biggest transport volumes was realized in Italy, about 680,000 million PKM in 2012 (from this value, over 78% was realized by passenger cars). The lowest passenger transport volumes were realized in Montenegro and Albania with the amount of approximately 4,000 and 7,000 million PKM, respectively. Similar values of around 25,000 million PKM were realized in Croatia and Slovenia. In Greece was realized transport volumes about 5.5 times lower than in Italy, in the amount of about 120,000 PKM. A similar situation exists in the case of freight transport volumes. Italy leads with a share of 72% of the total value. Following are Greece, Slovenia and Croatia with the amount of 12%, 9% and 5% respectively. Freight transport volumes in Albania and Montenegro are negligible, less than 1%,
- It is expected approximately constant value of passenger car PKM in Greece up to 2030 in the real scenario. In the same period bus PKM will decrease. The largest increase in passenger car PKM is expected in the medium-term period in Croatia, Montenegro and Slovenia (71%, 52%, and 36% respectively). A significant increase of bus PKM in the medium-term period is expected in Montenegro in the amount of 91%. From the standpoint of freight transport volumes, the highest growth in the medium-term period is characteristic for Albania and Montenegro (almost four times higher value than in 2010),
- In the short-term period, the results of the assessment indicate the lower realization of passenger car transport volumes by about 8% in relation to the medium-term period, throughout the whole macro-region. Bus

transport volumes are mainly slightly changed except Croatia and Slovenia where the rates of decline will amount from 8% to 14%. The decreasing of the freight transport volumes in the short-time period (compared to medium-term period) will be in the range of about 20 to 24% for Albania, Montenegro, Croatia and Slovenia. Somewhat smaller percentages are characteristic for Italy and Greece, 7% and 13% respectively,

- In this paper are analyzed two hypothetical scenarios which indicate the maximum possible variation in the quantification of realized road transport volumes in the Adriatic-Ionian Macro-Region region. Variations are valid for assessing of transport volumes in the areas of ports that are observed within EA Sea-Way project (Trieste, Chioggia, Ravenna, Anconna, Termoli, Bari, Koper, Bar, Vlore, Sarande and Igoumenitsa). For the Croatian ports (Rovinj, Pula, Krk, Mali Lošinj, Rab, Split and Dubrovnik) must be additionally to take into account seasonal traffic flows variations in the period 1 July to 31 August.

Acknowledgments

This paper is based on the Europe Adriatic EA Sea-Way project, co-financed by the European Union in the framework of the IPA Adriatic Cross-Border Cooperation Programme 2013-2016.

Abstract: This study is aimed at analyzing public transportation system within the urban area in Amman, the capital city of Jordan. Amman is having increased growth in population and private auto ownership resulting in congestion which is becoming one of the most frustrating daily problems encountered by most commuters. This increased growth n both population and auto ownership is accompanied with a stigma that is commonly attached to public transit users, in which most commuters prefer to use other modes of transportation in their daily trips. This research work investigated public bus system in Amman City in order to search for the factors that have impact on bus ridership. A survey was collected from 1532 respondents in Amman City in order to find the most important factors affecting the choice of mode of transportation among commuters. Binary logistic regression model was used to model the ridership of bus users. Results of this research work indicated that bus ridership is significantly affected by work trips, income, and private vehicle ownership. It was found that the main riders of public transport users are those whose trip purpose is work, families with low monthly income and those with no private vehicles owned.

Keywords: bus ridership, logistic regression, Middle East, survey.

1. Introduction

Mobility is an essential requirement for any type of meaningful involvement in our modern society. Without some form of adequate transportation, it would not be possible for individuals to shop, to socialize, to work, to worship, or to participate in many other activities (Hough et al. 2002). Moreover, over the last two decades there has been an increased concern with the decline in air quality, increased congestion, and negative impacts to the environment resulting from patterns that are favorable to the automobile (Badoe and Miller, 1999). As a result, improving urban transit services in ways that increase the competitiveness of transit relative to the private automobile and which reduce the growth in car dependence are desirable.

Developing countries in general experience a continuous change in the frameworks in which the urban transport sector exists, and often change rapidly. One of the reasons for this change is because society itself is changing. In other cases, it is because a framework is lacking or contains inherent weaknesses that need to be adjusted (Finn 2011).

Jordan sets an example for framework change where the Land Transport Regulatory Commission (LTRC) of the national Ministry of Transport controls, manage and regulate all land transport services throughout the country. Due to a conflict between Municipality of Amman and Ministry of Transport, in 2007, all responsibility for urban passenger transport in Amman, including the regulatory role, was transferred to Greater Amman Municipality while LTRC continues to regulate services elsewhere in the kingdom.

The culture of public transportation in developing countries, including Jordan, is suffering from different factors that would affect the reputation of its usage. These factors may include mismanagement of transportation facilities, delay and time scheduling, randomness of routes and pathways, undefined bus stops, daily fluctuations of number of buses for every route, lack of planning studies that define important variables to predict number of vehicles required for every zone or route, etc. These factors would make people reluctant to use public transportation; instead they would prefer to own their private vehicles regardless of economical situations.

Limited studies have been performed to evaluate mobility in cities of developing economies, where most of the research found on mobility is done for developed countries and therefore the results obtained cannot be used to evaluate mobility in developed economies, given large differences between them, such as infrastructure, economic conditions and administrative capacities. To this end, this study is aimed at predicting the individual's likelihood to ride buses using logistic regression using socio-economic and travel behavior characteristics.

2. Literature review

Mobility in developing world is affected with many factors that include increased motorization where urban structure is incompatible with the increased motorization, as well as, high demand that exceed capacity of facilities accompanied with increased population, increased wealth, a life style that encourages car ownership, etc (Gakenheimer, 1999).

On the other hand, there is a great need for a more sustainable urban transport for the future because of environmental deterioration, growing energy crisis, and traffic congestion combined with financial constraints. Koushki et al. (1999) tested the transit management awareness of passenger needs due to what have been noticed of a general lack of up-to-date information on the assessment of customer satisfaction with current services and future needs in Kuwait and other Persian Gulf region. In order to determine levels of management awareness of passenger priorities, and passenger satisfaction with the current performance of the bus service, two structured questionnaires were developed; one of these questionnaires was filled by top and middle managers of the transit system; while the other questionnaire was filled by passengers. These questionnaires were performed over a 10-month period; their results indicated that 93% of bus riders

[1] Corresponding author: mobaidat@just.edu.jo

in Kuwait were low income expatriates from 16 different nationalities.
A computer-based phone survey was conducted by De Palma and Picard (2005) in Paris area and suburbs in which 4137 person were questioned in order to study the impact of travel time on route choice for private and/or public transportation commuters and introduced an index that measures the preferences towards risk in choice, also, the impact of key socio-economic factors (gender, employment, purpose of trip, etc.) on the risk of choice were considered, a discussion of three alternative models was performed in order to remove the unrealistic assumption that all users select the shortest route.
Commuters of different occupations differ in their mode choice according to their departure time, hence value of time and work time flexibility differ among different sectors of careers; self-employed workers as well as professionals value their times highly and they have flexible schedules, where employees have rigid work schedules, but have a less value of time; consequently higher incomes enables people to pay out-of-pocket money to avoid inconvenient modes of transportation (Arnott et al. 1994), (Evans, 1992), (Cohen, 1987), (Small, 1983).
Transit ridership modeling is normally performed using either multivariate regression or discrete choice models. Ahmad and Puppim de Oliveira (2016) employed multivariate regression in an attempt to estimate the amount of transport (private and public) using a nationally representative household survey from the 98 largest Indian cities. In addition, they used binary logistic regression to model choices between motorized and non-motorized, and private versus public transport. Findings revealed that densification in Indian cities reduce the amount of transport as well as enhances the probability of using public transport. Small and medium sized cities predominantly use private transport, whereas large cities prefer public transport but lack non-motorized transportation. Moreover, income was found to be the most important determinant of the amount of transport and the use of motorized and private transport.
Abdel-Aty (2001) used an ordered probit model to explain the likelihood of using transit based on a stated preference survey in two metropolitan areas in California. The study investigated whether advanced transit information would increase the acceptance of transit, and to determine the types and levels of information that are desired by commuters. the results indicated that the frequency of service, number of transfers, seat availability, walking time to the transit stop and fare information are among the significant information types that commuters desire. Factors found to contribute to the likelihood of using transit given information was provided were: income, education, and commute time by transit and whether the commuter is currently carpooling.
Al-Shili and Sadeq (2003) presented a study to evaluate intercity ridership demand, evaluate the existing services and predict future ridership in Palestinian territories. An on-board survey of bus riders was conducted to identify variables that influence demand. They used a simple linear regression to model ridership demand using the following variables: population of the origin city, population of destination city, bus fare, and percent of employees at origin city and percent of higher education students at origin city.
Nkurunziza et al. (2012) analyzed individual commuter preferences towards a proposed bus rapid transit system in Dar-es-Salaam, Tanzania. A stated preference survey was conducted in an attempt to identify how commuters perceived and value the proposed service quality variables. They following variables were considered: travel time, travel fare, and comfort; where the results of the survey were analyzed using a binary logit model. The findings revealed that comfort was the most valued variable compared to travel time and travel fare.

3. Data and methodology

3.1. Survey

A survey was conducted among citizens of Amman city in order to find out factors affecting their mode of transportation choice behavior.
Respondents were interviewed on bus stops all over Amman city where 1532 in person interviews were conducted and respondents were asked questions concerning their socio-economic characteristics as well as their travel behavior characteristics. The main purpose of this survey was to study the behavior of commuters especially those of public buses in order to estimate the factors that contribute in bus ridership.
The first part of survey attempts to better understand the individuals and household characteristics such as: gender, age, income, number of family members, type and location of work, number of family members above 18 years, preferred home-based-work travel mode, number of household's automobiles, distance between home and job.
The second part of the survey attempts to better understand the bus commuter's information such as: time to reach a bus stop, trip purpose, and travel time on bus. These questions are the variables of the models to be developed, in which bus ridership is assumed to be a function of variables used in the survey.
Questions concerning origin-destination exact location were excluded, since most of respondents have ignored these questions, Table 1 shows the variables included in the survey as well as the counts and percentages of responses obtained under each category of variables.

3.2. General description of survey answers

According to Table 1 the total interviewed sample had 29.5% females. In addition, 88.7% of interviewed people were above 18 years. Most of the interviewed persons were either employees or university students with percentages of 38.3 for each. Approximately 80% of the surveyed sample ride buses in their daily trips, 45.56% stated that they use buses daily for home-based-work trip. Regarding household size, more than 65% were members of households of six or more. All interviewed individuals reported having at least one family member above 18 years old, 62% of interviewed sample have monthly income below JD 500, while less than 4% earned more than JD 1500 per month. Approximately 40.4% of sample has no autos owned by household, where 38.7% have only one auto owned by household. Regarding distance between home place and work place, 71% of individuals estimated the distance to be more than 3km, while 12% estimated the distance to be in between 2-3km.

In bus trip length, min	30-44 45-59 >60	400 255 184	26.1 16.6 12.0

In the second part of the survey, those using buses in their daily trips were asked to give their answers. 26.4% estimated the time to reach the closest bus stop to be less than 10 minutes, while 17.4% answered as belonging to the category of more than 30 minutes. Bus was used in 26.8% of daily trips to university, where 26% used buses in their daily Home-Based-Work trips. Travel time by bus was estimated by 25.5% of individuals to be less than 30 minutes, and about 12% estimated the travel time by bus to be more than 60 minutes.

3.3. Binary logistic regression

The variables' data from the survey was analyzed using a random utility model. This type of models is considered the most used model for processing data from choice experiments in transportation research (Ben-Akiva and Lerman 1985; Louviere et al.2000). The assumptions made by the model are that travel decision makers encounter a utility maximization problem based on the cost and quality of service rising from using a given mode and the uncertainty of choosing the given mode (Ortuzar and Willumsen 1994).

In this research; the response variable, bus ridership, is a binary variable and the independent variables are categorical, and hence the logistic regression is a suitable technique to be used. Table 2 includes a detailed description of the statistically significant variables incorporated in the statistical analysis.

Binary logistic regression is a type of generalized linear models (GLM), which models how a binary response is dependent on a set of explanatory variables. The explanatory variables can be discrete, continuous or a combination (Shafique and Hato, 2015).

Consider these factors or explanatory variables be represented by $X=(X_1, X_2, \ldots, X_k)$ with observed value $xi=(x_{i1}, x_{i2}, \ldots, x_{ik})$ for a survey respondent. Let Y be the binary response variable where $Y_i=1$ if the respondent rides bus and $Y_i=0$ if otherwise. The probability (π) that the person ***i*** is a bus rider can be formulated as follows:

$$\pi_i = Pr(Y_i = 1|X_i = x_i) = \frac{exp(\beta_0 + \beta_i x_i)}{1 + exp(\beta_0 + \beta_i x_i)}$$

Or

$$logit(\pi_i) = log\left(\frac{\pi_i}{1-\pi_i}\right)$$
$$= \beta_0 + \beta_i x_i$$
$$= \beta_0 + \beta_1 x_{i1} + \cdots + \beta_k x_{ik}$$

4. Results and analysis

4.1. Variables and cross tabulations

In this research, we use cross tabulation and binary logistic statistical model based on the survey data to determine the various variables influencing passengers' willingness to use the bus service as described by the dependent variable bus ridership.

Table 2
Variables used in model, their Symbols, categories and coding

Variable	Symbol	Categories	Coding

Cross tabulation was used to analyze the responses of the respondents whether they use buses in their daily trips or not in order to find out the differences between these two groups as shown in Table 3. Respondents were divided into two groups: bus riders and not bus riders, where the interviewed sample had 80.2% of bus riders and the remaining 19.8% of not bus riders. As illustrated in Table 3, both groups do not differ in the fact that most of the riders belong to ages above 18 years old, where university students and employees were the categories that ride buses on a daily basis with percentages of 41.33% and 34.50% respectively, while the employees was the category with highest percentage of riding other modes of transportation with a percentage of 53.80% in the not bus rider group.

Regarding gender of riders, it can be seen in both groups that the majority of riders are males with percentages of 70.38% in bus riders group and 70.96% in not bus riders group, with a small higher percentage of females in the bus riders group.

Most of the respondents work in Amman with a higher percentage of bus riders who use the bus from outside Amman workers. The highest percentage of bus riders belong to families with 6 members, while an unexpected result was found in the not bus riders group were most of the respondents belong to families of 7 and more than 7 family sizes. Most of the respondents belonging to either group came from families with 2 members above 18 with percentage of 21.97% for bus riders, and 24.42% for not bus riders. As expected, most of the bus rider have monthly income below JD 500, while most of the not bus riders have monthly between JD 1000-1500. Regarding number of autos owned by household, most of the bus riders group has at most 1 auto, while those belonging to not bus riders have mostly 1 or 2 autos owned. Finally, most of the respondents in the two groups have their daily work trips for distances longer than 3 km.

Table 3
Cross tabulations of survey responses related to bus ridership

Variable	Categories	Ride bus, %	Don’t ride, %
Gender	Female Male	26.62 70.38	29.04 70.96

4.2. Bus ridership

The collected data from the 1532 surveys was divided into two samples: a training sample which is used to train the model and a testing sample which is to validate the model developed using the training sample. The results are summarized in the following sections.

4.2.1. Modeling of bus ridership

Seven hundred and sixty six survey data was used to develop a binary logistic model in order to predict ridership of buses. SPSS v.21 was used for model development and analysis; the results of the best model obtained are described herein.
As shown in Table 4, the omnibus tests of model Coefficients table gives the result of the Likelihood Ratio (LR) test which indicates that the inclusion of these variables contributes significantly to the developed model fit. A p-value (sig) of less than 0.05 for the model means that the model is a significant improvement to a model with a constant only.

Table 4
Omnibus tests of model coefficients

Chi-Square	Degrees of freedom (df)	Sig
372.615	8	0.000

From Table 5, we can conclude that 66.8% of variation in bus ridership can be explained by the model developed, where the correct classification rate obtained using this model is 93%.
The p-values are all below 0.05 which means that all included variables in the model are significant. The model results indicates that using a bus for work trips (X_6) increases the odds of riding a bus by 585.688 times more than other going to work using other modes of transportation. The results obtained indicate that riding a bus for work trips is the most important variable in the bus ridership model.
The second most important variable that was found to affect bus ridership and hence increases the likelihood of an individual to use bus service is when the family does not own an automobile (X_{10}) with 39.169 times to more likely ride a bus than families that own more than 3 automobiles. A less effect on ridership was found when the monthly income is between JD 500-749 (X_{9_2}) and when the monthly income is below JD 300 (X_9), with 11.693 and 10.268 times respectively more likely to use a bus than families with a monthly income of more than JD 1500.
The variables with the lowest contribution to bus ridership were in order of importance: when the number of family members was 5 (X_{7_5}) and 6 (X_{7_6}); when the individual uses his/her automobile for work trip (X_{6_5}); or when the individual uses a Taxi for work trip (X_{6_2}) with the following odds ratio respectively: 5.962, 4.469, 4.276, and 3.788.
To this end, variables that have the most significant effect on bus ridership were: daily work trip is by bus, families with no automobiles owned and monthly income below JD 749. Etminani-Ghasrodashti and Ardeshiri (2015) found that individuals lifestyle which includes leisure activities such as going to a club for exercise, strolling in malls and

shopping centers for fun or going to natural gardens, due to the long distances, increases the likelihood of doing them by private car which is in accordance with findings herein, where daily work trips were found to increase the likelihood of riding a bus. In addition Taylor, et al (2009) also found that employment affects bus ridership.
Taylor, et al (2009) found that amongst other variables that car ownership was found to affect bus ridership which supports the findings found herein in which it was found that families with no vehicle owned increased the likelihood of bus ridership.
Moreover, results herein indicated that low income increases the likelihood of riding the bus; previous studies also reported the same result as found by Shaaban and Khalil (2013), Taylor, et al (2009) and Mujalli (2007).

Table 5
Model used for predicting bus ridership

Predictor variable	Coefficient	S.E	P-value	Exp (B)	95% C.I. for EXP (B)	
					Lower	Lower
Constant	-2.586	0.383	0.000	0.077		
X_6	6.373	1.059	0.000	585.688	73.455	4669.914
X_{6_2}	1.332	0.490	0.007	3.788	1.449	9.903
X_{6_5}	1.453	0.494	0.003	4.276	1.632	11.266
X_{7_5}	1.785	0.509	0.000	5.962	2.199	16.165
X_{7_6}	1.497	0.489	0.002	4.469	1.715	11.645
X_9	2.329	0.478	0.000	10.268	4.021	26.220
X_{9_2}	2.459	0.435	0.000	11.693	4.989	27.407
X_{10}	3.668	0.414	0.000	39.169	17.385	88.246
-2 Log likelihood	285.632					
Nagelkerke R2	66.8%					
Classification rate	93.1%					

4.2.2. Validation of prediction error rate

The reliability of the prediction error rate observed in the training sample was examined by applying the chosen prediction rule to a validation sample as illustrated in Table 6. The new prediction error rate is about the same as that for the training data set, then the latter gives a reliable indication of the predictive ability of the fitted binary logistic regression model and the chosen prediction rule.
In the current study, the fitted logistic response function based on the training sample given in Table 5 was used to calculate the estimated probabilities for the 766 cases of validation sample. The chosen prediction rule is applied to the estimated probabilities as predict 1 if $\pi_i \geq 0.5$ and predict 0 if $\pi_i < 0.5$. The percent prediction error rate for the validation sample given in Table 6 is 85.6 while the rate for the training sample was 93.1. Thus the total prediction error rate for the validation sample is not considerably higher than the training sample and it can be concluded that it is a reliable indicator of the predictive capability of the fitted logistic regression model.

Table 6
Predicted classification table based on training sample and validation sample taking 0.5 as cutoff

Training sample				Validation sample			
Observed (Y)	Expected (Y)			Observed (Y)	Expected (Y)		
	0	1	% correct		0	1	% correct
Do not Ride bus (0)	90	28	76.3	Do not Ride bus (0)	150	35	81.1
Ride bus (1)	25	623	96.1	Ride Bus(1)	75	506	87.1
Overall percentage			93.1	Overall percentage			85.6

5. Conclusions

The main objectives of this research work were to find out the factors that have the most significant effect on bus ridership in Amman City using socio-economic and travel behavior characteristics. Work trips commuted by bus were found to have the highest positive impact on bus ridership. It was also found that the bus riders are more likely to be those belonging to families with low-income, which has created a poor local image of the service and driven other population categories away from using the service. In addition, low vehicle ownership was found to increase the probability of riding buses.
In order to encourage public buses riding, public buses need to be improved in order to compete with other modes of travel such as private cars and taxis. Emphasis on improving the image of buses should be a priority.

SESSION 11: ROAD TRAFFIC AND TRANSPORT RESEARCH - SAFETY PERSPECTIVE

THE CARGO SECURING BASED ON EUROPEAN STANDARDS AND ITS APPLICABILITY IN OFF-ROAD TRANSPORT CONDITIONS

Martin Vlkovský[1], Kateřina Pochobradská[2], Pavel Foltin[3], Václav Zajíček[4], Tomáš Binar[5]
[1,2,3,4,5] University of Defence, Czech Republic

Abstract: The cargo is secured with respect to inertial forces in the Czech Republic, which are based on the anticipated acceleration coefficients specified in relevant European standards (particularly in EN 12195-1:2011). The paper deals with the evaluation of a sample of off-road transportation, for which the true values of acceleration coefficients were found. The data are statistically processed; the local extremes of functions are found and compared with the average values of acceleration coefficients defined normatively. The paper was written with the support of research project no. SV16-FVL-109-VLK funded by the Ministry of Education, Youth and Sports. The fundamental goal of this research project is to determine whether the differences between the acceleration coefficients defined normatively and true value of these coefficients are statistically significant and based on that to optimize the cargo securing. Preliminary measurements detected that especially during off-road transport, or due to specific obstacles (e.g. railway crossings, speed bumps, expansion joints of bridges, holes and potholes on the roads), the acceleration coefficients are significantly higher. The model example demonstrates the importance of the measured differences in the cargo securing with using the lashing straps.

Keywords: off-road transport, cargo security, inertial forces, acceleration coefficients.

1. Introduction

In civilian sector transport accounts for about 60-70 % of logistic activities. In the Army of the Czech Republic (ACR) it is estimated that the percentage corresponds with the civilian sector. A major difference in the implementation of the transport; physical relocation of cargo (or persons); is the fact that transportation in the ACR are often carried out under different conditions. This applies especially during realization of Intra-Theater Transport, which uses mainly road transport. This paper focuses on road transport under specific conditions, especially outside of normal communication or off-road.

Each cargo must be secured against movement and the mounting is based on norms, standards or internal regulations, which further regulate mentioned norms and standards. In Europe is generally used standard EN 12195-1:2011, which (among other things) mentions the coefficients of acceleration in particular axes and formulas for calculating the various mounting methods. Mentioned coefficients of acceleration are stated empirically (outcomes of empirical studies) and stated in **average values**.

Preliminary analysis and experiments (see eg. Vlkovský et al., Crede Expert, 2016) so far showed short-term shocks – fluctuations above commonly mentioned (averaged) values determined normatively, especially in the z-axis. The paper is based on the assumption that non-standard conditions of transport – terrain will cause even greater fluctuations in the z-axis (or the other two axes). Significant for mounting method are the values that significantly exceed the normative set values (eg. 100 % or more). Standard EN 12195-1: 2011 mentions values of the coefficients of acceleration in particular axes (c_x, c_y and c_z) in the interval *0.5* to *1.0 g*, where g is the gravity acceleration (EN 12195-1, 2011).

For illustration if the cargo is mounted with respect to the anticipated effect of inertial forces when the individual acceleration coefficients are maximum *1.0 g*, then the mounting with values for example *2.0 g* is totally insufficient. One-ton cargo in such cases, "behaves" like a two-ton and mounting agent is thus doubly burdened than assumed in accordance with normative established values of the acceleration coefficients and formulas for determining the value of inertial forces.

Application of such research suggests itself primarily in military conditions (especially in multinational operations) and in the integrated rescue system, respectively other entities which execute transportation (generally) outside of normal communication. Specific with even higher risk is transport of dangerous goods in off-road conditions.

2. Transportation experiment

The object of the transport experiment is to prove on a sample data set imperfection of normative established acceleration coefficient values, including their averaging. For statistical analysis a survey is carried out on a sample of drivers during **Advanced Training in Military Vehicles Driving**, which took place on 1st June 2016 in the training area Vyškov-Dědice in the Czech Republic, from 8:37 to 11:43 a.m. The weather on that day was standard for June, the surface was dry, visibility was excellent, and there were no rainfalls during training. Selected vehicle was equipped with an accelerometer – tri-axial shock data logger OM-CP-ULTRASHOCK-5 serial number P93709 which recorded acceleration (shock) in multiples of *g* in all three axes. Recording was done at frequency of 512 Hz, when the highest, respectively the lowest value of the given axis is recorded into the data logger every second (Jakar Electronics, 2016).

[1] Corresponding author: martin.vlkovsky@unob.cz

2.1. Background of the transportation experiment

A relatively new type of truck – Tatra T-810 DO AŠ which is used in ACR was chosen for statistical evaluation. Used vehicle was in very good technical condition with relatively small mileage (34,000 km). Part of the vehicle was cargo – simulated cargo of 2,160 kg (01-0601-CZE/00, 2007).
The training was conducted at the polygon marked in green color (see Fig. 1) where the drivers according to schedule took turns; one went the route there and the second one went the route back (sectors 1 and 2 on the chart – see Fig. 2); respectively each of them went the route there and back (sectors 3-7 – ibid). The polygon is composed of stones and bricks embedded in concrete – it is a normal transport route in the training area Vyškov-Dědice. Terrain to a certain extent simulates conditions in multinational operations in countries with limited transport infrastructure, where except the backbone roads the transport network consists from only partially metalled or non metalled roads.
The aim of the training was to improve driving of selected vehicles, in this case the Tatra T-810 DO AŠ under the supervision of an experienced instructor – professional driver. Part of the training with the given type of vehicle was not overcoming obstacles, etc., as it was in the case of other types of vehicles at the same training day. Transport conditions at the polygon were therefore in terms of road (terrain relief) relatively homogeneous.
The total number of drivers was 14 + 1 professional driver who always moved the vehicle along the red route for interchange of drivers at the polygon. Mentioned (red) route back was realized by professional driver himself – see the sections of the route in red rectangles on the graph in Fig. 2. Transports with two drivers in one direction only were implemented in sections 1 and 2. That means the first from the pair launched a transport at the conversion of red and green section (after handover to the professional driver) and drove the end of green route, where the truck turned (using reversing) and handed control to the second driver from the pair. In the remaining sections with regard to plenitude of time each of transport of drivers in training was realized through the entire polygon, that means back and forth, including a turn at the end of the polygon.

Fig. 1.
Testing polygon (green), route for translocation (red)
Source: (Google Maps – modified)

2.2. Statistical evaluation of the transportation experiment – *z*-axis

It is obvious from the data that the acceleration in each axis is significantly influenced by driving style of the driver and by speed. Individual drivers can be compared with each other, respectively with professional driver. The differences are

mainly caused by different experiences of drivers, because some of them have much less experience with the given type of vehicle than others (eg. difference between 5th and 6th sector) and driving style.
Road roughness significantly affect primarily z-axis which according to the standard should be within the interval *<–1,1>*. In the graph it corresponds with values of *0-2g* as an imaginary zero of the graph corresponds with *1g*. However the graph shows that big amount of data, *1,631* values (*18.66 %* of the total, with no vehicle standstill – see below) measured in the z-axis exceeds *2g*, which corresponds to the normative given limit *1g*. In further *53* cases (corresponding to *0.61 %* of the total, with no vehicle standstill) the values of the given axis even exceed the limit of *3g*, which reflects the double overrun of normative set values (specifically *2g*). In this case cargo during transport "behaves" as though it had twice the mass – the value of inertial force F_z (ceteris paribus) is twofold. By analogy arithmetic mean of the values in the z-axis can be mentioned: $\mu_z = 1.76g$; median: $Me_z = 1.74g$ and the most common value (modus): $Mod_z = 1.69g$. Mentioned statistical values show that according to statistical evaluation they fall within the normative specified interval (in the graph in Fig. 2 into the already mentioned *0-2g*). Standard deviation is: $\sigma = 0.37$.
Interesting is also the kurtosis, which indicates the occurrence of very low and very high values (extremes) $\gamma_{2z} = 26.38$. To be complete skewness is near zero $\gamma_{1z} = -0.22$, then a distribution almost corresponds with standardized normal distribution. For the "negative" shock any relevant data with the exception of two rare variations were not measured. Sporadic variations; which are not statistically seizable; shown in the seventh section of the z-axis value of over *4g* (resp. over *3g*), respectively almost *–6g* (corresponding to almost *–7g* relative to the subtraction of scale from *1g*) and in the third section the value of *5g* (resp. over *4g*). Variations in the other axes also correspond with mentioned extremes. Although the data does not have great importance to statistics, it can be stated that such a short-term shock; only one is often sufficient during transport; may cause release or even damage (rupture) of the appropriate fixative (eg. textile mounting belt that is most often used for this type of vehicles). For the greatest shock in the z-axis which has been measured takes effect *2,160 kg* inertia force on the cargo which corresponds with the formula:

$$F_z = m \cdot c_z \cdot g \qquad [N]$$

where F_z is the value of the inertial forces in the z-axis, m is the cargo weight, c_z is the acceleration coefficient in the z-axis, and g is the gravitational acceleration that corresponds to the latitude of the Czech Republic $g = 9.81\ ms^{-2}$. The resulting value of the inertial forces is, after introducing the highest measured value from the Table 1, as follows:

$$F_z = 2{,}160 \cdot 6.75 \cdot 9.81 \qquad [N]$$
$$F_z = 143{,}030\ N$$

Based on the calculation simple conclusion can be made the value of the inertial forces in the z-axis is *6.75* times greater than what can be calculated using normative given values c_z. For the particular mounting method entire calculation is additionally affected with additional input data: acceleration coefficients in the other axes, angles formed by the mounting belts, the dynamic coefficients of friction, etc. This fact would lead even to deterioration of the resultant straining of mounting mean in comparison with the simple calculations using Newton's second law of motion.

Table 1
The biggest measured variations in particular axis (grey cells) and comparison with other axes

Date	Time	*x*-Axis (g)	*y*-Axis (g)	*z*-Axis (g)
2016-06-01	11:18:52	5.50	–1.74	–6.75 (–5.75)
2016-06-01	09:24:19	3.40	–2.28	5.35

Note: For z-axis data logger (akcelerometr) measured value of –5.75g, however the value is indicated not from zero but from value of 1g.
Source: (Own)

From Fig. 1 also results that under the given conditions (for a given polygon) extreme variations in one axis are usually accompanied by large fluctuations in other axes. For the x-axis and z-axis is the time of the greatest (for x-axis), respectively the smallest (z-axis) variation the same – see the first line of the table.

2.3. Statistical evaluation of the transportation experiment – *x*- and *y*-axis

The statistical evaluation is not so attractive for the other two axes as for the z-axis. Values of statistical quantities are, with few exceptions, less significant than for the z-axis. Acceleration coefficients are according to the standard set on $c_x = 0.8$ and $c_y = 0.6$.
From the point of view of statistical quantities the values are normal: $\mu_x = 0.06g$, resp. $\mu_y = 0.05g$ (arithmetic mean), $Me_x = 0.19g$, resp. $Me_y = 0.21g$ (median) a $Mod_x = 0.42g$, resp. $Mod_y = 0.25g$ (modus). Standard deviation is in case of x-axis bigger than for z-axis: $\sigma_x = 0.46$, resp. $\sigma_y = 0.32$. Kurtosis is also less important: $\gamma_{2x} = 5.40$, resp. $\gamma_{2y} = 2.29$. Skewness is completely unimportant, by analogy same as for z-axis: $\gamma_{1x} = -0.01$, resp. $\gamma_{1y} = -0.32$.

3. Conclusion

The benefit of acceleration coefficients determination and their statistical evaluation consist in adjusting the normatively set values for the calculation under specific conditions. Terrain, respectively rocky road in the training area showed significant deviations from the maximum normatively set values, which were determined through empirical studies and data were subsequently statistically processed (averaged). The lack of average values was perceptible for example in z-axis in part 2.2. Although only *0.61 %* of the values from *8,741* (consolidated data, when from the total number of measured values *11.181, 2,440* values represented standing of the truck) crossed the border of *3g* (resp. *2g* related to the initial value of *1g*). However in absolute numbers *53* times release of cargo could happen because the values that are more than double compared to expectations may stand for a significant risk to the cargo.
In accordance with the European Commission – Mobility and Transport (Road Safety) assessment of the weaknesses in cargo mounting includes inappropriate mounting methods or inappropriately selected mounting mean among major or dangerous deficiencies, depending on the particular deficiency (European Commission M & T, 2014). In extreme cases inappropriately chosen method of cargo mounting can cause damage to human health, whether drivers or loading/unloading group.
In further research there is an assumption to compare larger sample of data under comparable conditions and also perform data collection in very specific conditions, such as terrain. A necessary condition is usage of multiple dataloggers on a single vehicle, which will at least partly lead to elimination of sporadic fluctuations in measurements or verification that the fluctuations are not caused by measurement error, but actually influence the cargo.

There is the assumption to compare outputs with simulations and models within the further research, which are based on technical parametres of the vehicle and use e.g. bondgraphs (Gupta, A.; Rastogi, V., 2011 or Gupta, A.; Rastogi, V., 2015), or another type of accelerometers based on MEMS technology with GPS (Sokolovic, V et al., 2015).
With regard to basic research the conclusions may not fully correspond with premises, but preliminary measurements in contrast indicate values greater than originally expected. In other words, the specific conditions of transport (road – terrain) can very negatively influence the cargo and its mounting system. Impact on mounting also depends on the used fixative mean. In the ACR the most often used are different variants of mounting belts which can deform with when overload, fray and even break in extreme cases. Unambiguously we can talk about the negative impact on the mounting belts lifetime which in such conditions cannot be guaranteed and cannot match the lifetime mentioned in the product documentation. A very important fact is also responsibility for any damage of the cargo, which, in such cases, loading group would be held responsible, not the manufacturer, who guarantees lower values of inertial forces (normatively given, averaged).
Transport of the dangerous goods where the pressure to strict adherence to the given mounting ways should be even greater is a particular issue. Presumption for future research is to verify the selected transport of dangerous goods under military conditions (e.g. ammunition, explosives).

Abstract: This paper studies the vehicle-road interaction, in order to determine the most effective characteristics of a speed reducer, to extract the maximum amount of energy from the vehicle, with a minimum impact on it. To study and evaluate this interaction, a computational model was developed and incorporated in ROADVISS, a previously developed software, allowing to define both vehicle and speed reducer parameters, and determining the vehicle oscillations, forces induced on the speed reducer and energy lost, as well as the energy received by the speed reducer. Different surface shapes were considered, with different dimensions, allowing to conclude that the currently used speed reducers shapes are not the most effective. With an appropriate speed reducer shape and dimensions, it is possible to maximize the energy extraction by more than 40%, minimizing the impact on the vehicle in more than 80%, when compared to standard speed reducers.

Keywords: vehicle-road interaction, speed reducer, road safety, simulation software, ROADVISS.

1. Introduction

Road accidents are considered by the World Health Organization (WHO) one of the main problems affecting public health in the WHO European Region, the cause of death of about 120,000 people annually and the leading cause of death in children and young adults aged 5 to 29 years old (WHO, 2010). Additionally, WHO estimates that each year about 2.4 million people are seriously injured as a result of road accidents only in the WHO European Region. Worldwide, estimates that there are about 1.24 million deaths due to road accidents (WHO, 2013).

WHO recommends six strategic points for action in order to reduce effectively and rapidly the number of accidents, especially with vulnerable road users, being the first and more relevant an effective speed reduction.

This issue is of great importance at several levels. Firstly because, as it is properly studied and based on traffic engineering and road safety manuals (Seco *et al.*, 2008; Elvik *et al.*, 2009), the higher the speed, the greater the time and distance for braking and stopping and, consequently, the greater the severity of accidents. The state of the pavement (dry or wet) also has influence on the braking and stopping distances, but the main factor is the vehicle speed at the moment that it begins to brake (Seco *et al.*, 2008). Similarly, it is studied that the probability of an accident involving a pedestrian be fatal is greatly reduced with the reduction of impact speed, being this probability of 80% if the speed is 65 km/h, 45% if the speed is 50 km/h and is lower than 10% if the speed is 30 km/h. These numbers highlight the importance of controlling the speed to keep it below 50 km/h in urban areas and below 30 km/h in residential areas, especially near crosswalks.

Traffic calming measures have emerged as a way to minimize negative impacts of traffic on places where vehicles moves, by moderating their speed, with the main objective being to approach the speed of motorized vehicles to the speed of non-motorized vehicles and/or pedestrians moving in the same space. One of the most effective measures is the change in vertical alignments, especially through the implementation of speed reduction equipment (SRE), as speed bumps. SRE is the traffic calming measure most used globally because it ensures a significant reduction in vehicle speed (Seco *et al.*, 2008; Elvik *et al.*, 2009).

This solution has the advantage of reducing the vehicle speed, not so much in a direct way, with the impact on the vehicle, but indirectly, by forcing drivers to reduce the vehicle speed before hit the equipment, to avoid the impact (Silva, 2010). This equipment increase the respect between vehicles and pedestrians in crosswalks areas and are able to reduce the number of road accidents by 41% (Silva, 2010), although many entities indicating substantially lower values, such as the ITE pointing reductions of 13% (Ewing and Brown, 2010). According to Gifford (2004), this reduction in 20 mph zones (32 km/h) can reach 60%.

Due to the impact of these devices in vehicles and their occupants, such solutions are not suitable for application in crossing roads of locations where the design speed is usually between 40 and 50 km/h (Seco *et al.*, 2008), limiting its range of applications. Another major drawback of SRE is the noise generated by the impact of the vehicle with the equipment, which in residential areas is quite annoying, especially at night (Silva, 2010; Freitas *et al.*, 2013).

From the analysis that was performed, it can be concluded that traffic calming measures presents some effectiveness, yet limited, having margin to be improved and evolved. In the particular case of the SRE, which is presented as the most effective solution in speed reduction, but at the same time presents some restrictions in the possible implementation places, if such solution was optimized and have less invasive characteristics in terms of its impact on vehicles, maintaining the effectiveness in terms of speed reduction, the potential application of these devices would be much greater and their contribution to an effective speed reduction would be higher, allowing a significant decrease in the road accidents rate.

Based on this, the present study intends to overcome an existing gap, by presenting a new approach to reduce road vehicle speed through an innovative SRE, with new characteristics that allows to reduce the impact on vehicles, especially its surface profile, increasing the energy removed to the vehicle and maximizing its speed reduction.

[2] Corresponding author: adelino@dec.uc.pt

Achieving this, it will be possible to implement these devices in places where vehicles move at speeds higher than 40 km/h and reduce their speeds without cause discomfort to their occupants.

2. Standard Speed Reduction Equipment

2.1. Equipment

To improve traffic safety, vehicle speed needs to be reduced in various places, both in and outside urban areas. Three types of measures can be adopted for this purpose: horizontal alignment changes (chicanes, narrows, roundabouts, etc.), vertical alignment changes (humps, platforms, raised crosswalks, etc.), or complementary measures, such as illumination, urban features, among others (Elvik *et al.*, 2009; Ewing and Brown, 2010). The most effective measures to control vehicle speeds are the vertical alignment changes, as these usually affect the vehicle and their occupants, if speed limits are not respected. However, there are some design rules in order to guarantee softness and, therefore, the design speed.

So, SRE should have an impact on vehicles when they travel above the design speed, which causes discomfort to their occupants and, at the same time, should have minimum impact on the vehicles if they travel under the design speed. This is achieved through their geometry and surface profile.

Speed bumps and speed humps built directly in the pavement (with concrete or bituminous mixture) are not considered products in this work, as these are built by the infrastructure manager in accordance with existing standards.

Considering the existing products on the market, mostly speed humps and speed bumps, manufactured with a high-strength rubber (usually vulcanized) with convex or sinusoidal surface profiles, the mostly used products have a maximum height at its center of 3 or 5 cm and widths of 50 or 90 cm, respectively (3M, 2016). The 3 cm height speed bumps are used in places with a speed limit not exceeding 35 km/h, while the 5 cm height are used in places with a speed limit not exceeding 20 km/h.

Some manufacturers have different surface profiles, such as triangular or trapezoidal, maintaining the high strength rubber as the predominant material, using also recycled plastic as the main alternative (TSS, 2016; Hongqiao Traffic, 2016).

There is not an international uniformity regarding the geometric aspects of SRE, including its shape, height, length and width. Considering other research works (Johnson and Nedzesky, 2004; Szurgott *et al.*, 2009), individual countries recommendations (DGV, 2004; Ewing and Brown, 2010) and the previously mentioned products, it can be concluded that the mostly used surface profiles on SRE are, respectively, convex (S1), sinusoidal (S2), trapezoidal (S3) and triangular (S4), being these presented in Figure 1, with L_{max} being the maximum width and h_{max} the maximum height of the surface.

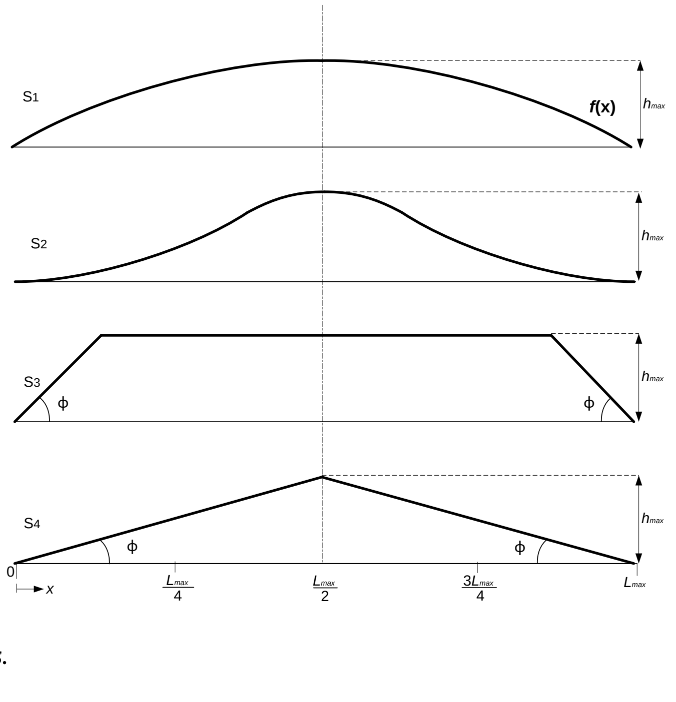

Fig. 1.
Typical SRE surface profiles.

2.2. Vehicle Model and Energetic Analysis

Modeling of four-wheeled vehicles has been studied for the last 50 years. The dynamics and characteristics are well understood and validated models have been developed for many applications, including the study of vehicle vibrations (Gillespie, 1992; Wong, 2001; Blundell and Harty, 2004; Jazar, 2008; Popp *et al.*, 2010; Rajamani, 2011).

To model a vehicle and study the vehicle-road interaction (VRI), the most simple model is the quarter car model, which is the most commonly used and most useful model of a vehicle suspension system (Blundell and Harty, 2004; Jazar, 2008; Popp *et al*., 2010; Rajamani, 2011). This model only represents the sprung mass of the vehicle, the unsprung mass, the suspension system, and the tire, being represented in Figure 2 a). For more complex and detailed studies, regarding only forward linear motion, the most suitable model is the bicycle car model, which is represented in Figure 2 b), and includes the vehicle sprung mass (equal to half of the vehicle), the front unsprung mass, rear unspung mass, front and rear suspension systems, and front and rear tires. The most suitable model to study the interaction between a vehicle and an obstacle in the pavement, as a SRE, is the bicycle car model, being its motion equations defined in the main *Vehicle Dynamics* references (Blundell and Harty, 2004; Jazar, 2008; Rajamani, 2011).

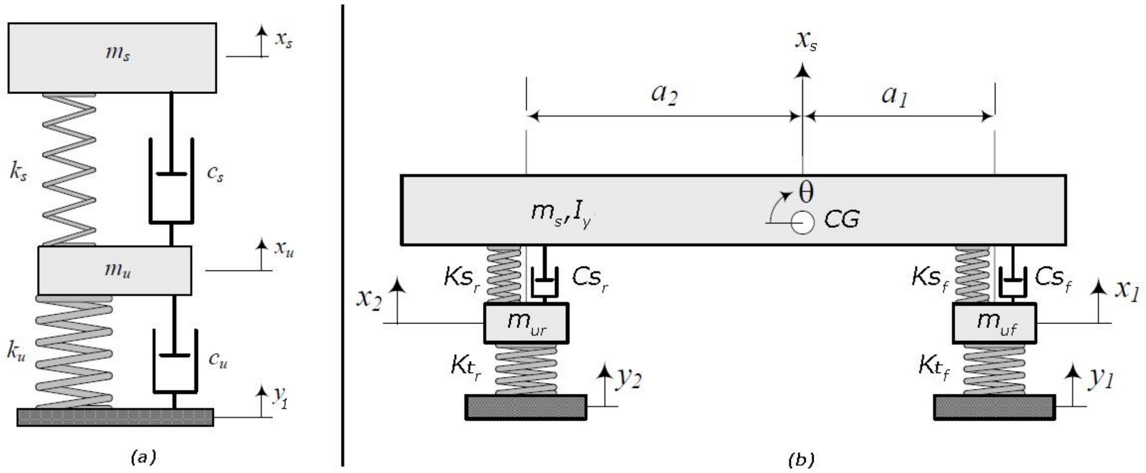

Fig. 2.
(a) Quarter car model and (b) bicycle car model (adapted from Jazar, 2008).

The energy released from the vehicle can be determined using the vehicle speed reduction, which is associated to the lost of kinetic energy (K), using equation (1), with m_v representing the vehicle total mass, v_i the vehicle initial speed and v_f the vehicle final speed, both in m/s.

$$\partial K = \frac{1}{2} m_v \times (\partial v^2) = \frac{1}{2} m_v \left(v_f^2 - v_i^2\right) \quad (1)$$

3. New Speed Reduction Equipment Concept

3.1. Surface profile

The surface profiles represented in Figure 1, typical for standard SRE without surface displacement, have a common feature: its initial and final height is the same, at the road pavement level, so that the vehicle wheel starts and finishes the contact with the equipment at the pavement level.
When the SRE surface has a vertical motion, moving downwards with the force exerted by the moving vehicle wheel, its final height should not be the same as its initial height, so that the vehicle's tire can reach the pavement level immediately after leave the contact with the SRE surface. So, at the surface maximum length, the surface profile height should be the same as the surface maximum displacement. To accomplish this important feature, four different surface profiles were developed, being presented in Figure 3. Each surface profile has the following denomination: *Ramp* (S5), *S Profile* (S6), *Scale Up* (S7) and *Crest* (S8).

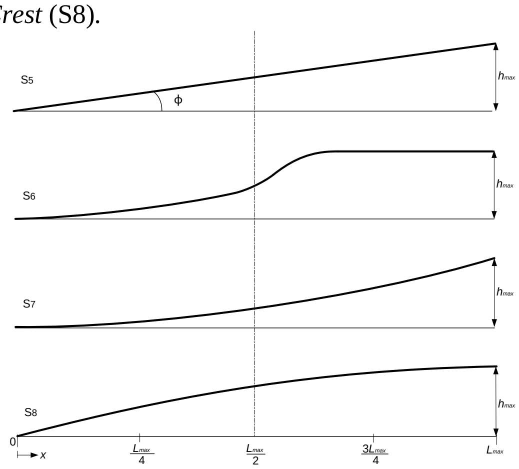

Fig. 3.
New SRE surface profiles for a one degree of freedom movable surface.

3.2. Vehicle Model and Energetic Analysis

The main models to study the VRI were presented in section 2, with special emphasis for the bicycle car model, the most appropriated model to study the interaction between a vehicle and an obstacle in the pavement. Those models were validated for pavements without a movable surface. However, when considering a device with a vertical motion of its surface due to the actuation of the vehicle, the models are incomplete.
The inclusion of a surface with vertical displacement in the pavement for the bicycle car model is represented in Figure 4, being implemented under the equipment surface a one degree of freedom movable system with a displacement x_h, a mass m_h, and a spring with stiffness K_h, responsible for the opposition force to the surface motion, for the mechanical energy storage and for the surface position replacement. The governing differential equations of motion for this model are presented by equations (2-6).

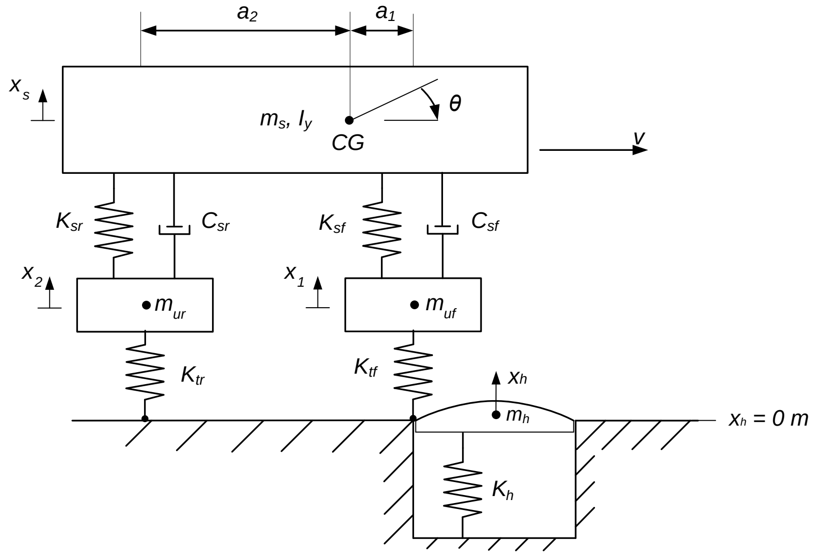

Fig. 4. *Bicycle car model with a movable surface applied on the pavement.*

$$m_s\ddot{x}_s + C_{sf}(\dot{x}_s - \dot{x}_1 - a_1\dot{\theta}) + C_{sr}(\dot{x}_s - \dot{x}_2 + a_2\dot{\theta}) + K_{sf}(x_s - x_1 - a_1\theta) + K_{sr}(x_s - x_2 + a_2\theta) = 0 \quad (2)$$

$$I_y\ddot{\theta} - a_1C_{sf}(\dot{x}_s - \dot{x}_1 - a_1\dot{\theta}) + a_2C_{sr}(\dot{x}_s - \dot{x}_2 + a_2\dot{\theta}) + a_1K_{sf}(x_s - x_1 - a_1\theta) + a_2K_{sr}(x_s - x_2 + a_2\theta) = 0 \quad (3)$$

$$m_{uf}\ddot{x}_1 - C_{sf}(\dot{x}_s - \dot{x}_1 - a_1\dot{\theta}) + K_{tf}(x_1 - x_h) - K_{sf}(x_s - x_1 - a_1\theta) = 0 \quad (4)$$

$$m_{ur}\ddot{x}_2 - C_{sr}(\dot{x}_s - \dot{x}_2 + a_2\dot{\theta}) + K_{tr}(x_2 - x_h) - K_{sr}(x_s - x_2 + a_2\theta) = 0 \quad (5)$$

$$m_h\ddot{x}_h - K_{tf}(x_1 - x_h) - K_{tr}(x_2 - x_h) + K_hx_h = 0 \quad (6)$$

The energy released from the vehicle is determined using the vehicle speed reduction, which is associated to the lost of kinetic energy, through equation (1).

4. Technical Analysis

Based on a software tool previously developed by the authors to simulate the VRI from an energetic perspective, named RoadVISS (Duarte et al., 2016), the equations of the SRE with a movable surface were incorporated, both for the new surface profiles and for the vehicle dynamics model with a moving surface and a spring.
The purpose of the simulation software is to study this interaction in great detail, with the possibility of fully characterizing the vehicle under study, by defining its class, weight, axles, wheels, geometry, speed, acceleration, suspensions and tires, defining all the mechanical parameters, such as damping and stiffness for each suspension and tire, as well as fully characterizing the pavement or SRE surface, by defining its material, shape, geometry and, for a surface with displacement, its maximum displacement, mass, and stiffness. The selected vehicle model for this analysis is the bicycle car model.
The software tool calculates all the displacements, both for the vehicle and the SRE surface, the applied and received forces, and the energy transferred, released from vehicle and received on the SRE surface, presenting the results both graphically and numerically. From the vehicle's chassis displacements and from the motion equations, the software also

quantifies the vertical and horizontal accelerations, important to determine the discomfort induced on the vehicle passengers.

In this section the simulations performed with RoadVISS for two scenarios will be presented: standard speed reducers, without surface motion, and the new SRE proposed, for different surface profiles, maximum displacements and geometries, in order to identify the most effective solution, both in terms of speed reduction and ride quality.

According to Uys *et al.* (2007) and considering ISO 2631-1 (ISO, 1997), the vertical acceleration induced by the vehicle on the passenger is a key factor for measuring the ride quality. According to these references, for a vertical acceleration lower than 0.32 m/s^2, the driving is comfortable; between 0.32 and 0.63 m/s^2, the driving is a little uncomfortable; between 0.5 and 1.00 m/s^2, the driving is a fairly uncomfortable; between 0.80 and 1.60 m/s^2 the driving is uncomfortable; between 1.25 and 2.50 m/s^2 driving is very uncomfortable; and above 2.00 m/s^2 driving is extremely uncomfortable. Thus, it is intended that the SRE do not induce vertical accelerations above 0.80 m/s^2 in the vehicle's chassis.

To perform the simulations with RoadVISS, a four wheeled light vehicle with a 1,500 kg total weight was considered as input, having a 90%-10% relation between sprung and unspung masses and moving at 50 km/h in a free rolling scenario.

4.1. Standard SRE

Considering the SRE available on the market, more specifically commercial speed bumps, which have a convex and sinusoidal profile, with different widths (400, 600 and 900 mm) and maximum heights (20, 30 and 50 mm), and also some products with triangular and trapezoidal surface profiles, as presented in Figure 1, a set of simulations were performed for a vehicle with the presented characteristics, in order to determine the impact of the different SRE on the vehicle, both in terms of maximum induced force form vehicle to the SRE (F_z), vehicle released energy (K), chassis maximum vertical displacement (x_s), maximum vertical acceleration ($\ddot{x}_s$), maximum horizontal acceleration ($\dot{\boldsymbol{v}}_{\boldsymbol{x}}$), and the vehicle speed reduction. The simulation results are presented in Table 1.

Table 1
Standard SRE simulation results

Surface profile	Width [mm]	Max. height [mm]	$F_{z\ max}$ [mm]	Vehicle rel. ener. K [J]	$x_{s\ max}$ [mm]	$\ddot{x}_{s\ max}$ [m/s^2]	$\dot{v}_{x\ max}$ [m/s^2]	Speed reduction [km/h]
Bump S1	400	20	5,691.16	760.00	1.61	2.25	-3.24	0.13
	600	30	6,685.55	1,200.00	3.37	3.58	-3.47	0.21
	900	50	7,739.05	2,248.00	6.48	5.11	-3.82	0.39
Bump S2	400	20	6,588.26	776.00	0.95	1.68	-2.12	0.13
	600	30	7,669.48	1,028.00	2.34	2.95	-2.95	0.21
	900	50	9,738.73	2,680.00	3.89	4.83	-4.1	0.47
Trapezoidal S3	500	30	7,045.11	3,368.00	3.25	3.13	-6.15	0.59
	750	40	8,345.22	4,562.00	5.89	4.04	-6.99	0.79
	1,000	50	10,301.18	5,782.00	8.67	4.94	-7.11	1.01
Triangular S4	400	20	6,006.95	570.00	0.98	1.54	-0.75	0.10
	600	30	7,025.51	864.00	1.79	2.47	-0.83	0.15
	800	40	7,603.11	1,040.00	2.89	3.23	-0.84	0.18

From the results presented in Table 1 it is possible to compare the differences between each SRE, depending on its particular characteristics. Some conclusions can be drawn from the analysis of the results:

- All the analyzed SRE induces a vertical acceleration higher than 0.80 m/s^2, which indicates, according with ISO 2631-1 (ISO 1997), that all SRE induces an uncomfortable ride quality to the vehicle passengers, when passing over the SRE at 50 km/h; in fact, most part of the studied SRE presents a vertical acceleration higher than 2.50 m/s^2, meaning that it induces an extremely uncomfortable ride quality to the vehicle passengers,
- Comparing among each studied SRE, one can conclude that the *Triangular* surface profile (S4) presents the lowest vertical acceleration induced to the vehicle passengers, but is also the profile with the lowest energy extraction and, consequently, the lowest vehicle speed reduction,
- The convex *Bump* surface profile (S1), which is the mostly used profile on municipal roads, specially the version with 600 mm width and 30 mm maximum height, induces an extremely uncomfortable ride quality to the vehicle passengers, and only promotes a direct speed reduction of 0.21 km/h,
- The sinusoidal *Bump* surface profile (S2), when compared with the convex *Bump* surface profile (S1), induces a lower vertical acceleration to the vehicle chassis, so, a lower discomfort to the vehicle passengers, for similar results in terms of speed reduction, meaning that this profile is more appropriated to improve ride quality,
- The *Trapezoidal* surface profile (S3) presents the highest speed reduction values; however, due to the very high vertical acceleration induced to the vehicle passengers, its use should be very limited.

4.2. New SRE with movable surface

Considering the new solution proposed for a SRE with a movable surface and considering the same vehicle and motion conditions as the previous simulations for standard SRE, a set of simulations were performed for the different surface profiles presented in Figure 3, with different widths (200, 400 and 600 mm) and maximum heights (20, 25 and 30 mm), being the maximum displacement equivalent to the surface maximum height. The total spring stiffness is 200,000 N/m, and the surface material is recycled plastic with a rubber layer on top, having a total mass of 20 kg. The simulation results are presented in Table 2.

Table 2
New SRE with movable surface simulation results.

Surface profile	Width [mm]	Max. height [mm]	$F_{z\ max}$ [mm]	Vehicle rel. ener. K [J]	$x_{s\ max}$ [mm]	$\ddot{x}_{s\ max}$ [m/s^2]	$\dot{v}_{x\ max}$ [m/s^2]	Speed reduction [km/h]
Ramp S5	200	20	3,634.22	574.00	0.12	0.36	-0.61	0.10
	400	25	3,471.54	490.00	0.07	0.38	-0.35	0.09
	600	30	4,507.51	534.00	0.16	0.99	-0.42	0.10
S profile S6	200	20	3,848.77	242.00	0.17	0.37	-1.13	0.04
	400	25	3,934.52	224.00	0.15	0.34	-0.83	0.04
	600	30	4,888.78	326.00	0.14	0.92	-0.65	0.06
ScaleUp S7	200	20	3,077.12	90.00	0.08	0.46	-0.44	0.02
	400	25	2,937.22	130.00	0.28	0.52	-0.65	0.03
	600	30	3,619.58	224.00	0.40	0.62	-0.10	0.04
Crest S8	200	20	4,203.21	844.00	0.63	1.05	-3.35	0.15
	400	25	4,157.48	912.00	0.73	0.96	-3.18	0.16
	600	30	4,290.05	938.00	1.18	0.86	-3.19	0.16

From the results presented in Table 2, it is possible to compare the differences between each surface profile and SRE characteristics. Some conclusions can be drawn from the analysis of the results:

- Surface profiles *Ramp* (S5), *S profile* (S6) and *Scale Up* (S7) induces a vertical acceleration lower than 0.80 m/s^2, for a 200 and 400 mm width, meaning that these three surface profiles allows a passage with a comfortable or little uncomfortable ride quality, while energy is being harvested from the vehicle, leading to a speed reduction,
- Surface profile *Crest* (S8) induces a vertical acceleration between 0.86 and 1.05 m/s^2, values that are considered uncomfortable in terms of ride quality,
- In terms of speed reduction, *Crest* is the surface profile that allows to harvest more energy from the vehicle and, consequently, to maximize its speed reduction, followed by the surface profile *Ramp*, *S Profile* and *Scale Up*, respectively,
- The surface profile that presents the best relation speed reduction versus ride quality is the *Ramp* (S5), with special emphasis for the 200 mm width and 20 mm maximum displacement equipment, that allows to reduce the vehicle speed in 0.10 km/h only in 0.20 meters, meaning that with five consecutive devices applied in the pavement it would be possible to have a 0.50 km/h speed reduction in only one meter, with a good ride quality (little uncomfortable).

5. Conclusion

In this work a new solution was proposed to reduce vehicle speeds by extracting kinetic energy from their motion, being applied directly in the road pavement, making it impossible for the vehicles to overcome it without interact with it. This solution is different from the existing SRE, as it has a one degree of freedom movable surface, with a specific profile and geometry that allows to minimize the impact on the vehicle, keeping acceptable ride quality and without affecting vehicle passengers.

The existing SRE have a small impact in vehicle speed reduction, lower than 0.50 km/h for the most used speed bumps (S1 and S2), inducing however a great discomfort to the vehicle passengers, with vertical accelerations higher than 2.0 m/s^2 for almost all equipment. From all the simulations, it can be concluded that all SRE induces very uncomfortable or extremely uncomfortable ride quality to the vehicle passengers, while do not induces high values of speed reduction to vehicles. The effectiveness of these devices is due to the discomfort caused to vehicle passengers, which leads to a speed reduction before the equipment due to a braking action, and not by the equipment captured energy.

When comparing the results achieved with a movable surface and surface profiles S5-S8 to the standard SRE with surface profiles S1-S4, one can conclude that the relationship vehicle speed reduction versus ride quality is much better for the new proposed device with movable surface, for all the studied surfaces, both in terms of speed reduction and ride quality.

Different surface profiles and dimensions were evaluated, and the solution that presents the best relation between the energy harvested from the vehicle and the vertical acceleration induced to the vehicle chassis is the *Ramp* surface profile, with 200 mm width and 20 mm maximum height, having a maximum displacement of 20 mm. When comparing with standard speed bumps, it can extract 44% more energy for the same width, with an impact on the vehicle chassis 90% lower, for the same device height.
The main difference of the proposed solution when compared with the existing equipment is that speed reduction is performed by extracting energy from the vehicle without any action of its driver, instead of inducing a great discomfort on the vehicle occupants.
Has the movable surface concept induces both a small vertical acceleration and a chassis vertical displacement (lower than 1 mm for almost all scenarios), it allows to implement multiple SRE consecutively on the pavement, without or with a very small distance between each other, allowing to maximize the vehicle speed reduction in a very small distance.
The next steps of the current research will be the design of a SRE with the proposed characteristics and the experimental development with a prototype construction and laboratorial tests, before the real environment tests be performed.

Abstract: The current status of assessing the amount of environmental damage is mainly focused on the long-term consequences of negative factors, such as traffic and industry emissions. Significant damage may be caused even due to short-term effects, such as an accident during transportation of hazardous substances, where there is a loss caused either by the vehicle failure, or road accident. Damage which is subsequently solved, in most cases reflects only the costs associated with the removal and rehabilitation of the affected area. It is however important to note that since the damage occurrence until the return of the environment to its original state, if at all possible, there are many changes bearing other related costs associated with their replacement. The paper analyses the current status of assessing the amount of environmental damage and suggests appropriate methods for the unification process in the framework of expert activities.

Keywords: traffic, road accident, environment, damage, assessment, valuation.

1. Introduction

The assessment of environmental damage amount is associated with high demands on knowledge in science, technology and economics. Damage to the environment can occur for a variety of reasons, but mostly due to anthropogenic activities. Human society is an important factor which affects the nature and its resources, both in positive and negative ways. Damage can be caused due to prolonged exposure of negative factors such as industry or traffic. In the short-term effect it is an accident at stationary objects with the loss of dangerous chemicals. These events are a part of the issue of environmental protection, which is becoming one of the priorities of the European Union (EU) and other developed countries. However, the accidents with the dangerous chemicals during their transit are not taken into consideration adequately primarily in terms of legislation. One of the reasons could be in this case the mobility and the lack of ability to predict where the event could occur, under what conditions and what character of the affected site there would be. The complexity of the situation is also enhanced by the fact that there is currently no unified process to assess the amount of potential damage to the environment. The current methodology of solutions is based primarily on experts' experience and on the expert knowledge of application of methods not only in the Czech Republic but also abroad. The chosen methods are most often based on cost method of valuation, especially for removal and rehabilitation work related to accidents. It is however important to realize other connections, such as damage to the environment components and an inability to fulfil their functions. Because of the ever-increasing frequency, the volume of the transported dangerous chemicals and the absence of determination of transport routes, the risk of serious damage to the environment after the accident increases. Therefore, it is important to look for possible approaches for the unification of the assessment of the amount of already incurred or arising damage in a comprehensive manner, which does not reflect only the costs of certain measures.

2. Analysis of the current state

Currently, the quantitative expression value of the assessed entities is preferred while the valuation of the environment. The applied methods focus primarily on production (market) feature of natural components which are in most cases private goods. For the non-productive (non-market) functions of these components the methods based on a qualitative and often a heuristic approach are frequently chosen. This discrepancy is getting into a confrontation with the use of these components of the environment in which a person uses both functions simultaneously, as nature creates a complex system with the mutual interaction of the link between its elements. From this perspective, it is necessary to choose a comprehensive solution and to realize mutual connections in cases such as the damage to the environment after the loss of dangerous chemicals during their transportation caused by the disruption of links and elements of the environment. The first part analyses the problem of valuing the environment in order to define approaches for assessing the value of individual natural ingredients and their components. Subsequently the methods of assessing the amount of damage were analysed which can be applied in the event of accidental release of hazardous substances into the environment.
The assessment of the value of natural resources is exercised mainly in products which are traded on the market, as stated, for example, by Mendelsohn and Omstead (2009), Frey et al. (2009) or Sawe and Knuston (2015). From the perspective of an expert the activity valuation is then necessary, for example, to assess what impact the negative factors have on the environment or its components, or what is the yield value of natural production ingredients. However, the question still is, why the environment is not generally classified as a system, with all its benefits, and not only market ones.

[2] Corresponding author: barbora.schullerova@usi.vutbr.cz

The preference of valuation of production components of the environment is also evident from the perspective of EU (European Commission, 2016) and Czech legislation (Act No. 151/1997 Coll., on Property Valuation). Therefore, it is currently possible to seek solutions in the set of partial findings arising from the experience with the application of the methods of valuing the environment not only in the Czech Republic but also abroad. The inconsistency in the approach of the environment value underlines the need for a solution in search of a unified approach of assessing the amount of damage to the environment.

Damage to the environment is defined by Act No. 17/1992 Coll. on the Environment when it leads to the occurrence of a greater concentration of chemicals in soils, water and other natural ingredients and may even reach the level of environmental burden. Another interpretation of the terms in the legislation relates mainly to long-term sources of environmental pollution or accidental loss of dangerous chemicals from stationary objects which deal with these substances. An example is Directive 35/2004 / EC, which was implemented in the Czech legislation, specifically Act No. 167/2008 Coll. on Prevention of Environmental Damage. In case of damage of the environment the rule is laid down - the polluter pays, along with the ways of remedying it. At the same time, however, certain activities are excluded from the scope, which include the transportation of dangerous substances. The method of damage compensation is further defined in the Act No. 89/2014 Coll. of Civil Code, but only in respect of pecuniary damage, where a specific environmental component must be a subject of property.

2.1. Methods of the assessment of the amount of damage to the environment

The choice of methods of assessing the amount of damage caused to the environment component is based on the nature of the damage and the events that caused it. To select a particular method, the initial information gathering and its analysis are necessary. Additionally, the experience or expert studies of events that have already happened can be taken into consideration and the amount of damage has been assessed. Some of the current methods arose from research projects; others were made for specific cases and the nature of the damage, such as oil spillage and contamination of water sources. It is also important to emphasize that even though some methods and approaches are designed for stationary sources of pollution, some of these methods can be applied to solve the assessment of the amount of damage to the environment in connection with the transport of hazardous substances, or to use their methodology to combine them with other methods (Adamec et al., 2016a). The methods based on the cost method are most often chosen (Quantification of damage to the environment based on the renewal / replacement cost, Quantification of environmental damage based on changes in productivity, the Method of cost of prevention, damages or renewal of environmental resources, the Method of opportunity cost of the so-called opportunity costs, etc.). The above-mentioned methods are based on the principle of preferential and non-preferential access, as is in the case with the methods of valuing the environment (Tošovská, 1999, McCracken- Rietbergen and Abaza, 2000, Roosberg and Thorsteinsson, 2002, Seják, 2010). The loss of value of the damaged components of the environment, and the given costs of preventing damage or vice versa removal of damage are monitored. Although this approach may seem to be sufficient, it is necessary to point out that every methodology of each method is different and does not cover the total spectrum of damaging of both the production and the non-production functions and components of the environment.

2.2. Risks of assessing the amount of damage to the environment

The selection of the correct method with regard to the abovementioned becomes a risk activity when the application of only one method or its improper use may cause obtaining poor or insufficiently meaningful results. The risks associated with the assessment of the amount of damage to the environment include, for example, a poor definition of the evaluated area, conceptual inconsistencies, identifying only visible damage to the environment, a wrong choice of valuation methods, insufficient information and analysis of the evaluated area, ignorance of the applied methods, the individual evaluation without using an objective view of the surroundings, a lack of feedback control and etc.

Those risks are only a partial list of possible factors which may have an adverse effect on the final outcome of the process of assessing the amount of damage. Therefore, the application of methods of engineering risks was selected. Specifically, the analysis "What will happen if ..." was chosen, Fault Tree Analysis (FTA) and Event Tree Analysis (ETA), whose task was to identify and verify whether all detected damage to the environment caused in connection with accidents and loss of dangerous chemicals as well as if characterized damage is related to this event and could not be caused by any other factor of the surroundings (Roosberg 2002, Nilsson 2003, Burgmann, 2005 Adamec et al., 2011 Aven, 2014 Adamec et al. 2016b). The method of analysis Check List was further applied to the draft, whose purpose is to keep the individual procedure steps and their accuracy. The importance of addressing issues of transportation and loss of dangerous chemicals into the environment, where they cause damage, emphasized the result of the analysis of the current state of the transport of these substances on the road.

2.3. Risks of transportation of dangerous chemicals in connection with the occurrence of damage to the environment

In the Czech Republic road, rail and ship (river) transport are most frequently used to transport dangerous chemicals. The most frequent type is road transport according to the international agreements ADR (ADR, 2015), among which the major threat is the ever-increasing volumes and unspecified, or better said unset routes through which the transportation is done (Schüllerová, 2014). The most commonly transported dangerous chemicals are flammable and highly flammable substances such as gasoline, diesel and heating oil, referred to the 1202 and 1203 UN code (Bocana, 2014), within EU countries about 4-8% of the total goods transportation. More than 50% of transported volumes are flammable liquids, mostly in the form of fuel, followed then by compressed and liquefied gases. In 2013 in some European countries an increase in transported volumes of almost 100% was recorded (Estonia, Luxembourg, and Great Britain). In the Czech Republic the international transportation prevails, which reaches almost 60% of representation, and from 2010 to 2014 the quantities of transported quantities had risen [mil.tkm] by 22, 3% (Eurostat, 2016). The statistical data provided by the Police Presidium of the Czech Republic shows that every year nearly one hundred of road accidents involving vehicles under ADR occur (Bukovsky, 2015). The result of the loss of dangerous chemicals escaping can have a different character in connection with the adverse effects on the environment (Garbolino et al., 2012):

- the explosion of expanding vapour of boiling liquid, the so-called BLEVE – the damage is caused by a hot explosion stream,
- the explosion of cloud formed by flammable gases and vapours, the so-called UVCE – the damage is caused by the effects of overpressure,
- the loss of toxic substances and mixtures of undesirable impact on humans and the environment.

Dangerous chemicals can be spread into the atmosphere, if the substances are in gaseous form, liquids can distribute by infiltration, flushing or discharge. The spreading of the substance loss can be also influenced by a slope of the terrain, porosity, composition and the type of affected soil, the absorption capacity, the type of soil micro flora, soil moisture, current weather conditions, time of exposure, but also the time between the accident occurred and the start of rehabilitation. Particularly dangerous are such substances against which the environmental components are vulnerable and these substances are toxic for them.

3. Materials and Methods

To solve the problem of the absence of a unified methodology for assessing the amount of damage to the environment, a systemic approach and its attributes according to Janíček (2014) were selected. For their definition and the settings methods of engineering risks were chosen as supporting tools. Simultaneously the approaches for assessing the vulnerability of affected components of the environment and the categorization of damage incurred were created in connection with dangerous chemicals loss into the environment and their consequences.

3.1. Attributes of a systemic approach to assess the amount of damage to the environment

Based on the researched methods and approaches to assess the amount of environmental damage caused in connection with the transportation of dangerous chemicals especially on the road, it was assessed that it is necessary first of all to choose a general approach on the basis of which different methods and procedures will be chosen. The system approach fulfils these requirements and is thus a suitable choice to solve the stated objective, because it is formed gradually and by logically related steps. The basic attributes of the systems approach are:

- The definition of the area of interest,
- The approaches to problem solving,
- The assessed specifications of the area of interest,
- The definition of methods for analysing the considered area,
- The ethical standards and compliance with them.

3.2. The use of risk engineering methods to assess the amount of damage to the environment

The system approach is also implemented in methods of engineering risks, some of which have been chosen as a support tool to assess the amount of damage to the environment. Their importance is reflected primarily in identifying, analysing and evaluating of the extent of the consequences arising from the accidental loss of dangerous chemicals. They are also a tool for controlling the operations conducted and their correctness, thereby minimizing the risk of inadequate interpretation of results and the subsequent assessment of the amount of damage which is not complete. The risk assessment is based on available information collection, data analysis to determine solutions and formulate problems, application of risk analysis for the identification and characterization of potential incurred damages, risk and identified damage assessment divided according to the importance.

The applied methods are based on a qualitative approach and are used for identification and definition of the assessment area and identification of interdependencies in terms of the impact of the accident on the environment. When applying this approach, a more precise definition of the first group of system attributes is achieved. The chosen methods of engineering risks, which are based on this approach, include:

- The Check List Analysis (CLA) is a simple method, which is based on creating a list of steps, tasks or items, according to which the completeness or accuracy of the method is verified.
- The analysis "What will happen if ..." (What If Analysis) helps to create a basic framework for defining locations where damage can be assumed and characterized,

- Fault Tree Analysis Method (FTA) based on a deductive approach helps to find the root causes of the peak events such as damage to the environment at the crash site.
- Event Tree Analysis Method (ETA) is a method based on an inductive approach to identify possible consequences of the events and the probability of their initiation Aven (2014). In this case, it is an accident during transportation of dangerous chemicals and the consequences of the damage caused. The application of ETA method will help to create a presumption of the extent of the accident and to identify the potential damage that may not be obvious at first sight.

Identification of damage according to vulnerability due to dangerous chemicals loss

Vulnerability is an important property of components and elements of the environment, which is important to be implemented into the process for assessing the extent of the damage. The advantage of this feature is that based on the assessment of the elements of the affected area, any damage incurred and its importance can be more easily identified. The valuation is based on the definition of ecotoxicity of the dangerous chemicals loss and their amounts, including determining the extent of contamination of production and non-production functions of components of the environment.

Modelling of emergency situations

The results will be verified on a model situation of the accident with the dangerous chemicals loss to the chosen destination. This phase of a solution requires at the same time the assessing of demands to assess the extent and amount of damage, which is different in each case of the damage. The software tool Areal Locations of Hazardous Atmospheres (ALOHA 5.4) will be used, which was created by U. S. EPA and NOAA (U. S. EPA, 2016). This software is freely available and can be used free of charge. The software is used for modelling the dangerous chemicals loss with a possibility to display outputs in the map data, such as geographic information systems (GIS) or Google Earth map data (Google, 2016).

3.3. Methods for assessing the amount of damage to the environment

The methodology for assessing the amount of damage to the environment will be based on ensuring comprehensiveness in accordance with predefined attributes of a systemic approach. Choosing of the recommended methods is based on a prior evaluation of the extent of the damage and its importance according to the risk categorization made according to form, meaning and affected environmental components. The recommended methods for assessing the amount of damages will create a suitable combination to assess the damage to public and private environment estates, including the measures to ensure the safe transportation and measures applied to their removal and rehabilitation of accident and damage incurred.

4. Results

The implementation of a system approach to the issue of assessing of the amount of damage to the environment, in connection with the transportation and the loss of dangerous chemicals during the accident, contributed significantly to the achievement of the results presented here. At the same the methods of engineering risks were used as support tools for identification, analysis, evaluation and characteristics of the damage incurred and also as a control tool for minimizing the risk of errors. Given the complexity of solving this problem the assessment of vulnerability of components of the environment and the classification of damage caused to the environment have been also included into the overall process. The procedure of setting requirements for respecting the systems approach, together with methods of determining the extent and importance of damage, has been used to create a user-friendly software tool, which aim is to determine the importance of damage to individual components of the affected area and to define the recommended methods for assessing the amount of damages.

4.1. Application of a system approach to assess the amount of damage to the environment during an accident while transportation of dangerous chemicals

The system approach and its application to solving specific problems, was chosen considering its complexity and unity, which is very significant for a solution to assess the amount of damage to the environment. The basic methodology has been used in order to meet the necessary steps for its implementation (Figure 1). At the same time the support tools and methods were implemented, whose task was to provide a comprehensive, qualitative and easy way to assess the amount of damage caused to affected components of the environment where there was a contamination or otherwise unwanted results of the dangerous chemicals loss.

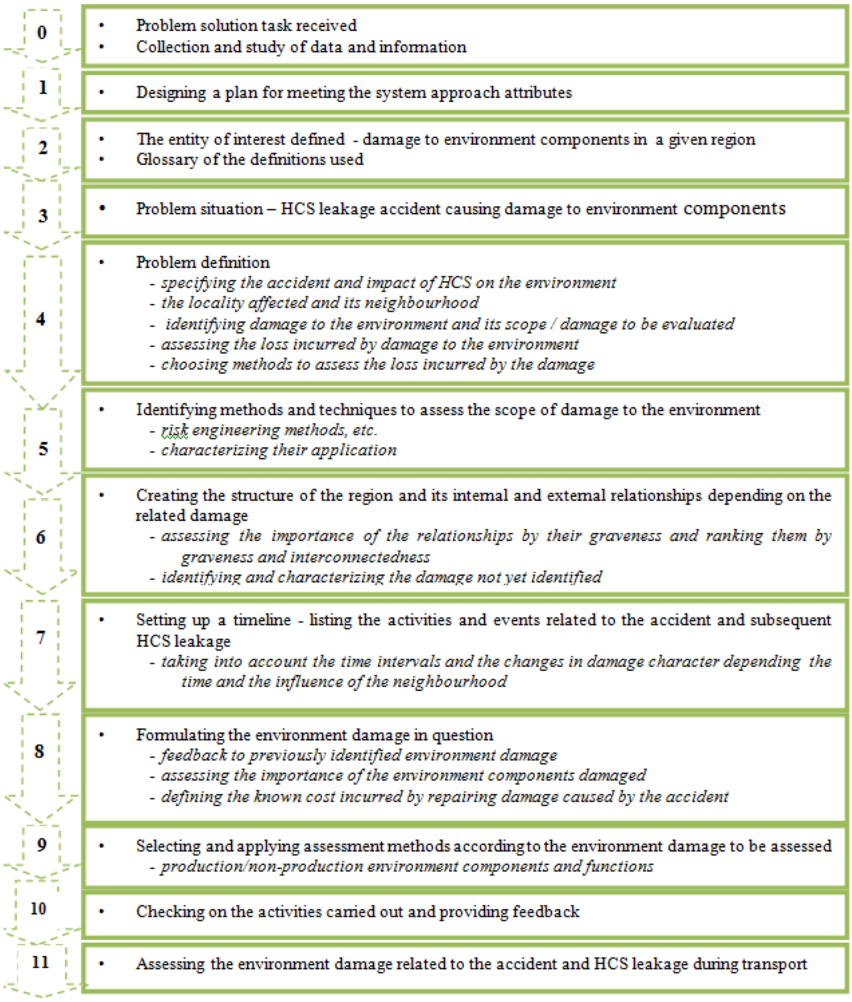

Fig. 1.
System approach activities (algorithm)

4.2. Application of risk analysis to identify and assess the damage to the environment in connection with accidents and the loss of dangerous chemicals during transportation

To correctly implement the mentioned attributes, the methods of risk engineering were chosen, which allow based on the controlled methodology to identify and describe the extent of damage (Figure 2). Also the purpose of their application is to minimize the risk of errors and to increase the quality of outputs. Mainly qualitative methods were used within the various stages of preparation and application of the design of the proposed approach - identification and definition of the particular entity and its solutions, identification and characterization of damage incurred or potential damage to the environment based on the analysis during the accident, checking of the correct and complete application of the systems approach for assessing the amount of damage to the environment (Table 2).

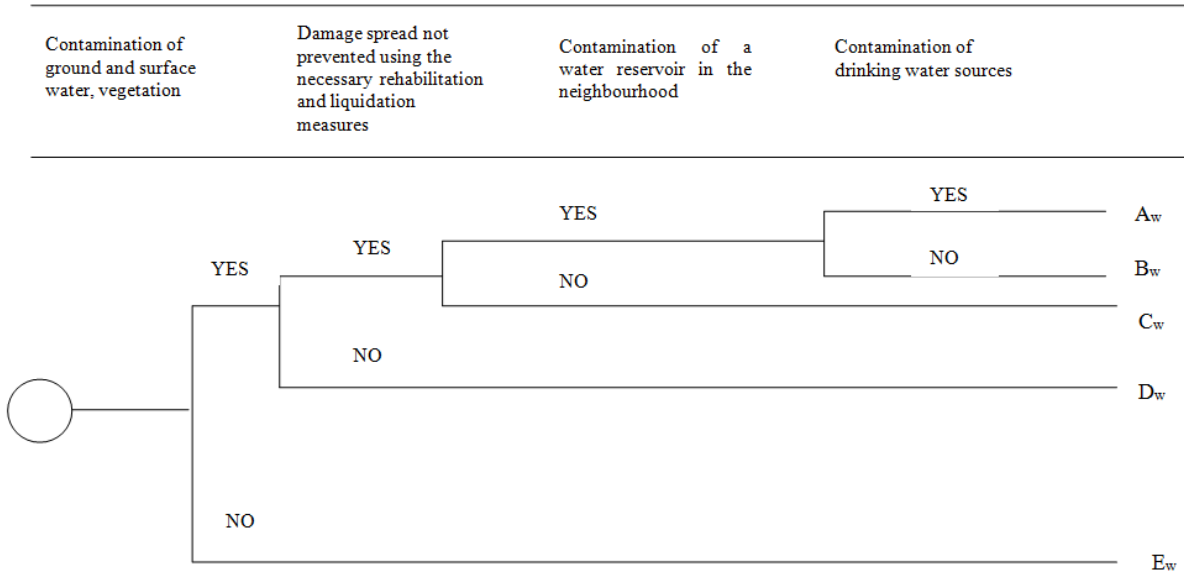

Fig. 2.
Examples of ETA analysis application and damage identification for a particular environment component (water environment – w)

Table 1
Example of assessing the ETA analysis final events for water environment (w)

Final element	**Meaning**
A_w	HCS has spread into neighbourhood through ground and surface water, damage to vegetation, loss of animals are expected, more damage than for B_v assumed). Trout water in part of a river or stream contaminated. A fish farming water reservoir contaminated. Drinking water sources contaminated through ground water.
B_w	HCS has spread into neighbourhood through ground and surface water, damage to vegetation, loss of animals are expected, more damage than for C_v assumed). Trout water in part of a river or stream contaminated. A fish farming water reservoirs contaminated. Contamination of drinking water sources prevented.
C_w	HCS has spread into neighbourhood through ground and surface water, damage to vegetation, loss of animals are expected, more damage than for D_v assumed). Trout water in the affected part of a river or stream contaminated. Contamination of water reservoirs prevented.
D_w	Damage caused in the place of leakage (spread prevented), damage to vegetation, loss of animals expected.
E_w	The spreading HCS has not contaminated ground or surface water.

4.3. Vulnerability assessment of environmental components related to damage occurrence

Damage to the environment is varied as mentioned in the chapters above. Among the significant factors is the vulnerability of the components and elements within the area affected. Based on the application of the methods mentioned, damage has been defined including its brief characteristic, which is related to the area affected. If the vulnerability element is considered in the assessment, the expert will be able to determine the seriousness of the damage better. For this purpose, a simple assessment procedure has been established, which is based on qualitative assessment. The following characteristics have been specified to be used as the basis for a qualitative assessment, the assessment of the degree of vulnerability, the endangered function of the environment, the seriousness of the disruption to the environmental function considering the necessary corrective measures.

4.4. Categorizing environmental damage to determine its degree

Following the vulnerability assessment of the area affected and the identification of the vulnerable places, the characterization of the damage occurring may begin. By characterizing the environmental damage which has occurred, it may be classified and categorized based on its seriousness. Based on this categorization, the expert will be able to obtain an overview of all the damage caused or the damage that may still manifest itself after the accident in connection with the effect of HCS. At the same time, it will be possible to evaluate whether suitable measures have been applied to eliminate and repair the damage.
The categorization of environmental damage related to the transport of HCS was based on processing data on real accidents during the transport of HCS. The statistical data evaluated were provided by the Police of the Czech Republic

(Bocán, 2014, Bukovský, 2015). Based on this analysis, characteristics have been established describing the nature of the accident related to the damage occurrence as well as the nature of the environmental damage occurring afterwards. Specifically, it is the stage in which the accident happened, the type of the HCS, its toxicity and other dangerous properties, the amount of the HCS leaked with regard to the toxicity, the components affected with regard to the ecotoxicity, the components affected with regard to the established vulnerability in relation to the HCS leaked.

4.5. A proposal of a solution methodology procedure

Based on the results obtained, a proposal of a unified approach to determining the amount of damage to the environment related to an accident during the transport of HCS has been outlined. A solution methodology has been developed based on the knowledge about the current situation in determining the amount of environmental damage, about the transport of HCS on roads and the approaches and methods suitable to be implemented in the issues in question. This methodology responds to the fact that there is no unified procedure which would be both clear and which would minimize the risk of omitting some environmental damage. That is why basic rules have been set for applying each particular method and approach.

The basic approach, which permeates the entire methodology, is a system approach. The risk engineering methods selected and the vulnerability assessment and damage categorization have been applied as a support tool for fulfilling the attribute of a system approach, making the solving of complex problems clearer and improving the quality of results.

The rules mentioned have been divided into three stages within which the individual assessment steps are introduced. The preparatory stage focuses on the right specification of a problematic situation and the problems that arise from it. First of all, however, a specific entity of interest must be defined. It is defined based on the attributes of a system approach. They are supplemented by the recommended risk engineering methods; the „What happens if..." method (identifying the components and elements of the area affected and determining the basic assessment boundaries), the ETA method (creating scenarios and identifying the interrelations between the damage and the affecting factors), the FTA method (verifying the causes leading to the occurrence of the environmental damage in connection with an accident during transport and the leakage of HCS). Each step must be accompanied by a recheck, which has been included in the proposed approach in the form of a Check list, which does not allow obtaining a specific result if a certain step is not carried out.

In the second stage, the extent of environmental damage is determined including its characteristic and classification based on the environmental elements affected. Its seriousness is also described with regard to the liquidation and corrective measures already taken and the current state being assessed. Therefore, this characteristic is then analysed using the risk engineering methods and their classification by the environment components affected, the assessment of the seriousness of the damage to the environment regarding the vulnerability, which is described by the rules for assessing and classifying environmental damage using the existing classification method. Based on the assessment of the damage to the environment, methods can be chosen for determining the extent of the damage caused.

The first two stages constitute a clear and comprehensive base which will allow the expert to use the selected methods. The selection of the methods for determining the extent of damage should take into consideration not only the liquidation costs but also other factors such as preventive or corrective measures. The selection of suitable methods should therefore be carried out by a combination based on the categories of liquidation, correction, prevention, and compensation.

The selection of the methods for determining the extent of damage which are in compliance with the categories mentioned should produce a comprehensive set of methods which will help to determine an objective and unified total extent of environmental damage. With regard to the place of the accident occurrence and its extent, it is suitable to also select methods based on preferential evaluation or to include this method in the given combination. This mainly concerns accidents involving the leakage of HCS with a significant impact on the surroundings, when the area is either completely devastated or it cannot be used in the usual way for a certain time interval. One of the examples is a ban on entry into the forest or other areas intended for recreation, social purposes etc. Forming the right combination of methods depends on the basic algorithm created with regard to the preceding stages and specific problems which are solved on a given entity.

4.6. Environmental damage assessment methodology and its application to a software tool

When the proposal mentioned was being prepared, another problem had to be dealt with. It was the uncertainty concerning the uniformity of recording the required information and data and a possible loss of orientation during the application to a specific case. That is why a simple programme has been developed allowing the expert to proceed step by step and form a comprehensive basis for determining the extent of environmental damage. The tool selected for this programme is Microsoft Office Excel 2007 (Microsoft, 2016). The reason was its enhancement and easy usage. The programme setting is based on a simple algorithm of meeting or not meeting a specific condition. As Table 2 shows, there is a total of seven stages, the last of which serves as a checking one. Stages A – G consist of 33 steps including help for filling them in.

Table 2
Division of the stages of the software tool

Marking	Name
A	Familiarization with the task
B	The location of an accident involving leakage of HCS
C	Leakage of HCS
D	Damage to the environment
E	The extent and seriousness of the environmental damage caused
F	Time axis
G	Checking

Checking whether the steps and stages have been fulfilled is accompanied by verbal and graphical coloured illustrations. If all the steps in one of the stages have been fulfilled, it becomes highlighted in green, the help disappears and it is possible to proceed to the next stage. However, if any of the steps is not fulfilled, the check boxes remain red. This may happen in two cases:

- some of the steps have not been fulfilled or the answer is not given in an appropriate form,
- fulfilling the step is not possible since the required condition has not been met.

In the first case, each step must be checked again in the stage where the check boxes remained red and they must be completed. In the other case, the checking stage provides help which says how to proceed. For example, where information needs to be looked up, which step has to be repeated or whether it is possible to determine the extent of damage at all.

Most of the steps were made in the form of a selection from several options offered. Each step is accompanied by help which says whether one of the options should be selected or whether a description is necessary. For stages D-F, the application of the risk engineering methods given is recommended. Stage F is subsequently interconnected with the assessment of vulnerability of the environment. The last stage G was created for secondary checking whether all the stages and steps have been fulfilled and described in the right way. If this stage is fulfilled as well, the results are generated. They are based on specific conditions being met in each stage.

The output is a description of which components of the environment were or may be damaged and an evaluation of the seriousness of the damage. Specifically, damage is specified for water, soil and rock environment and a biotic component. For each of these components, three classification levels of the seriousness and extent of damage have been defined including measures recommended for verifying whether all the damage related to the leakage of HCS during transport has been identified. Each description also contains a recommendation of how the leaking substance can spread in the given environment and where it is therefore necessary to carry out a check using, for example, the results of the monitoring. The basic environmental damage categories have been created as follows:

- highly serious damage,
- serious damage,
- anticipated or less serious damage.

What is also recommended are different methods and their approaches and methods of determining the extent of environmental damage. It is always a combination of methods taking account of the conditions of assessment complexity. The following are selected categories of methods of determining the extent of environmental damage recommended with regard to the defined extent of damage:

- cost-related,
- quantificational,
- preferential.

The number of the recommended approaches and methods depends on the category and the component of the environment affected by the damage (Figure 3). For each one, however, there is a recommended group of methods including the representation of each category.

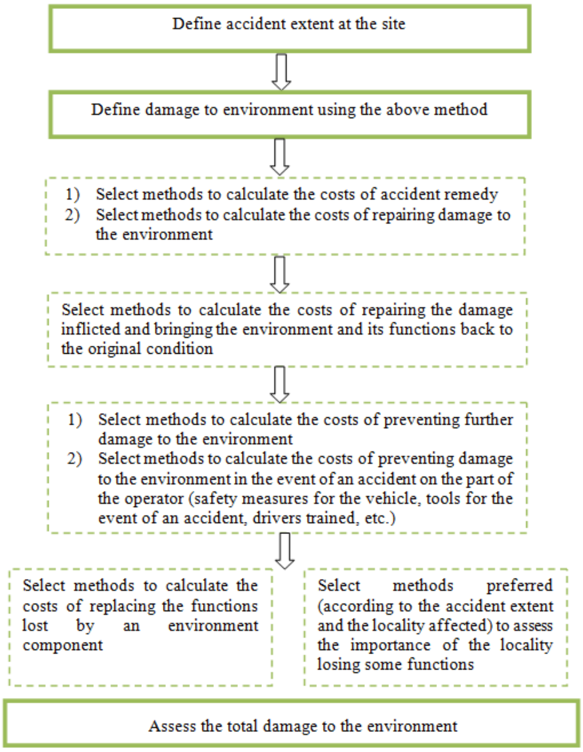

Fig. 3.
Algorithm for selecting methods to assessing comprehensive environment damage cost

It is also important to mention that each accident including the leakage of HCS during transport on roads has its own hazard scenario and development as well as a heterogeneous environment in which it occurs. That is why the methods are recommended not strictly prescribed. Although the software tool was created with an emphasis on its complexity, there are certain limitations which must be taken into consideration:

a) *The veracity of the data entered*

The software tool currently contains a measure checking whether each stage and the steps have been fulfilled. In some steps a warning is also provided if, for example, a verbal statement is given instead of a numerical one. It does not, however, check the relevance and correctness of the values and data entered. This condition cannot be met with regard to the heterogeneity of the events and the variable conditions which occur. At the same time, however, especially the expert must remember the obligation to adhere to ethical standards and the responsibility for the correctness of the information and interpretation of the results.

b) *Entering more types of HCS at once*

If there is leakage of more types of hazardous substances at the same time and their impact on the environment may be different, it is necessary to apply the software tool separately for each type of the HCS. The aim is to obtain relevant data and to ensure that all the damage which occurred or the potential damage has been identified in a comprehensive way including a recommendation concerning the application of the methods of determining the extent of environmental damage.

The aim of creating this software tool was to make fulfilling the requirements for observing a system approach to dealing with a specific field of interest more simple and clear adding support tools.

3. Conclusion

A system approach to determining the extent of environmental damage related to an accident and leakage of HCS during transport is an area where a lot of difficulties must be dealt with. They are for example dealing with these problems within the legislation, the definition of the terms damage to the environment and compensation for damage, differences between accident scenarios which cannot be precisely predicted due to the mobility of the vehicle, the absence of routes designated for transport of HCS with regard to the potential risk etc. The main problem, however, is a missing unified approach which would allow experts to assess the extent of damage and based on which appropriate methods would be selected for determining the total amount. Based on the information obtained, on materials from foreign sources and on consultations with experts, approaches and methods have been selected which are used most often when dealing with these events. It has also been found that these methods most often focus on the expenses connected with liquidation and rehabilitation of the environment, especially in the production functions and components of the environment. That is why the resulting proposal also contains methods taking account of the significance of non-production functions. The solution proposal was subsequently applied in a user-friendly software tool. Further research in this area may continue to be developed attempting to create a universal tool based on a unified and most importantly system approach to assessing environmental damage not only in connection with accidents on roads.

EVALUATING THE EFFECTIVENESS OF NON-PHYSICAL SPEED MANAGEMENT MEASURES

Stanislaw Gaca[1], Mariusz Kiec[2], Marcin Budzynski[3]
[1,2] *Institute of Road and Railway Engineering, Cracow University of Technology, Poland*
[3] *Gdansk University of Technology, Poland*

Abstract: The subject of the Authors' analyses is a group of non-physical speed management measures. How effective they are depends primarily on how willing drivers are to accept restrictions. Social and cultural factors play a major role. The effectiveness of these measures is not clear and requires further research. The authors conducted such research and evaluated the effects of non-physical speed management measures on driver behaviour and road safety. Changes in behaviour were evaluated by examining speed parameters and how they changed depending on the measure. When evaluating the effects of selected speed management measures on road safety, the analysis looked at crashes using the simple "before" and "after" method with trend control. The so called "power model" was also used for the evaluation with some of its parameters modified.
The research covered: local speed limits, area speed limits TEMPO 20 and TEMPO 30, sections with traffic calming measures and sections with additional speed control signs. Empirical speed tests were conducted at the total of 88 test sites on regional roads. The crash data analysis covered 152 test sites. The research helped to estimate speed reductions caused by the particular speed management measures. Depending on the measure the average speed went down by 6.8-16.3%. The paper includes the results of evaluations studying the effects of selected speed management measures on the crashes. The measures were found to be very effective for serious injury and fatality crashes. Based on speed and crash data coefficients of "power model" were evaluated The effects of the speed management measures under analysis on road safety are strongly linked to local conditions.

Keywords: speed, power model, accident, speed limit, speed management

1. Introduction

Speed management is a set of measures designed to set reasonable speed limits and influence the drivers' choice of speed. This can be achieved through urban planning, infrastructure and traffic layout, enforcement, education and advanced technologies. The basic goal of speed management is to achieve a state of traffic where vehicle speeds are adjusted to the road and traffic making the speeds potentially safe. If properly managed, speed control can help reduce traffic noise and air pollution.
There is evidence from research and practical experience that road safety can be significantly improved through consistent speed management, which includes road engineering measures. There are a number of engineering solutions that can help to reduce vehicle speeds such as road infrastructure design that helps drivers to choose the right speed, physical means to control driving speed and reasonable speed limits. Some of the measures are not very restrictive and leave the decisions to drivers (how willing they are to accept a restriction) and local road and traffic conditions. In this case the actual benefits from changing speeds and better road safety depend on social and cultural factors. As a consequence, overreliance on the results of international speed management research may not offer the same effects in Central and Eastern European countries. This has prompted new research into how different speed management measures affect driver behaviour and road safety. The following measures were studied:

- local speed limits,
- area speed limits TEMPO 20 (residential zone) and TEMPO 30,
- sections with traffic calming measures, sections causing drivers to change vehicle trajectory while maintaining good passage for large vehicles (series of central islands),
- sections with additional sing to inform of a possible speed control.

The paper describes the effectiveness of selected speed management measures and the effect they have on road safety. To that end the power model was used. It was calibrated based on research results. The work is helpful with developing speed management guidelines for Poland's regional and local roads. An overview of speed management measures, especially those less restrictive, precedes the presentation of research results.

2. The effects of speed management on road safety

The effectiveness of speed management measures and how they contribute to better road safety can be analysed using direct (road incident data – collisions and accidents) or surrogate measures that describe the potential hazards. One way to understand the effects of speed management on road safety is to estimate how a specific safety measure has changed. The rate is a quotient of the assumed change in safety on a treated section and the mean value of that same measure on an untreated control section. This is referred to in the Highway Safety Manual as CMF (Crash Modification Factor) which is the basic rate with which to evaluate how different road safety treatments change road safety (CMF; HSM,2010). Table 1 lists selected CMF rates estimated from a variety of international studies for different speed management measures, location (local, regional and national roads), types of accidents and their severity.

[1] Corresponding author: sgaca@pk.edu.pl

Table 1
Estimated CMF rates for different speed reduction measures

Speed management measure	Location	CMF	Type of accident	Accident severity
speed limit reduced by 9 km/h	all	1.17	all	all
speed limit reduced by 16 km/h	all	0.96	all	all
speed limit reduced by 24-32 km/h	all	0.94	all	all
speed bumps	urban, suburban	0.5 - 0.6	all	serious and slight injury
traverse acoustic stripes (horizontal marking)	urban, suburban	0.66	all	all
	urban, suburban	0.64	all	serious and slight injury
comprehensive traffic calming	urban	0.89 – 0.94	all	serious and slight injury
raised pedestrian crossings	urban, suburban	0.54 -0.7	all	serious and slight injury
raised junction	none	1.05	all	serious and slight injury
junction replaced with roundabout on low speed roads	all	1.099	all	all
	all	0.473	all	accidents
edge lines along traffic lanes on straight sections and curves	rural	0.963	speed-related	all
raised cycle crossing	none	1.09	vehicle-cyclist	serious and slight injury
comprehensive traffic calming	built-up – primary network streets	0.92	all	all
TEMPO 30, TEMPO 20 (residential zone)	built-up area	0.40	all	all
	built-up area	0.73		fatality and serious injury
	built-up area	0.68	involving pedestrians	all
	built-up area	0.63	all	fatality
		0.92	all	all

Source: www.cmfclearinghouse.org/resources_hsm.cfm

The effects of a speed management measure on road safety can also be estimated using surrogate rates such as change in vehicle speed as a result of the measure. There is evidence that speed can be used as an surrogate road safety rate known from international and Polish research. The statistical relation between speed and road safety is logical and has been demonstrated many times before (Gaca, 2002, Elvik et al., 2009; Cameron and Elvik, 2010).

To estimate how a change in vehicle speed triggers a change in road safety, we can use the "power model" (Cameron and Elvik, 2010). It helps to predict accidents and accident casualties based on the difference in mean speed "before" and "after" a measure has been applied. To this is used the equation below:

$$W_1 = (V_1/V_0)^a * W_0 \tag{1}$$

where:

W_0 – selected road safety measure in the observation period prior to treatment,
W_1 – selected road safety measure in the same observation period after the treatment,
V_0 – average speed prior to treatment [km/h],
V_1 – average speed after the treatment [km/h],
a –model parameter with the value based on literature or set individually.

A key assumption when using the relation (1) is that during the "before" and "after" analysis, none of the other road safety determinants change, except speed.

Research described in (Cameron and Elvik, 2010) was used to determine the following values of a in equation (1) (Table 2):

Table 2
The a parameter in the "power model" equation

Type of accident	Rural roads		Urban roads	
	***a* parameter**	**Confidence level 95%**	***a* parameter**	**Confidence level 95%**
Fatality accident	4.1	2.9 ÷ 5.3	2.6	0.3 ÷ 4.9
Fatality and serious injury accident	2.6	-2.7 ÷ 7.9	1.5	0.9 ÷ 2.1
Total accidents involving casualties	1.6	0.9 ÷ 2.3	1.2	0.7 ÷ 1.7

Source: Cameron and Elvik, 2010

If we assume the above *a* values, in the case of urban roads a speed limit reduction from 60 km/h to 50 km/h, for the average baseline speed of 60 km/h and a speed reduction of 2.5 km/h, fatality accidents would drop by 10.5% with total accidents going down by 5%. With improved speed limit compliance (e.g. through enforcement or physical means of traffic calming) and a real reduction in average speed by 5 km/h, fatality accidents could drop by 21% and total accidents by 10%.
Table 3 lists the research results of how a reduction in existing speed limits changes the number of accidents and casualties and reduces average vehicle speeds (Austroads, 2010). The measures applied are not very restrictive, i.e. no extra enforcement following the introduction of new speed limits.

Table 3
The effects of new speed limits on average speed and accident reduction

Country	Change of speed limit [km/h]	Recorded change in average speed	Accident reduction
Denmark	from 60km/h to 50km/h (local roads)	3-4km/h	fatalities -24%, serious injury -7%, slight injury -11%
Germany	from 60km/h to 50km/h	-	accidents -20%
Australia (Victoria)	from 60km/h to 50km/h (local roads)	2-3km/h	fatality accidents -21%, serious injury -3%, slight injury -16%, casualty -12%, fatality pedestrian accidents -25%, serious injury pedestrian accidents -40%
Australia (South Australia)	from 60km/h to 50km/h (local roads)	3.8km/h	casualty accidents -20%, serious injury -20%, slight injury from -23% to -26%, fatality -40%
Australia (West Australia)	from 60km/h to 50km/h (local roads)	1km/h	casualty accidents -21%, pedestrian accidents -51%

Source: Austroads Ltd.: Infrastructure/Speed Limit Relationship in Relation to Road Safety Outcomes. AP-T141/10, 2010.

The examples above are a good illustration of how useful speed restrictions are in enforcing speed limits. If left untreated, the actual reduction in average speed after a "new" speed limit is introduced will usually be around ¼ of the difference between the "new" and previous limit (Elvik et al., 2009, Gaca and Kiec, 2005).
The less restrictive speed management measures include signs giving "recommended speeds" telling the drivers how fast they should go on a section. This will usually produce a speed reduction on average of 3.2 ÷ 5 km/h (FHWA, 2012).
As well as the less restrictive measures, physical traffic calming measures are also used. These are much more effective and include speed bumps and raised surfaces. International research (FHWA, 2012) suggests that speed bumps are highly effective and help to reduce vehicle speeds by about 32 km/h and about 27 km/h when speed tables are applied. Raised pedestrian crossings used as an obstacle produce results similar to speed bumps with average speed reductions by 4.0 ÷ 6.5 km/h. Please note, however, that while speed bumps reduce speed locally, speed increases in between the bumps which increases emissions (accelerating and braking is more frequent). This is why it makes more sense to use comprehensive traffic calming measures with speed reductions distributed evenly on a designated road section. Mini roundabouts and small roundabouts in place of regular junctions reduce average speed by 36 km/h and 54 km/h respectively.
The results make it very clear that speed management is most effective when physical traffic calming measures are used. Despite that, before any such treatment, an analysis should be conducted to look at the effectiveness of other measures such as active speed limit signs, intensive enforcement, adding or removing lines separating traffic lanes and allowing vehicles to be parked along the road. It is also important to remember that physical traffic calming measures cannot be used freely e.g. on main roads or roads frequently used by emergency services.

3. Research and results

Research into the effectiveness of speed management measures included accident and casualty analyses "before" and "after" a treatment (in locations where the date of a treatment was known). If the date of a treatment was not known, the trends in accident numbers were analysed. Surrogate safety measures were studied too, i.e. vehicle speeds. The research covered the following cases:

a) local speed limits (Figure 1a) – 44 locations for accident analysis and 27 locations for speed analysis
b) TEMPO 20 residential area (Figure 1b) – 10 locations for accident analysis and 8 locations for speed analysis
c) TEMPO 30 area speed limit (Figure 1c) – 35 locations for accident analysis and 12 locations for speed analysis
d) sections with mild traffic calming measures (change in vehicle trajectory while providing good passage for heavy vehicles, Figure 1d) – 33 locations for accident analysis and 29 locations for speed analysis
e) sections with additional sign to inform of a possible speed control on section (Figure 1e) – 30 locations for accident analysis and 12 locations for speed analysis.

Fig. 1.
Examples of analysed speed management measures

3.1. Speed analysis

Due to the conditions on site speed was measured using three measurement methods:

- manual (observations in the field in subsequent measurement cross-sections or analysis of recorded video),
- automatic (pneumatic detectors)
- a combination of manual and automatic measurements.

Manual measurements helped to determine vehicle speeds in free flow traffic only, split into two types of vehicles (light and heavy vehicles). The advantage of the method is that it is done without the drivers noticing. This method was used in Tempo 20 and Tempo 30 zones and in the case of local speed limits.

Automatic measurements helped to ensure that speed was recorded very accurately while differentiating between vehicle speeds in the entire traffic flow and in free flow traffic. The test devices were able to identify vehicle types. This method was used on sections with local speed limits, mild traffic calming measures and on speed control sections.

Speed was measured on sections with speed management measures and on control sections (with no speed management measures). In the case of area speed limits the control sections were selected on streets with Tempo 20 and Tempo 30 characteristics. Mild traffic calming measures were represented by results from sections of a similar characteristic (roadside, cross-section, accessibility). Untreated sections of the same road were also considered. Local speed limits and section control were represented by the following cross-sections: app. 150 m before the sign (as a control section), at the sign and behind it (app. 150 m). Control sections representing local speed limits had similar geometrical parameters. Table 4 lists the results of speed management effectiveness for speed reduction.

Table 4
Results of speed tests in free flow traffic on control sections and on treated sections

Speed management measure	**Control cross-section**				**Treated cross-section**				**Reduction**		
	Mean speed *V*	**85th percentile speed V_{85}**	**Speed variability *WZV***	**Share of those above the speed limit *UVd***	**Mean speed *V***	**85th percentile speed V_{85}**	**Speed variability *WZV***	**Share of those above the speed limit *UVd***	**Mean speed *V***	**85th percentile speed V_{85}**	**Speed variability *WZV***
	[km/h]	[km/h]	-	[%]	[km/h]	[km/h]	-	[%]	[km/h] [%]	[km/h] [%]	- [%]
Speed limit 40	64.4	75.5	0.185	45	60.0	69.7	0.173	89	4.4 6.8%	5.8 7.7%	0.012 6.5%
Speed limit 50	69.9	82.1	0.185	47	60.8	70.7	0.179	77	9.1 13.0%	11.4 13.9%	0.006 3.2%
Speed limit 60	82.3	97.0	0.174	24	70.4	80.7	0.152	81	11.9 14.5%	16.3 16.8%	0.022 12.6%
Speed limit 70	79.9	93.2	0.170	19	70.6	83.3	0.194	43	9.3 11.6%	9.9 10.6%	-0.024 -14.1%
Residential area (TEMPO 20)	38.0	45.5	0.203	77	32.9	40.5	0.237	95	5.1 13.4%	5.0 11.0%	-0.034 -16.7%
TEMPO 30	45.4	53.7	0.185	44	38.0	45.5	0.203	77	7.4 16.3%	8.2 15.3%	-0.018 -9.7%
Mild traffic calming measures	60.0	70.0	0.173	79	53.8	62.1	0.167	68	6.2 10.3%	7.9 11.3%	0.006 3.5%
Speed control sections	66.6	76.7	0.159	88	56.1	64.6	0.166	71	10.5 15.8%	12.1 15.8%	-0.007 -4.4%

The results in Table. 4 show that:

- local speed limits help to reduce average speed significantly compared to the control cross-section (no speed restrictions). The reduction depends on the limit and changes from app. 6.8% to 14.5% on treated sections;
- temporary speed enforcement signs help to reduce speed for longer compared to speed cameras. This measure reduces average speed by about 15.8% compared to the control section;
- mild traffic calming measures help to reduce average speed by about 10.3% with vehicle speeds becoming similar;
- while Tempo 30 zones help to reduce speed by app. 16.3% compared to control sections, the spread of speeds was quite strong with speeds depending on the local road conditions and environment;
- residential area (Tempo 20) results show a speed reduction by about 13.4% in free flow traffic compared to control sections. Just as with Tempo 30 zones, the spread of speeds was significant and depended on local road conditions. Please note the high percentage of drivers going above the speed limit in living areas.

3.2. Accident analysis

With limited data availability, the analysis of speed management effectiveness was simplified. The annual number of accidents and casualties was determined for all the locations under analysis from 2006 to 2014. The next step was to choose those locations whose date of treatment was known and fell within the period 2007 – 2013. Once selected, the locations were then analysed for their annual average road safety rates "before" and "after" the treatment. This produced the quotients of the "after"/"before" measures under estimation for the specific speed management measures. The lower the value of the quotient, the higher the effectiveness of the measure. This is a typical approach to "before" and "after" effectiveness evaluations. Because accidents may change regardless of the treatment, an additional comparison was made of the quotients to general accident trends in the regions under analysis. The effectiveness of the measures was estimated by comparing the "after" quotients to the "before" situations for the treated sites and control sections. The bigger difference between treated site and control section values, the more effective the treatment is (under the assumption that test site values are lower than those in control areas).

Table 5 lists the effectiveness indicators of the speed management measures and the resulting accident and casualty reduction. Grey boxes mean that the measure has had no positive effect. The other boxes mean better road safety as a result of a measure. Because residential areas have a low number of accidents (Tempo 20), those test sites were analysed together with Tempo 30 zones.

Table 5
Analysis of the effects of speed management on road safety

Speed management measure	CMF [-]							
	All accidents		Speed-related accidents		All serious injuries and fatalities		Speed-related serious injuries and fatalities	
	Treated group	Control group	Treated group	Control group	Treated group	Control group	Treated group	Control group
Speed limit	1.19	0.72	0.94	0.86	0.45	0.82	0.32	0.65
Residential area (TEMPO 20) and TEMPO 30	0.78	0.71	0.63	0.65	0.65	0.74	0.47	0.68
Mild traffic calming measures	0.87	0.62	0.75	0.59	1.00	0.58	1.12	0.60
Speed control sections	0.37	0.79	0.36	0.79	0.43	0.77	0.34	0.79

The results show that speed enforcement (signing of speed control section) and area speed limits are effective in improving road safety. It is important to note, however, that the results are based on a relatively small sample and more research is required.
With the evaluation of how different speed management measures affect road safety on Poland's lower class roads, it is clear that the effects differ from measure to measure. Using the results of "before" and "after" comparisons and taking account of the general road safety trends, the following are the initial evaluations of how the particular measures affect road safety:

- no positive effects were established in Tempo 20 and Tempo 30 zones on accident reduction. Fatalities and serious injuries, however, are down – the average reduction rate being 27%;
- contrary to expectations, mild traffic calming measures had no positive effect on accident reduction or casualty reduction;
- sections of roads with local speed limits have seen a positive effect of the restrictions with fewer accidents (a 19% reduction) and serious injuries and deaths (an 11% reduction);
- sections with speed limit enforcement measures have seen very positive effects both in terms of accidents (a 40% reduction) and serious injuries and deaths (a 42% reduction).

3.3. Power model calibration

The next step of the analysis was to calibrate the "a" parameter for the "power model" given in equation (1) using the speed results and accident analysis. The factors calculated include speed-related accidents, severity of all accidents and speed-related accidents which should have a strong relation to speed. Table 6 gives the parameter's values for the measures analysed. The "*a*" parameter for a local speed limits has not been evaluated because of insufficient accident sample for each value of speed limit.

Table 6
The "a" parameter in the "power model" equation based on authors' research

Speed management measure	Power model's *a* parameter		
	Speed-related accidents	Total serious injuries and fatalities	Speed-related serious injuries and fatalities
Speed limit	-	-	-
Residential area (TEMPO 20)	3.2	3.0	5.2
TEMPO 30	2.6	2.4	4.2
Mild traffic calming measures	2.6	0.0	-1.0
Speed control sections	6.0	4.9	6.3

4. Conclusion

The research into the effects of speed management measures on road safety shows that the measures have a varying effect on safety when measured with direct rates such as accidents and accident severity and with indirect rates such as vehicle speed.

As regards the less restrictive speed management measures, especially mild traffic calming measures, the results show that compliance is poor and the effect is low or non-existent when it comes to accidents and casualties. Speed enforcement is most effective as can be seen both from direct and surrogate measures. Area speed management (residential area, Tempo 30), especially when accompanied by physical speed reduction measures such as speed bumps or raised junctions is highly effective. When used outside the zones, however, the measures help to reduce speeds locally only.

Given the specificity of the research, the results are difficult to compare to other countries' results. Despite that, we can see that mild traffic calming measures in particular such as refuge islands or islands on entry to a town, are not as effective as in other countries. This may be the result of culture and sociology in general where regional or motorisation differences play a role. A review of those measures should be conducted and more research is required.

The results can be used to build "power models" that help to understand the effectiveness of speed management measures. This will ensure that proposed treatments will offer the best effectiveness for a given set of conditions.

Abstract: Article shows carried out crash tests between front part of moving and side part (cabin for passengers) of stationary vehicle. The goal of the article was to investigate and observe as many impact parameters as possible, which are necessary for correct traffic accident analysis. Authors carried out experiments with impact speeds of impacting vehicle between 36 and 55 kph. Emphasis was put on investigation of post-crash motion, depth of deformations on vehicles and amount of deformation energy as the parameters for accident reconstructionist. The amount of deformation energy has been compared to results for impacting vehicle gained from CRASH3 module calculation in software PC-CRASH ver. 10.2 and also with simulations with the help of simulating software Virtual CRASH ver. 3.0. Sufficient results correlation at comparable tests between those methods has been found.

Keywords: side crash test, impact parameters, energy equivalent speed, deformation energy.

1. Introduction

The issues dealt with in this article fall within forensic science, particularly within traffic accident reconstruction. Experts who within the framework of a complex analysis of a traffic accident often use simulation programs such as PC Crash (2016) and Virtual CRASH (2016) in order to process the actual plot of the accident must always enter only those input parameters that are in a technically acceptable range. For the verification of the collision parameters in particular it is necessary to use the data from the real crash tests performed for such needs. The works (Campbell, 1974), (Strohrer, 1986), (Batista, 2005) (Seiffert, 2007) and (Cichos, 2008) deal in detail with the issue of sought parameters such as force, energy intensity of impact, stiffness of a given part of a vehicle or vehicle deformation depth. These obtained parameters are subsequently used in traffic accident reconstructions. Many authors and publications such as (Burg, 2009), (Branch, 2011), (Huang, 2002) and (Hugemann, 2007) deal with traffic accident reconstruction that aims to find out the cause of an accident.

The work focuses on side crash tests, when a passing vehicle crashes into the side of a stationary vehicle. All the principal world organisations dealing with safety research and vehicle testing (EuroNCAP, 2016; NHTSA, 2016; IIHS, 2016) have included similar impact configurations in their testing programmes. Euro NCAP as the European independent testing authority uses a deformable barrier running at a speed of 50 kph as a “ram” which crashes into the side of a tested vehicle at an angle of 90°. The ram has a weight of 950 kg as well as a front deformable honeycomb panel size of 500 x 1500 mm (height x width). The organisation called National Highway Traffic Safety Administration (NHTSA) tests the side of vehicles by impact at an angle of 90° which is caused by a deformable barrier running at a speed of 61 kph. The ram’s weight is 1507 kg and its front part has a height of 600 mm. Insurance Institute of Highway Safety (IIHS) performs two different vehicle side tests. The first impact test is coincident with the NHTSA organisation if, and only if, a higher moving deformable barrier of at least 760 mm in height is used. This higher barrier corresponds better to higher front parts of vehicle, in particular to SUVs. The second test (performed by NHTSA as well) differs in mutual impact configuration when a tested stationary vehicle is turned at an angle of 27° towards the longitudinal axis of the moving deformable barrier. The barrier has a weight of 1360 kg and crashes at a speed of 61 kph.

The above-mentioned list of performed side crash tests is focused on the research and testing of safety of new vehicles introduced to the market. The possibility of injury to the crew members of these vehicles, who are replaced with dummy figures during testing, is the main sought parameter. The publication (Chan, 1998) focuses on a correlation between the penetration depth of a part of the vehicle body into its interior – DEPTH, the Thoracic Trauma Index TTI and Pelvic Lead. The work (Stolinski, 1998) concentrates on investigation into the possibility of injury to the vehicle crew in case the impact occurs at a side of the vehicle more distant from the passenger position.

During four performed proper crash tests the vehicles were not fitted with dummy figures and the main attention was therefore focused on investigation into the impact parameters of the vehicles themselves. In particular, they include post-impact velocity, post-impact movement (trajectory), post-impact deceleration and subsequent calculation of deformation energy of vehicle collision and its redistribution to individual vehicles. The deformation energy acting on individual vehicles was quantified by energy equivalent speed (EES).

The performed crash tests were carried out using older vehicles more or less affected by bodywork corrosion. Corrosion significantly reduces the stiffness of vehicle bodywork and larger deformations therefore rationally occur at the same parameters. Such deformations would result in more serious injury to the crew of such a vehicle than to the crew of a new vehicle. However, this fact may not be entirely wrong, especially once we realize that for example in Germany the average age of a vehicle is from eight to nine years; nevertheless, in the Czech Republic it already ranges from fourteen to fifteen years.

[1] Corresponding author: stanislav.tokar@usi.vutbr.cz

The investigation thus aimed to perform crash tests, analyse obtained data and on the basis of this data determine the EES parameter for individual vehicles. It further aimed to compare obtained data with the computational solution carried out using CRASH3 module in PC CRASH version 10.2 simulation program on the basis of comparable vehicle stiffness database and also to apply obtained data and verify it by means of simulation with support of Virtual CRASH version 3.0 simulation program.

2. Methods

In total, four crash tests within an impact speed range of 36 to 55 kph were performed. It was always a collision of the front part of a moving vehicle with the side of a stationary vehicle at an angle of 90°: during crash test no. 3 there was a mutual angle between the vehicles of about 83° whereas during crash test no. 1 the mutual angle between the vehicles was ca. 94°. In two cases (tests no. 1 and 2) the Honda Civic was used as a stationary vehicle. During crash tests no. 3 and no. 4 Skoda Felicia, or Skoda Felicia Combi, was used as a running vehicle. Therefore even from this perspective an appropriate comparison of damage range to vehicles of the same type is possible at different parameters. The performed crash tests were carried out with the participation of an IFE team for the following vehicle impact configurations:

1. A Nissan Almera crashed into the side of a stationary Honda Civic at a speed of ca. 55 kph,
2. A Chrysler Sebring crashed into the side of a stationary Honda Civic at a speed of ca. 43 kph,
3. A Skoda Felicia Combi crashed into the side of a stationary Mercedes Benz at a speed of ca. 50 kph,
4. A Skoda Felicia crashed into the side of a stationary Opel Omega Combi at a speed of ca. 36 kph.

Fig. 1.
Side crash test between Nissan Almera (moving vehicle) and Honda Civic, 3D scan in final position

The determination of deformation energy absorbed by the deformation zones of a vehicle during a collision with an obstacle (or another vehicle) is one of the important parameters in the solution of vehicle collision itself. The entire movement of vehicles during the plot of an accident depends on this amount, particularly the calculation of the driving speed of vehicles just before collision. In an expert's practice the only clue to determining the deformation energy is the range of vehicle damage or the deformation depth of its relevant sections. If we knew the stiffness characteristics of the relevant sections of particular vehicles, we could determine the consumed deformation energy on the basis of a relationship:

$$E_D = \frac{1}{2} \cdot k \cdot x^2 \tag{1}$$

Where; E_D: deformation energy [J], x: deformation depth [m], k: car stiffness [N/m].
Unfortunately, the stiffness characteristics are not commonly available for reconstructionist. In an expert's practice the expert estimate of EES, which expresses kinetic energy of a vehicle proportional to the deformation energy that is needed to reach an appropriate range of permanent deformation. This article should serve for verification of these estimates, while, on the contrary, the consumed deformation energy, or EES of the vehicles, will be determined from the input parameters. During the actual process of determination of the deformation energy during vehicle collision we will proceed from the law of the conservation of energy, therefore the (vehicle) system energy before collision must be equal to the total system energy after collision. In vehicle collision mechanics three types of energy are distinguished:

$$E_P = m \cdot g \cdot h \tag{2}$$

$$E_{K_T} = \frac{1}{2} \cdot m \cdot v^2 \tag{3}$$

$$E_{K_R} = \frac{1}{2} \cdot I \cdot \omega^2 \tag{4}$$

$$E_D = W_D = \frac{1}{2} \cdot m \cdot EES^2 \quad (5)$$

Where; E_P: potential energy [J], E_{KT}: kinetic energy of translation [J], E_{KR}: rotation energy [J], E_D: deformation energy [J] which is determined by performing deformation work W_D, m: vehicle weight [kg], g: acceleration due to gravity value [m/s^2], h: vehicle centre height [m], v: vehicle speed [m/s], ω: vehicle angular velocity [rad/s], I: vehicle moment of inertia [kg.m^2], EES: energy equivalent speed [m/s].
The total energy balance of a vehicle colliding with an obstacle (vehicle) is therefore as follows:

$$\sum_{i=1}^{n} (E_{K_T i} + E_{K_R i} + E_{pi}) = \sum_{i=1}^{n} (E'_{K_T i} + E'_{K_R i} + E'_{Pi}) + \sum_{i=1}^{n} E_{Di} \quad (6)$$

Where; E_{KTi}, E_{KRi}, E_{Pi} :individual components of the ith vehicle (obstacle) energy before collision [J], E'_{KTi}, E'_{KRi}, E'_{Pi} :individual components of the ith vehicle (obstacle) energy after collision [J], E_{Di}: deformation energy of the ith vehicle (obstacle) [J].
From the total energy balance, we are able to determine the total deformation energy consumed for documented permanent vehicle damage cause. For simplification, the components of energy converted into heat energy are not taken in account. In the instance that we know the EES value for one vehicle it is possible from the following two equations - after the mathematical treatment on the basis of known depths of deformation to individual vehicles - to divide the deformation energy expressed for each vehicle in the EES form:

$$E_{Def} = \frac{1}{2} \cdot m_A \cdot EES_A{}^2 + \frac{1}{2} \cdot m_B \cdot EES_B{}^2 \quad (7)$$

With the use of the following equation we can, after the mathematical treatment and substitution method (7), obtain the division of the total deformation energy into deformation energy components for individual vehicles, for instance, on the basis of known depths of deformation to individual vehicles. For this method the vehicles should have preferably the same or at least similar bodywork stiffness characteristics in the area of collision.

$$\frac{EES_A}{EES_B} = \sqrt{\frac{m_B \cdot x_A}{m_A \cdot x_B}} \quad (8)$$

The data acquired from the performed crash tests was processed by three methods:

I. The determination of EES on the basis of deformation depth: the total deformation energy was calculated from the discovered parameters of vehicle impact and post-impact vehicle movement. This total deformation energy was divided into components for individual vehicles on the basis of known deformation depths. This method for chosen collisions is not entirely appropriate as it is the collision of the front part of the vehicle (with higher stiffness) into the side of the vehicle. It is appropriate to compare even those results achieved by this procedure in order to find out whether there will be any noticeable difference in older vehicles or not,
II. The determination of EES on the basis of stiffness parameters available from CRASH3 software data: when the stated EES values for moving vehicles were acquired from the database of vehicle stiffness parameters available in CRASH3 software, which is a part of PC Crash ver. 10.2 simulation program. Subsequently, on the basis of the known EES value for a moving vehicle and the total deformation energy values of a given collision the EES value of the second (stationary) vehicle was calculated with the help of the equation (7),
III. Vehicle impact simulation with the simulation program support: the data acquired from the performed crash tests were subsequently used for the vehicle impact simulation with the simulation program support. In this case Virtual CRASH ver. 3.0 simulation program was used for traffic accident reconstruction. Simulation of the vehicle impact and post-impact vehicle movement is carried out by means of gradual optimization of the input values. The impact simulation is carried out by means of forward methods, i.e. from the centre to the final position. The program uses for impact solution the so-called impulse-impact model which replaces all the contact forces acting in the deformed profile of the damaged part of the vehicle with a single force resultant passing through so called point of impact. On the basis of the position of the point of impact from the profiles of both vehicles in the moment of maximum deformation depth in a direction of impulse action the energy equivalent speed (EES) values are recalculated from the deformation energy.

3. Results

Individual crash tests and the acquired data, which was subsequently used for the determination of the EES parameter for individual vehicles, are described in this chapter.

3.1. Crash test no. 1 – Nissan Almera x Honda Civic

This crash test was carried out by the collision of a Nissan Almera running at a speed of 55 kph that crashed with its front part into the left side of a stationary Honda Civic. The angle of longitudinal axes of the vehicles was ca. 94°, see fig. 2. The parameters of the vehicles as well as the impact and post-impact movement necessary for the actual solution and calculation of deformation energy are stated in table 1. The breaking of the Nissan was taken into account for the post-impact movement. The post-impact rotation of the Honda vehicle was of an angle of ca. 34°. The post-impact movement of the Honda vehicle was taken as friction (skidding) over the surface (dry, clean asphalt).
In order to calculate the EES value for the Nissan Almera vehicle in CRASH3 program, the input parameters for recalculation chosen were the values from the crash test of a similar vehicle Nissan Sentra model year 1998, test number 2771, carried out by NHTSA.
For simulation the Virtual CRASH version 3 simulation program was used by i.a. Kudlich-Slibar impact model. A certain simplification occurs with this model – all the impact plot is situated in one moment of time and the impact forces are replaced with their resultant passing through the so-called point of impact. The input parameters were:

- Vehicle positions in the moment of the first contact (i.e. Exact point of contact and a mutual angle of rotation of the longitudinal axes of vehicles),
- Vehicle movement speeds just before impact,
- Angular speeds,
- Immediate vehicle weight,
- Size parameters of vehicle (according to the manufacturer),
- Adhesion (just for the conformity of vehicle runs to the final positions – does not affect the impact calculation),
- Deformation depth.

In order to reach conformity the collision parameters were varied:

- Impact point position (x,y,z),
- Restitution coefficient.

It was not necessary to vary the other impact parameters (friction, impact plane direction) as it was an impact completely without slide and therefore with a low impact point speed during collision.

Table 1
Parameters of impact and post impact motion of vehicles - Test no. 1 (author)

Nissan Almera (A) Length: 4340 mm; Width: 1690 mm; Height: 1395 mm	**Honda Civic (B)** Length: 4325 mm; Width: 1695 mm; Height: 1390 mm
Vehicle weight (m_A) = 1050 kg	Vehicle weight (m_B) = 1100 kg
Pre-impact speed (v_A) = 54,8 kph	Pre-impact speed (v_B) = 0 kph
Post-impact trajectory (S'_A) = 3,75 m	Post-impact trajectory (S'_B) = 4 m
Post-impact speed (v'_A) = 25,2 kph	Post-impact speed (v'_B) = 27,6 kph
Deformation depth (x_A) = 0,26 m	Deformation depth (x_B) = 0,25 m
Total deformation energy (E_D) ca. 61 kJ	

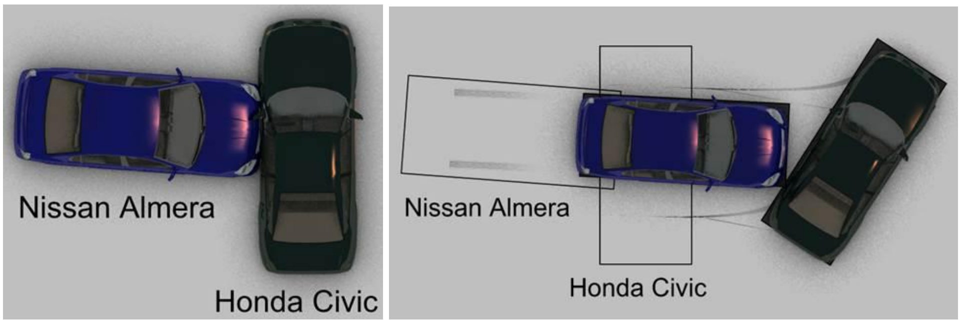

Fig. 2.
Side crash test no. 1, left – impact position, right – final position (Virtual CRASH)

3.2. Crash test no. 2 – Chrysler Sebring x Honda Civic

The crash test was carried out with a Chrysler Sebring vehicle running at a speed of 43 kph, which crashed with its front part into the left side of a stationary Honda Civic vehicle at an angle of 90° (see fig. 3). After the collision of vehicles the anticlockwise rotation of the Honda vehicle at an angle of ca. 90° took place, the vehicles subsequently got mutually wedged with their left sides and this way moved to their final positions.

In the calculation of the EES value for the Chrysler Sebring vehicle in CRASH3 program the input parameters for recalculation chosen were the values from crash test of similar vehicle Chrysler Sebring model year 2007, test number 5886 carried out by NHTSA.

Table 2
Parameters of impact and post impact motion of vehicles - Test no. 2 (author)

Chrysler Sebring (A) Length: 4844 mm; Width: 1792 mm; Height: 1394 mm	**Honda Civic (B)** Length: 4325 mm; Width: 1695 mm; Height: 1390 mm
Vehicle weight (m_A) = 1510 kg	Vehicle weight (m_B) = 1100 kg
Pre-impact speed (v_A) = 43 kph	Pre-impact speed (v_B) = 0 kph
Post-impact rotation (α'_A) = 0 °	Post-impact rotation (α'_B) = 90 °
Post-impact speed (v'_A) = 25 kph	Post-impact speed (v'_B) = 25 kph
Deformation depth (x_A) = 0,10 m	Deformation depth (x_B) = 0,20 m
Total deformation energy (E_D) ca. 44 kJ	

Fig. 3.
Side crash test between Chrysler Sebring (moving vehicle) and Honda Civic (author)

3.3. Crash test no. 3 – Skoda Felicia Combi x Mercedes Benz W210

The Skoda Felicia Combi vehicle crashed with its front part into the right side of Mercedes Benz W210 vehicle at a speed of 50,5 kph. The angle between longitudinal axes of the vehicles during the collision was ca. 83, see fig. 4. After the collision of vehicles, an anticlockwise rotation of the Mercedes Benz vehicle at an angle of ca. 30 ° took place.
In the calculation of the EES value for the Skoda Felicia vehicle in CRASH3 program, the input parameters for recalculation chosen were the values from crash test of similar vehicle Volkswagen Golf II model year 1986, test number 945 carried out by NHTSA.

Table 3
Parameters of impact and post impact motion of vehicles - Test no. 3 (author)

Skoda Felicia Combi (A) Length: 4237 mm; Width: 1635 mm; Height: 1420 mm	**Mercedes Benz W210 (B)** Length: 4818 mm; Width: 1799 mm; Height: 1441 mm
Vehicle weight (m_A) = 900 kg	Vehicle weight (m_B) = 1510 kg
Pre-impact speed (v_A) = 50,5 kph	Pre-impact speed (v_B) = 0 kph
Post-impact trajectory (S'_A) = 1,7 m	Post-impact trajectory (S'_B) = 2,2 m
Post-impact speed (v'_A) = 15 kph	Post-impact speed (v'_B) = 21 kph
Deformation depth (x_A) = 0,26 m	Deformation depth (x_B) = 0,25 m
Total deformation energy (E_D) ca. 53 kJ	

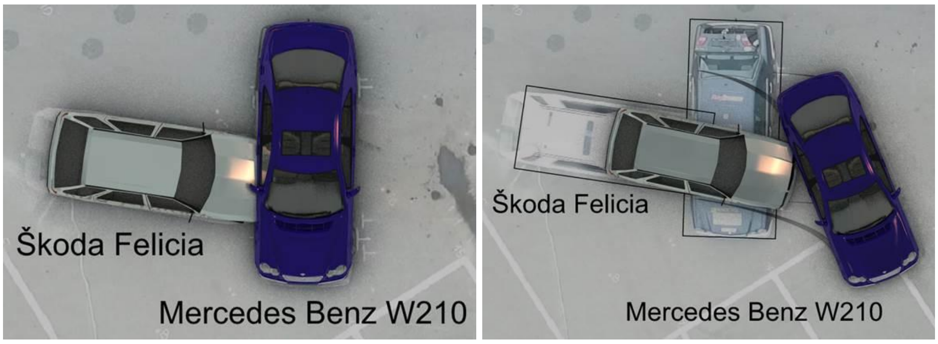

Fig. 4.
Side crash test no. 3, left – impact position, right – final position (Virtual CRASH)

3.4. Crash test no. 4 – Skoda Felicia x Opel Omega Combi

The Skoda Felicia vehicle crashed with its front part into the right side of Opel Omega Combi vehicle at a speed of 36 kph. The angle between longitudinal axes of the vehicles during the collision was ca. 90° (see fig. 4). After the collision of the vehicles no significant rotation of the Opel vehicle took place; it was therefore neglected in the solution of energy balance.
In the calculation of the EES value for the Skoda Felicia vehicle in CRASH3 program the input parameters for recalculation chosen were the values from the crash test of a similar vehicle, the Volkswagen Golf II model year 1986, test number 945 carried out by NHTSA.

Table 4
Parameters of impact and post impact motion of vehicles **-** *Test 4 (author)*

Skoda Felicia (A) Length: 3883 mm; Width: 1635 mm; Height: 1415 mm	**Opel Omega Combi (B)** Ĺenght: 4898 mm; Width: 1776 mm; Height: 1505 mm
Vehicle weight (m_A) = 925 kg	Vehicle weight (m_B) = 1750 kg
Pre-impact speed (v_A) = 36,3 kph	Pre-impact speed (v_B) = 0 kph
Post-impact trajectory (S'_A) = 1,1 m	Post-impact trajectory (S'_B) = 1,3 m
Post-impact speed (v'_A) = 12 kph	Post-impact speed (v'_B) = 15 kph
Deformation depth (x_A) = 0,20 m	Deformation depth (x_B) = 0,10 m
Total deformation energy (E_D) ca. 26 kJ	

4. Discussion

The achieved results are laid out in a well-arranged way in Table 5. The EES parameter value for individual vehicles was inacceptable accordance with the chosen methods (deviations found in system of kph units). In almost all tests the calculated EES value for moving vehicle was higher in the method II. This phenomenon would correspond with the higher stiffness of the front part of vehicle against the side. Nevertheless, the difference is not too significant as with regard to the condition of bodywork of individual vehicles, particularly with regard to the range and degree of corrosion the stiffness of those parts could be already considerably affected (reduced). Deformations of the same or similar vehicles from particular crash tests are shown and compared in fig. 5 – 7. By means of simulation in Virtual CRASH program a good accordance between calculated parameters and parameters recorded in real crash test was confirmed. It is possible to use further the obtained results in an expert's practice in traffic accident reconstruction, particularly when determining the EES value.

EVALUTION OF TRAFFIC ACCIDENTS HAPPENING IN RECENT YEARS IN TURKEY

Muhammed Yasin Çodur[1], Ahmet Ünal[2], Ahmet Atalay[3]
[1,2] *Erzurum Technical University, Engineering and Architecture Faculty, Department of Civil Engineering, Erzurum, Turkey*
[3] *Atatürk University, Narman Vocational High School, Erzurum, Turkey*

Abstract: Throughout the world, in traffic accidents many people get injured or die. Even though the developed countries are able to find a partial solution to this problem, such a case continues to be a major problem in undeveloped countries. The number of traffic accidents in Turkey is increasing depending on the increase in the number of motor - vehicles. However, there may be different reasons for the increment of the number of traffic accidents. Countries are seeking a variety of methods to reduce the frequency of traffic accidents. One of the effective methods to reduce the casualty number of traffic accidents is the construction of divided highways. In this study, common traffic accidents happening in Turkey were evaluated and their causes and measures to be taken to reduce their frequency are investigated.

Keywords: traffic accidents, analyzes, deaths, casualty, traffic law.

1. Introduction

The first motor vehicle accident in England happened in 1896, when Bridget Driscoll, a pedestrian, was hit by a car in London while it was in 1910 when the same thing happened in Beşiktaş, Istanbul, Turkey. Fortunately, the pedestrians were only injured in the accident (Mason and Purde, 2000). World Health Organization estimates that traffic accidents resulting in death will be the 7th leading cause of all deaths in the world by 2030 (WHO, 2015). The world population increased %1.18 last year. The population growth rate was %1.5 in Turkey in 2015. Turkey's population was 78.741.053, the number of vehicles was 19.994.472 by the end of 2015 (Wikipedia, 2015). Highway traffic is the main component of transport facilities in the country. The population growth all over the world has led to increased transportation needs. Due to transportation needs there are more vehicles on highways, thereby increasing the number of injuring and fatal traffic accidents, which was counted in 2015 to be 1.313.359 in 2015.
Several studies from various parts of the world have been conducted on various aspects of traffic accidents beginning mainly from mid – 1960s. In the following years, studies were carried out on traffic accidents, one of the first of which is that developed by Smeed who examined 20 different countries traffic data by considering the relationship between death, population and the number of vehicles (Smeed, 1949). On the other hand, Andreassen developed Smeed's model using different long term data since he wanted to make comments based on not a single year (Andreassen, 1985). Miaou and Harry (1993) studied the statistical properties of four regression models and two Poisson regression models in terms of their ability to model vehicle accidents and highway geometric design relationships. Kim et al. (1995) enhanced a log-linear model to classify the influence of driver characteristics and behaviors in the casual sequence conducive to more severe injuries. Mussone et al. (1999) benefited from neural networks to analyze vehicle accident happening at intersections in Milan, Italy. Abdelwahab and Abdel-Aty (2001) investigated the accident data belonging to 1997 for the central Florida area. In Turkey, studies on traffic accidents have newly been conducted. Hazardous locations were determined on Isparta-Antalya-Burdur highway through Geographical Information System (GIS) by Karaşahin and Terzi (2003). Traffic accidents were analyzed by Üstündağ and Duran (2009) using GIS in Elazığ city. Atalay and Tortum (2010) analyzed traffic accidents happening between 1977 and 2006 in Turkey. Traffic accidents were analyzed using web-based GIS (Durduran et al., 2011). Tortum et al. (2011) studied clustering analysis of the districts in Erzurum for traffic accidents between 2002 and 2007. Çodur and Tortum (2012) developed traffic accident prediction model with neural network. Kabakuş et al. (2012) evaluated traffic accidents happening in provincial districts of Erzurum using GIS. Çodur (2012) studied traffic accident prediction models: applications for surrounding highways of Erzurum. Tortum et al. (2012) modelled traffic accidents in Turkey using linear regression analysis. Çodur et al. (2013) studied Erzurum north ring road accident prediction model with generalized linear regression. Atalay et al. (2013) modelled clustering analysis of the provinces in Turkey according to traffic accidents in 2011. Çodur et al. (2013) studied Erzurum north ring road accident prediction model with artificial neural network. Çodur et al. (2013) studied Erzurum- Tortum road accident prediction model with generalized linear regression. Atalay et al. (2013) analyzed temporal traffic accidents. Atalay et al. (2013) modelled traffic accidents by using geographical weighted regression analysis. Çodur and Tortum (2013) studied Erzurum-Pasinler road traffic accident prediction model. Atalay et al. (2014) modelled traffic accidents by using factor analysis. Çodur et al. (2015) analyzed GIS aided traffic accident. Çodur and Tortum (2015) studied an artificial neural network model for highway accident prediction: a case study of Erzurum. Tortum et al. (2015) analyzed traffic accidents in Erzurum province and its districts through GIS.
In this study, traffic accidents happening in Turkey over the last years were analyzed investigating the effective factors on traffic accidents. Daily and monthly distribution of traffic accidents was analyzed taking the reasons into consideration for the differences between the values. In addition, based on the distribution data, measures to reduce traffic accidents were also evaluated and some suggestions were proposed especially for drivers' faults.

2. Case study area

Turkey is a Eurasian country located in the territories of two continents (Figure 1), Asia (97% so-called Anatolia) and Europe (3% so called Thrace). . Wide footprint of the mountains in Turkey is one of the main factors that make all types of transportation difficult. Highway transportation began to be used widely in Turkey and after especially 1950s, when number and use of motor vehicles also increased. Today, the length of existing road has reached around 65,000 km in the country (Table 1).

Fig. 1.
Location of Turkey

Table 1
Lengths of international roads in Turkey by the end of the 2015
Resource: General Directorate of Turkish Highways

International Roads in TURKEY	TOTAL (Km)
Trans European Motorway	6940
E Roads	9353
BSEC Roads	4472
ECO Roads	9987
ESCAP Roads	5247
TRACEGA Roads	8365
Pan-European Corridors	261
EATL	5563

Modern Turkish Republic was inherited 18.365 km long road network from Ottoman State and during the first years of the Republic (beginning from 1923), great priority was given to the construction of the railways until 1950s. Even though such a policy preference prevented the development of highway network, after 1950s a new era was opened for Turkey's highway development history with the establishment of General Directorate of Turkish Highways on March 1st 1950. Turkey at present covers a total of 2.159 - km motorways, 31.213 km state roads consisting of 14.393 km asphaltic concrete, 16.399 km surface treatment, 71 km stone block, 45 km stabilized, 17 km earthen road and 288 km primitive roads. Provincial roads consist of 33.065 km road network covering 2.702 asphaltic concrete, 27.327 km surface treatment, 699 km stabilized, 614 km earthen road, 191 km stone block and 1.532 km primitive roads.

3. Results

The number of the traffic accidents was reported to be 1.228.928 in 2011 reaching up 1.313.359 in 2015 while the ratio of the traffic accidents to the total number of motor vehicles was 0,076 in 2011 reaching down 0.065 in 2015. The number of traffic accidents in the last five years is shown in Figure 2.

Total Traffic Accidents

Fig. 3.
Yearly distribution of deaths in traffic accidents in Turkey
Source: Turkish Statistical Institute

Generally, there is a decrease in deaths in traffic accidents. It can be said that construction of divided highways and raising the standard of highways caused death rates to decrease. As another factor, the reduction of the number of people killed in traffic accidents can be shown to have been conscious of people in traffic accidents. Lengths of divided roads in the last five years are given in Figure 4.

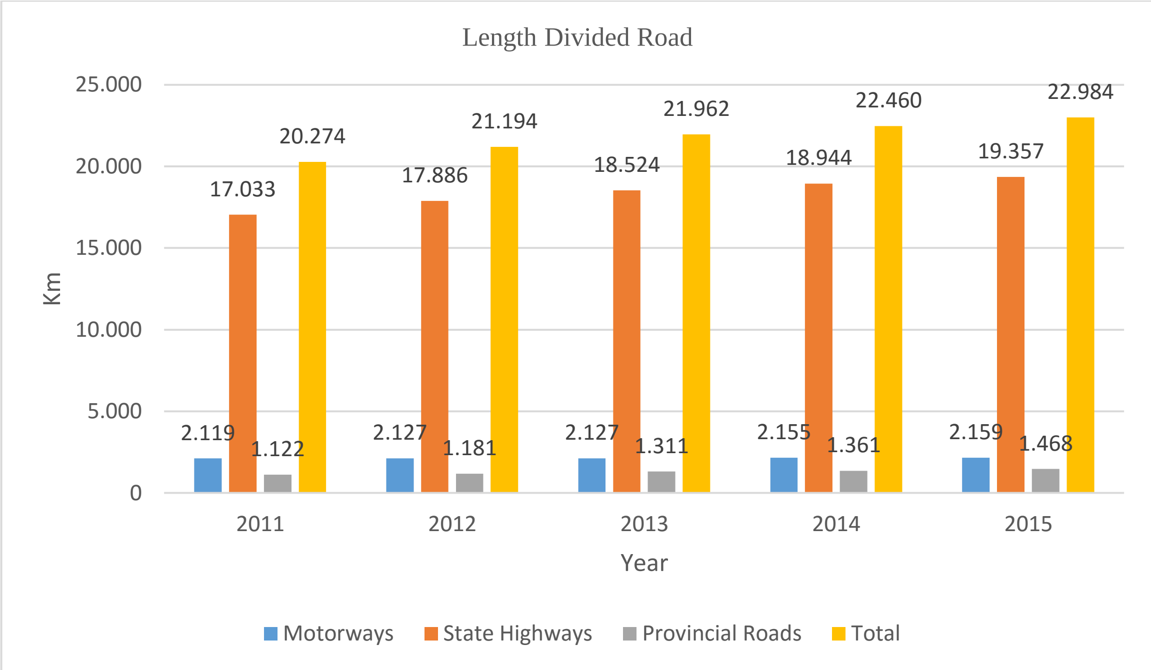

Fig. 4.
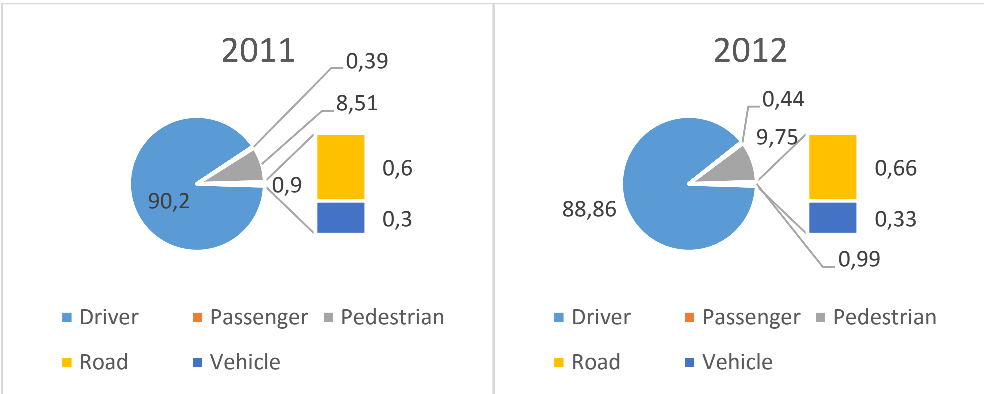
Yearly rates of divided road lengths (km)
Source: General Directorate Highways

The driver defects (faults) are accepted to be the most important factor in traffic accidents, followed by pedestrian behaviors, road structure, vehicle quality and passenger faults respectively. Application of traffic laws in Turkey is another effective factor on the high rate of driver faults. Yearly percentages of such defects leading to traffic accidents are given according to years are shown in Figure 5 (Turkish Traffic Law, 1983). Article 52 of NO 2918 Traffic Code is as follows;

Drivers,

a) must reduce their speed when approaching a junction, entering the turn, approaching the hill top, winding progresses on the road, the pedestrian walkway, the level crossings, tunnels, approaching the narrow bridges and culverts, construction and entering to repair areas,
b) must adapt the speed, the vehicle used to load and technical specifications to the road and the conditions required by the weather and traffic conditions.



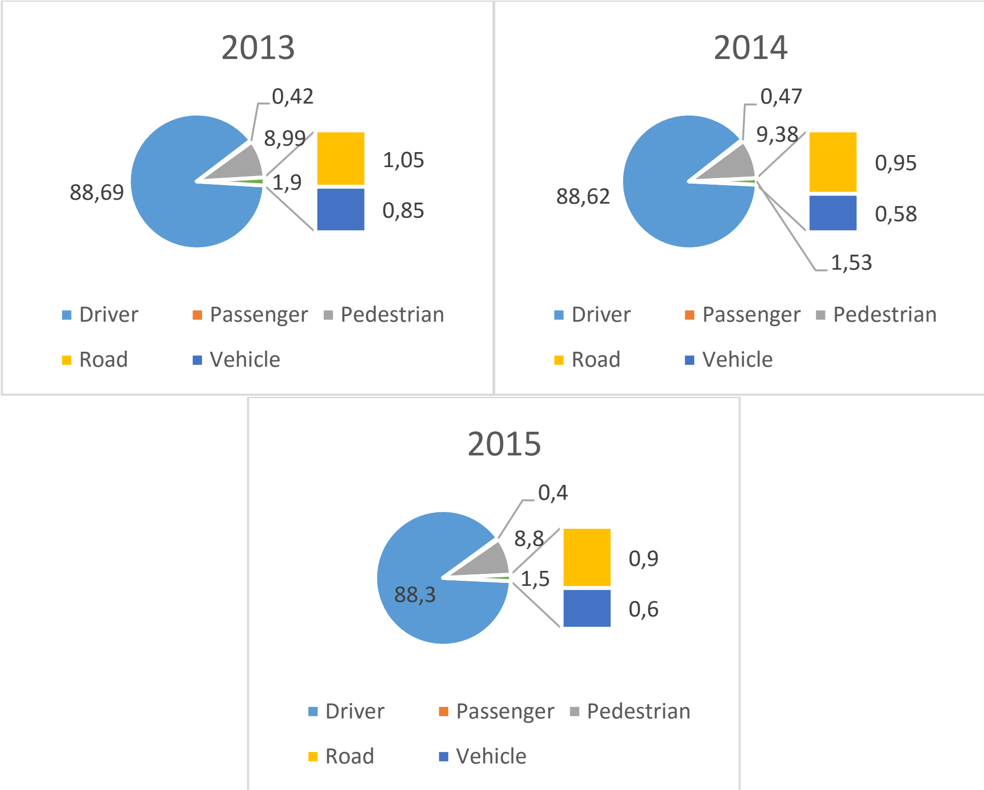


Fig. 5.
Faults causing road traffic accidents
Source: Turkish Statistical Institute

Monthly distribution of traffic accidents is given in Table 2. An increase is seen in the number of traffic accidents in summer months. The reason for this increase may be that in summer, people prefer to go on their holidays using densely highways.

Table 2
Monthly distribution of traffic accidents in 2015

Months	Number of Traffic Accidents	%	People Killed	%	People Injured	%
January	10.443	6,20	221	6,27	17.191	6,03

4. Conclusion

Traffic accidents cause death of thousands of people and loss of millions of dollars in Turkey as well as all over the world. Therefore, precautions must be taken to reduce their losses. This study analyses the data related to the traffic accidents happening last year in Turkey by presenting the situation with the help of tables and figures. Traffic accidents are events happening depending on various and numerous factors most important of which may be human, road, transportation and environmental ones. Data of traffic accidents were analyzed by considering the months of the year and time of a day. It can be seen that the highest rate of traffic accident is experienced in August and during daytime. Generally, the number of people killed in traffic accidents is in declining trend. As a result of this situation, it can be suggested to improve human security and the safety of vehicles in traffic and provide better standards of road.
It is possible to reduce traffic accidents by taking effective measures. Suggestions to reduce the rate of traffic accidents and analyze better traffic accidents are described below:

1) Most of the traffic accidents happen as the result of non-compliance with traffic rules. This case reveals the importance of traffic education. Therefore, government agencies and civil society organizations should raise the awareness of people about traffic and rules.
2) Although the seat belt is placed in passive safety systems, it reduces the risk of death and injury to a minimum. The decision was taken to advise on the use of seat belts by governments on 18 October 1983, seat belt was accepted to be a requirement in the scope of the Code put in to force on 16th June 1985.
3) It seems from traffic accident statistics in Turkey that drivers are responsible for the highest rate of defects. The defect from road structure is even under 1% (Figure5). A higher defect rate paths from the road in countries with higher standards than Turkey, this rate is close to 0 in Turkey. It is thought that this result may be caused by the effective application of article 52 of Code 2918.
4) Road transportation ranks the first among passenger and freight transportations in Turkey. In this case, the number of vehicles in traffic causes to be more. The use of other modes of transportation should be expanded. In this way the density of road traffic will slightly be reduced.

ROAD SAFETY PERCEPTION: GENDER DIFFERENCES – MONTENEGRO CASE STUDY

Mirjana Grdinić[1], Vladimir Pajković[2]
[1,2] University of Montenegro, Faculty of Mechanical Engineering, Podgorica, Montenegro

Abstract: Differences between male and female drivers in terms of crash rates are evident in a wide range of countries. Usually males were those who significantly being more at risk than females. A surveys show that females are more compliant with traffic regulations and that males are less concerned about road safety issues. In addition, males attach less importance to risky behaviours and consider accidents a less serious problem than do females. This research, conducted among young adult drivers and non-drivers in Montenegro, presents difference in males and females perception of road safety problems and risky behaviors.

Keywords: road safety perception, young adults, male drivers, female drivers, non-drivers.

1. Introduction

Road traffic accidents have become a major public health concern in both developed and developing countries. Driving safety has become a priority issue in developing countries in view of the increasing motorization levels (Akaateba and Amoh-Gyimah, 2013). Driving safety is affected by various factors, which together determine the level of traffic safety or risk. Several studies have suggested that the human factor plays an important role in road accidents. The influence of socio-demographic variables such as gender, age, educational levels and personality variables on driver behaviour has been widely established by several studies in high income countries. The Attitudes report produced in Spain highlights the fact that approximately 90% of the accidents are due to human factors such as unsafe driving, personality traits and attitudes (Gonzales-Iglesias et al., 2012). In addition, greater focus should be on driver attitudes and behaviour towards traffic safety. In most of the counties, including Montenegro, traffic safety campaigns have focused exclusively on the entire population with few or no targeted campaigns at specific groups of drivers. Therefore, identifying the gender and age differences in driver attitudes towards traffic regulations and traffic violations will provide relevant information towards more target-specific and effective road safety campaigns in the country.

2. Gender differences

Females and males have some differences in driving behavior and attitudes that affect their safety and crash experience. Differences between male and female drivers in terms of crash rates are evident, with males being significantly more at risk than females (SIRC, 2014). Male drivers account for about 65% of total passenger vehicle kilometers travelled and women account for only 35% (Ginpil and Attewell, 1994). This reflects both the fact that males are more likely to have a driver’s license and that, on average, male drivers travel more each year. The probability of being injured in traffic accident is 25% higher of man than that of women (Degraeve et al., 2015). On average, male car drivers are about 46% more likely to be involved in a fatal crash per distance travelled (Ginpil and Attewell, 1994). In Sweden, males were involved in 1.9 more injury crashes per 1000 licensed drivers than female drivers during the first year of licensed driving. In France, women have 2.5 times fewer points removed from their driving license, and are convicted 6.2 times less often for offenses (Degraeve et al., 2015).
According to the literature, males in general take more risk on the road, commit more driving violations, they are involved in more motor vehicle crashes than females and they are less concerned about road safety issues. In addition, males attach less importance to risky behaviours and consider accidents a less serious problem than do females (Gonzales-Iglesias et al., 2012). In contrast, female drivers drove less than males and evaluated their driving skill lower. Female drivers were less involved in accidents and they committed less traffic offenses than males. Female drivers showed a more positive attitude toward traffic safety and rules than males. This gender difference is most marked in the population under the age of 24 years, but is also evident among older drivers (SIRC, 2014).

2.1. Crash differences caused by male and female drivers

According to Ginpil and Attewell (1994), many of the differences reflect contrasting travel patterns. For example, female driver crashes are relatively more likely to occur during daytime and on weekdays. Men are more frequently involved in accidents related to traffic rule violation, however, fatal crashes caused by female drivers were much less likely to have involved drink driving or speeding. In 37% of fatal crashes caused by male car drivers, alcohol intoxication of the driver responsible for the crash was considered to be a contributing factor. The corresponding percentage for females was only 16%. Younger male drivers were more likely to be involved in single-vehicle and fatal head-on crashes while female drivers were more likely to involve in left-and right-hand crashes. Younger female drivers were more likely to be involved in fatal rear-end crashes compared to younger male drivers. Amarasingha and Dissanayake (2014) showed that approximately 30.5% of young female drivers had restrictions on their driver licenses at the time of crash. A majority of young drivers involved in crashes held valid driver licenses. About 4.0% of young

[1] Corresponding author: grdinicm@ac.me

female drivers and about 5.7% of young male drivers were not wearing seat belts at the time of the crash. Approximately 5.9% of young male drivers were under the influence of alcohol at the time of the crash. Also, about 24.7% of young-female-driver-involved crashes and 31.8% of young male driver involved crashes occurred in dark conditions. Mentioned survey also showed that holding a valid license, driving during weekends, crash avoidance, attempting to stop or back, involving non-collision overturn crashes, collision with a pedestrian, and involving head-on crashes were variables that were significant in the female model but not in the male model. Travel on unleveled roadways, travel with passengers, travel on concrete surfaces, travel on wet road surfaces, collision with a vehicle, and rear end collision were the variables that were significant in the male model but not in the female model. There were no differences in terms of the number of passengers carried by cars driven by male or female drivers, but women between the ages of 25 and 39 were most likely to have had young children in the car at the time of the crash. It has been suggested that many crashes involving women may be caused by inattention due to passenger distraction, especially with respect to young children. However, passenger distraction was the cause of only 2% of fatal crashes caused by car drivers with at least one passenger and there was no difference in the incidence of this causal factor for male and female car drivers.

Despite of all, women are still considered as being poor drivers. Many stereotypes of women drivers are still effective. Studies have shown that negative beliefs associated with women drivers could lead to an impairment of their driving performances. Analysis of how individuals perceive men and women drivers may be useful for apprehending and understanding the various speculations and discussion in this area (Degraeve et al., 2015). Women are usually perceived as drivers with high accident rates, which appear to be related to their poor vehicle control and the mismatch between the driving activity and the feminine role in society. In contrast, men are perceived as drivers who are skilled while being careless and committing offenses. In study results, this good driving quality goes hand-in-hand with the good match between the driving activity and the masculine role in society (Granie and Papafava, 2011).

3. Male and female perception

In literature, great effort is putting to portray a psychological understanding of driver behaviour and perceived risk, so several studies were conducted in order to address this issue. Opinions, beliefs and behavioral intentions of different groups of users regarding matters of road safety are a source of relevant information, since they reveal characteristics of their attitudes in relation to mobility and safety, their relations with other users, their experiences and their concerns. Many researches recognized differences according to age and gender. The basis for these differences according to gender may be due to neurochemical structure of humans, hormonal process, global socialization practices, and many others. Several studies were conducted in order to address the issue of drivers perceptions. “Road safety – Analytical report” is survey conducted in June 2010 by The Gallup Organization, Hungary, upon the request of Directorate-General Mobility and Transport, (Gallup, 2010). The research projects like this attempt to understand how individual drivers rate the driving within their country. Another alike project, the SARTRE – Social attitudes to Road Traffic Risk in Europe, (SARTRE 4, 2012) includes several of studies of attitudes conducted in European countries since 1993. Those surveys investigate and compare between countries road safety variables, attitudes, behaviors and support for safety countermeasures.

In Montenegro, a study was conducted during 2014–2015 (Pajkovic and Grdinic, 2014) in order to address the issue of drivers and non-drivers road safety perceptions. Survey questions were based initially on the questionnaire derived by Gallup Organization. The first survey approach was face-to-face questionnaires. These forms were handed out randomly in several locations in couple larger towns, Podgorica and Bijelo Polje, such as apartment’s complexes, supermarkets, and train and bus stations. Additionally, an online survey named *Road safety perception in Montenegro*, was constructed and implemented using GoogleDrive software and its URL was sent to students at University of Montenegro and was posted on Facebook asking young drivers/non-drivers who live in Montenegro to participate. There was a function within the GoogleDrive software that prevented participants from repeating the survey several times. Total number of respondents was 327, with 75% males and 25% females, between 18 and 45 years old: 85.63% of those were drivers (79.29% males and 20.71% females). Car drivers and non-drivers responses are presented focusing on differences between genders.

Firstly, frequency that respondents drive a car was investigated. As expected, larger number of those that drive a car most days were man: more than half respondents (55%), in contrast to 25% female. One in ten male respondents said that they did not drive a car; while almost third of female respondents answered they are not drivers, (Fig. 1).

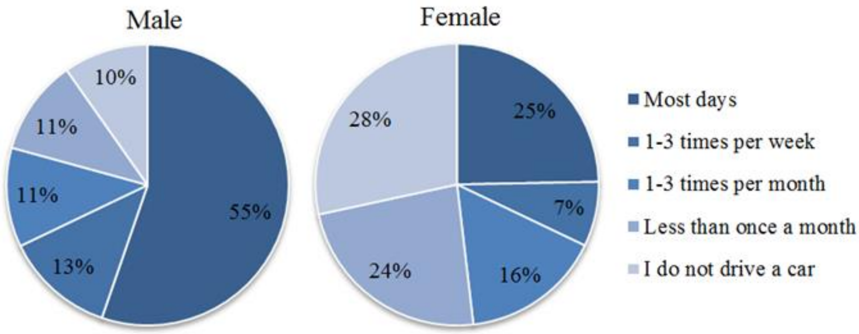

Fig. 1.
Frequency that respondents drive a car

In order to define general attitudes to road safety in matter of gender of respondants, all interviewees were asked to give opinions on if roads in Montenegro are safe, fairly safe, fairly unsafe or unsafe.

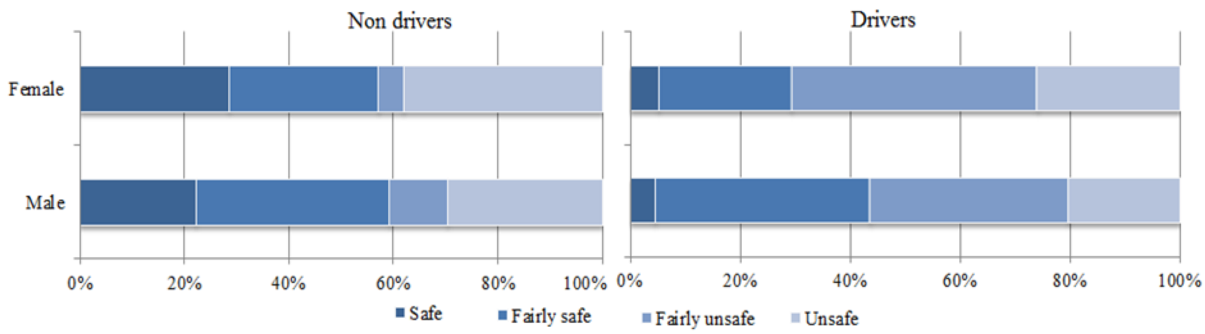

Fig. 2.
General attitudes about road safety in Montenegro

There is a small difference between those respondents who drive and those who aren't. About 25% of non-drivers (male and female) described road safety as safe, while only about 5% of drivers respondents both gender have the same answer. They usually described road safety as fairly unsafe (36% of males and 45% of females) and fairly safe (40% males and 25% females), with small difference between males and females answers. Overall, 60% of male and female non-drivers described the roads as safe or fairly safe, 10% higher than from those who describe as fairly unsafe or unsafe. When drivers are respondents, this proportion has some differences. While 45% of male drivers described road safety as safe and fairly safe and 55% described it as fairly unsafe and unsafe; only 30% of female drivers respondents described it as safe and fairly safe, in contrast to 70% of those who described it as fairly unsafe and unsafe. Based on the calculated average values of the survey respondents, the roads in Montenegro are considered as more or less dangerous, (Fig. 2).
Interviewees were asked about five potential road safety problems: for each one, they were requested to say if it was perceived as a problem and if so, whether it constituted a major or minor safety issue. Both male and female, whether been drivers or not, perceived the issue of people driving under the influence of alcohol to be the major safety problem (about 70% in every category). There is a small difference in answers between drivers and non-drivers that alcohol is a minor problem, where 15% of non-drivers perceive it as minor problem in contrast to almost 25% of drivers (males and females). 5% of female drivers perceive driving after drinking alcohol as not a problem, in addition, about 12% of males (drivers and non-drivers) seeing it as not a road safety problem. Speeding was regarded as the second most important issue. About 60% of all respondents recognized exceeding speed limits as major problem in the country, with small or no differences between males and females answers, or drivers and non-drivers. 25% of female drivers and 35% of female non-drivers perceived speeding as minor problem, while 30% of male drivers and 25 of male non-drivers perceived a same. Average 10% of all said it was not a problem. About 30% of male and female seeing not respecting traffic regulation as major problem, with mentioning only 16% of male non-drivers whose perceived it a same thing. There is a small difference between drivers and non-drivers in answering a question how they perceive when drivers or passengers not wearing seatbelt. About 20% of non-drivers (20% males and 18% females) perceived it as major problem, in contrast with about 15% of drivers (14% males and 16% females). About 75% of non-drivers (73% males and 82% females) perceived mentioned problem as minor problem, in contrast to about 50% (47% males and 57% females) drivers. There are some differences according to males and females attitudes about using mobile phone while driving. Many answers were that this is minor road safety problem, however 23% of male drivers and 12% of female drivers perceived this problem as not a road safety problem. In addition, almost half of female non-drivers (45%) and quarter of female drivers perceived it as not a problem, (Fig. 3).

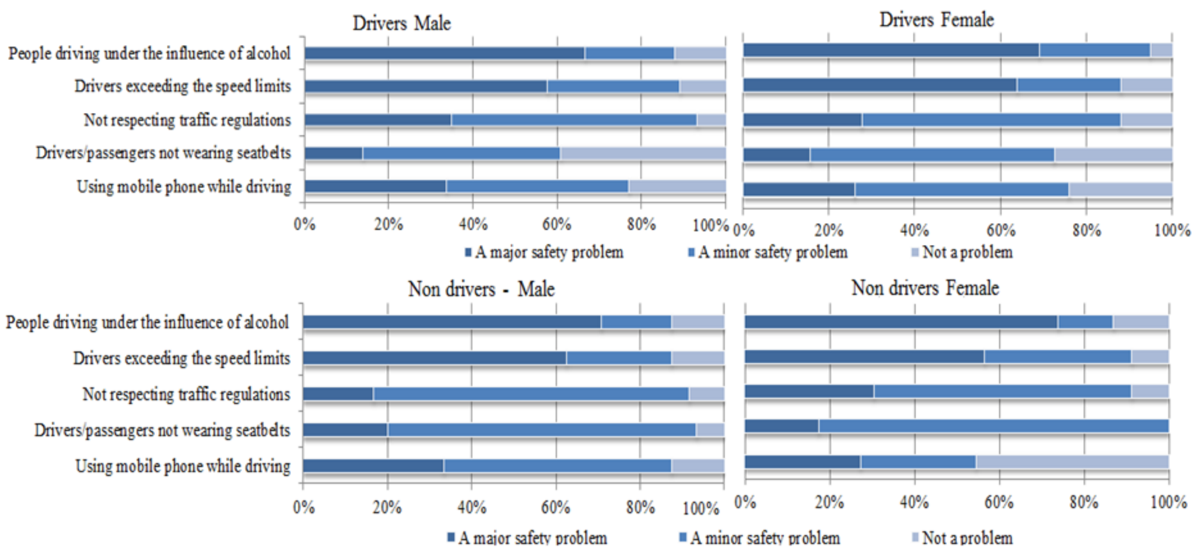

Fig. 3.
Perceptions about the seriousness of road safety problems: non-drivers and drivers

Interwieevers were asked of measures that could help to improve road safety situation. Most of the respondents agreed that first thing that government should do is to improve road infrastructure, which is at very low level, (Fig. 4). There is a slight difference between male and female attitude about increasing traffic monitoring. 17% of females non-drivers would apply this measure, in contrast to 8% of males. With drivers, there is opposite proportion: slightly larger number of males (13%) than females (10%) voted for this measure. Strict penalties are recognized as best measure by non-drivers, 36% of males and 26% of females. However, only about 10% of drivers, both males and females, would approve this measure. Road safety campaigns are last recognized measure by both genders, male and female, while pre-licensing was recognized by female drivers as measure which could help to improve road safety in Montenegro.

In folowing, interwieevers were asked about what government should do about listed measures for younger drivers. Possibilities were to give positive (yes) or negative (no) answer for introducing those measures in domestic law enforcement. Results are graphically presented in Fig. 5. Some differences between male and female answer can be noticed. Analyzing both, drivers and non-drivers, females are stricter according to every measure. Over 80% of female non-drivers approved zero-alcohol measure for young drivers, in contrast with 50% of males. Almost 30% female non-drivers would restrict driving from 23AM to 6PM for this category of drivers. Large gap between male and female attitude is related to limiting speed for young drivers. About 30% of male non-drivers would introduce this measure, in contrast to almost 90% of female non-drivers. Limiting power of vehicle which young drivers use, 30% of female non-drivers find as positive for road safety. In addition, only 10% of male non-drivers would apply this measure. Analyzing drivers answers, there are same conclusions for almost every measures except for limiting power of vehicle. Male drivers were stricter according to it, with above 50% of positive answers, in contrast to 35% of positive female answers. There is no difference between drivers and non-drivers answers, except for mentioned measure for young drivers, limiting power of vehicle, where female non-drivers doesn't see it as large problem and they are mostly against it.

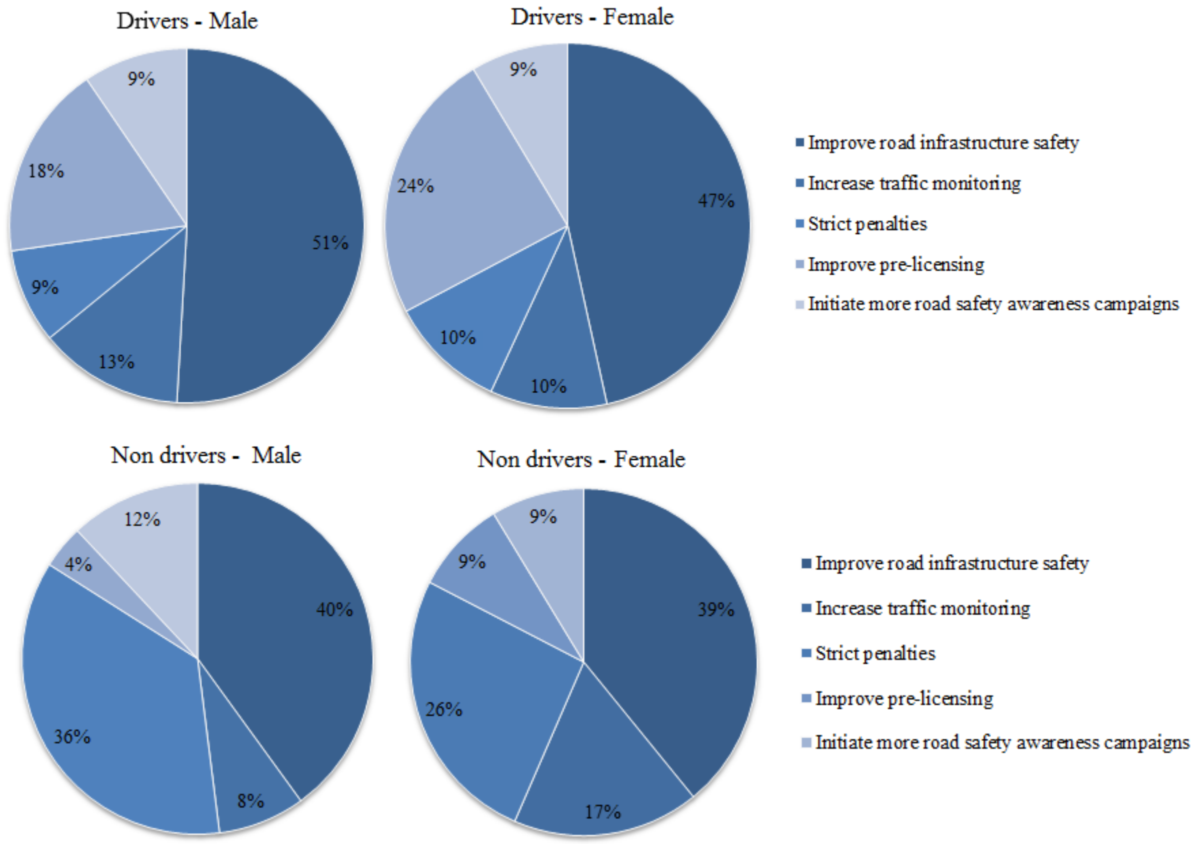

Fig. 4.
Measures to improve road safety

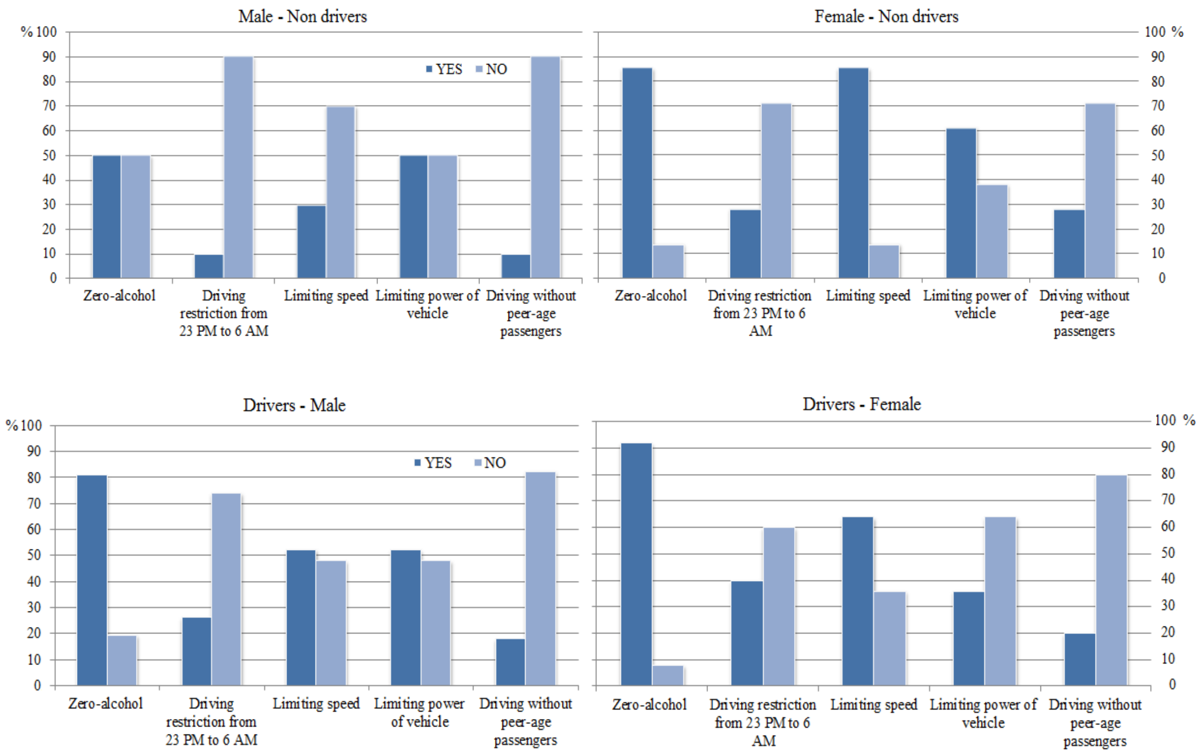

Fig. 5.
Measures for young drivers

4. Conclusion

There appear to be important differences between male and female drivers in terms of travel behaviour, crash characteristics and injury outcome. According to the literature, males in general take more risk on the road, commit more driving violations, receive more traffic citations, and are involved in more motor vehicle crashes than females. Men are perceived as having a higher crash risks than women, whereas women are perceived as having poorer driving skills. This seems to suggest that accidents caused by women are more linked to an inability to adopt the right behavior rather than a lack of caution. Also, there is some differences between male and female opinion of road safety problems. Female, drivers and non-drivers, have stricter opinion according to road safety problem an measures that should be implemented to increase a level of road safety.

HARMONIZATION OF PROCEDURES OF ROAD SAFETY INSPECTION IN ITALY AND POLAND

Salvatore Cafiso[1], Mariusz Kiec[2], Giuseppina Pappalardo[3], Fabrizia Trovato[4]
[1,3,4] Department of Civil Engineering and Architecture, Via S. Sofia 64, Catania 95123, Italy

Abstract: Even if, the European Directive 2008/96/CE gives great emphasis to road Safety Inspections (SIs) as an effective tool for safety management of existing roads, relevant issues remain in the use of SIs as source of information to prioritize measures and treatment sections with the highest safety benefit-cost ratio. In the framework of the IASP research program co-financed by the European Commission in the 2007, an inspection procedure aimed at improving the effectiveness and the reliability of the methodology has been defined and a Risk Index (RI) is calculated as a surrogate measure of safety. After the first implementation in the IASP project, further developments were carried out to improve the quality and efficiency of the safety inspections of road network by using low cost equipment (GPS, Tablet, Camera) and specific software tools to support the inspectors' task. The paper shows how the procedure, developed according to the Italian practice, was adapted to comply with the checklists and evaluation criteria of the Polish guidelines. Methods for conducting Road Safety Inspections (SIs) in Italy and Poland are described and compared. The different hazard categories of the two procedures were harmonized to an equivalent risk score taking into account also the regional crash type distribution. Finally, experimental application on about 100 km of road network in both countries shows the applicability of the procedure and gave the opportunity for a comparison of frequency and severity of safety issues in Italian and Polish two lane rural roads.

Keywords: road safety inspection, low cost equipment, Polish guidelines, two lane rural roads.

1. Introduction

The European Directive 2008/96/CE requires the member states to establish and implement procedures oriented on improvement of the existing network, namely: road safety impact assessments (i.e. evaluation of the projects of new investments regarding efficiency of road safety improvements), road safety audits (evaluation of road designs regarding traffic safety), the management of road network safety, and Road Safety Inspections (SIs; the management and security of existing roads in order to identify the road safety related features and prevent accidents). In the aforementioned Directive, great emphasis is given to road SIs as an effective tool for the safety management of existing roads stating: "Once road sections with a high accident concentration have been treated and remedial measures have been taken, safety inspections as a preventive measure should assume a more important role. Regular inspections are an essential tool for preventing possible dangers for all road users, including vulnerable users". Within the Article 6 of the "Safety Inspections" it is also recognized that member states shall carry out safety inspections on existing roads in order to identify the features related to road safety and to prevent collisions and accidents. The use of SIs is one of the measures to improve traffic safety in Europe associated with the assessment of the accident risk on the existing elements of road infrastructure. SIs can be a source of information needed to prioritize treatments in road sections which produce the highest accident reduction and/or the highest safety' benefit-cost ratio. The inspections should be performed periodically and by a competent entity. Member states are also encouraged to apply this directive on other national roads, which are not part of the Trans – European Road Network (TEN).
The aims of the study presented in the paper are the comparison and harmonization of Italian and Polish SIs procedures, the implementation of the Italian experience in conducting the SIs in Poland, and improving the efficiency of the periodic inspections using low cost equipment. Poland has already implemented road safety audit and road safety impact assessments and it is in the way of implementation of the SIs on national roads. Unfortunately, guidelines for carrying out road safety inspections (Budzyński et al., 2013), implemented in Poland by GDDKiA in 2014, do not allow quantification of the accident risk basing on the conducted SIs. Such a possibility is introduced in a method developed in Italy and described in "Identification of Hazard Locations and Ranking of Measures to Improve Safety on Local Rural Roads" (IASP) (Cafiso et al., 2008), in conjunction with Risk Index (RI) (Cafiso et al., 2007) used to predict frequency and severity of accidents when using SIs.
In order to describe problems this paper is divided into 3 main sections presenting:

- IASP procedure for road safety inspection;
- Harmonization of the Italian and Polish guidelines;
- Comparison of frequency and severity of safety issues in Italian and Polish two lane rural roads.

2. IASP Procedure for road safety inspection

The IASP project (Cafiso et al., 2008) was funded by European Commission (DG TREN) and Province of Catania (Italy) with the scientific coordination of the University of Catania. As part of the project, safety inspections procedures, which address rural two-lane highways, have been defined. Albeit many safety inspection procedures already exist, the IASP procedures present some innovative elements and, above all, they are very operational in nature.

[2] Corresponding author: mkiec@pk.edu.pl

IASP procedure is one of the twenty-one models or approaches to road safety management reviewed and assessed by TRL in a recent Project Report PPR770 (TRL, 2015). After comparison, it was selected as one of the six most promising models that should be tested in UK, with iRAP Star Rating, NetRisk, SURE, iRAP Risk Mapping, North Yorkshire Route Assessment Tool. The six models were chosen based on the scores they obtained from the review process and also the impression of how cost-effective they might be given the lack of good evaluation.
The IASP safety inspection can interest in one day about 50 km of road. At least three operators are needed: the driver, the inspector in front seat and the inspector in back seat. Recommended equipment are GPS receiver, digital video camera and checklists. The road is running in both directions at very low speed (about 30 km/h). Checklists are aimed at ensuring that important safety problems are not overlooked. Checklists are a prompt and not a substitute for knowledge and experience, that is, checklists should aid using safety engineering experience and judgment.
IASP checklists are very synthetic (Cafiso et al. 2008), since they relate only to the main safety features which usually are present along two lane rural roads. Moreover, only features which are easily detectable during inspections have been inserted. Features which concern horizontal and vertical alignment (geometric alignment, design consistency, etc.) are not considered since in the IASP safety analysis alignment evaluation is performed as a separate quantitative procedure.
Checklists must be filled in both directions. Front seat and back seat inspectors, which have different views of the road, compile different checklists filling the boxes with a step of 200 m (24 s at 30 km/h). In order to simplify the inspectors' task, any checklist is split in two parts: part A has to be compiled on site, part B can be compiled both on site and during the video examination performed in the office.
In order to get an easy and low cost solution to simplify the inspectors' work, it was decided to build an Android application. By means of an easy-to-use interface the application allows the user to insert inspection data for each section of the road using own tablet. To improve accuracy in vehicle positioning, an external GPS receiver can be connected with Android application running on the tablet. Finally, to associate also images of the road space, frames recorded by a video-camera installed on the vehicle can be geo-referenced and linked to the inspection data through a system of synchronization based on the GPS UTC time used as a metronome for all devices. The architecture and organization of the system is shown in Figure 1. More information about this system are available in Cafiso et al., 2014.

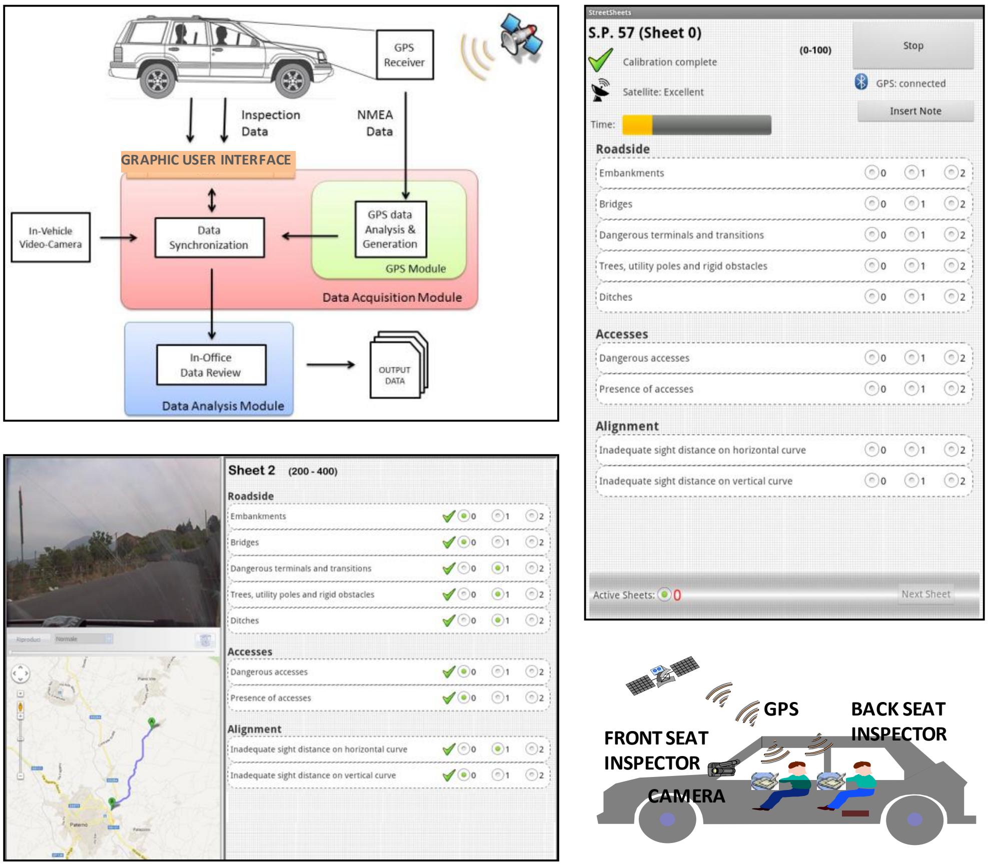

Fig. 1.
Architecture and organization of the system

In the IASP procedure, safety issues are ranked as:
- high score problem (rank 2),
- low score problem (rank 1),
- no problem (rank 0).

Ranking of safety issues can be used both as an aid for the prioritization of the safety measures and as an aid to road agencies in measuring the effectiveness over time of their safety improvement programs. After the preliminary

inspection, in the office, the team analyzes videos and (if wasn't done on site) complete part B of the checklists. Checklists are compiled in both directions referring in particular to the right side. By brainstorming among the team member checklist results are examined and the final version of the checklists is edited.
The IASP manual (Cafiso et al., 2008) suggests for each problem the recommendation typologies. Recommendations are engineering solutions to the reported problems. They indicate the type of measures, without specifying detailed technical issues. Problems and recommendations are disaggregated in order to highlight the safety issues of each road feature, but road safety improvement requires an integrated approach where interaction among different measures must be taken into account, as well. As final result of the meeting, a preliminary report describing general problems and recommendations is edited. Moreover, some sites requiring further specific inspection (site visits) might be identified.

3. Harmonization of the Italian and Polish guidelines

As defined in the Polish guidelines (Budzyński et al., 2013), the road safety inspections are carried out using three type of controls, General inspection, Detail inspection and Special inspection during the night and in road works.
General inspection applies to the national road network, are regulars and periodic and are performed during daylight hours inspecting the elements located along the road (roadway and roadside) and assessing their impact on road safety in order to allow an efficient and effective action of maintenance and planning of investment work consistent with the existing system of road maintenance in Poland. Detailed inspections consists in a specific control of sections or points where there is a concentration of accidents identified during the risk classification, or the results of the general inspections, during which you have identified a very high average risks of serious accidents (fatalities and serious injuries). Specials inspections by night and in road works are the analysis of the perception of road in the absence of natural light to verify that the road works are carried out properly organized and protected from the point of view of road safety, including the organization of the traffic in the work area and protection for all road users. Polish guidelines gives specific checklists for carrying out these controls, in which issues found along the road are grouped in characteristics of the road, elements of surrounding roads, marking, road safety and characteristics of traffic. These checklists are available for all Polish roads, without the creation of specific checklist for some class.
Polish checklists are formed by a high number of issues, that do not allow an easy filling out of sheets during the continuous analysis. Safety inspections are usually carried out manually without support of electronical devices.
This study focuses only on the checklists for General inspection than can be filled by two inspectors running the road with a vehicle instrumented with simple and low cost equipment (GPS, video camera, tablets). To this aim two separated checklists are taken into account: one for the front seat inspector and one for the rear seat inspector, with respectively 33 and 27 issues.
For this reason, the goal of the comparison between Polish guidelines and IASP procedures, has been to find a common checklist, synthetic and complete, that it could be adopted both in Poland and in Italy. Through a taxonomic approach, it has been observed that a lot of fields in the Polish checklist could be joined in existent Italian fields, while issues, that hadn't any correspondence, have been added in a new common checklist. The fields related problems at intersections are grouped in separate checklists, while issues that aren't present in two lane rural roads, have been excluded.
It is possible to see that there are some many correspondences with Italian issues, that have allowed us to create, based to the Italian module, a new checklist that can be compiled, during a continuous analysis, in a sufficient amount of time for sections of 200 m of length at a speed of 30 km/h. This new checklists, reduced in comparison to the original Polish checklist, for front seat inspector and for back seat inspector are shown in Figure 2.

Fig. 2.
Checklist ITA_PL for General Inspection (a): for Front Seat Inspector; (b) for Back Seat Inspector (I: Italian item; P:Polish item)

In Poland, each issues identified during the inspection should be initially classified as defects to be removed immediately and defects that are candidate for long term interventions. The defects should be evaluated and qualified within four risk categories:

- Class A – small,
- Class B – medium,
- Class C – large,
- Class D – very large.

Class D defects should be corrected as soon as possible. Pending the correction or repairs may need temporary protection. Defects in this class can cause serious consequences of road accidents, hence the need for a rapid intervention. Defects of Class B and C should be removed as part of maintenance and modernization in function of priority depending on the degree of irregularity, traffic volume and characteristics of the place. Defects of Class A are malfunctions to remove as part of the regular maintenance. In the checklist fields it is possible to give a score for each issues 0, 1, 2 in function of the severity of the problem found along the road (0: no problem, 1: medium score, 2: high score problem), complying with the rules explained in the IASP manual [6].
In a previous work (Cafiso et al. 2014) it was proposed a harmonization between Italy and Poland of the score in terms of equivalent safety risk (Figure 3). The interested reader may refer to Cafiso et al. (2014) for a more detailed discussion on the harmonization procedure.

		Polish risk category																	
Safety issue		Embankments	Bridges	Dangerous terminals and transitions	Trees, utility poles and rigid obstacles	Ditches	Inadequate sight distance on horizontal curve	Inadequate sight distance on vertical curve	Dangerous accesses	Presence of accesses	Lane width	Shoulder width	Friction	Unevenness	Chevron	Guideposts and barrier reflectors	Edge lanes	Center lines	Warning signs, regulation signs

Fig. 3.
Comparison of IASP severity score and Polish risk categories

4. Case study: RSI in Italy and Poland with IASP procedure

In Italy, the inspections were conducted on 18 sections of the two lane rural roads along a length of 207 km while in Poland, the inspections were conducted on 7 sections of the regional roads in Malopolska with a length of 184 km, of which 98 km were rural sections and therefore were included in the study. Other sections, passing through built-up areas, with a length of 86 km were not included in the study.
To compare the two national samples, the frequency distribution of safety issues is reported for each severity score in Italy and Poland. In the following details about the score classification and results of comparison are reported.
Figure 4 shows the results regarding embankments and terminal and transitions. For example, an embankment section is classified at high problem if at least one of the following conditions is present:
more than 5 m unshielded or shielded with ineffective barriers, or more than 3 m and steep slopes unshielded or shielded with ineffective barriers, or more than 3 m and steep slopes shielded by low containment safety barriers.
The situation in which it is advisable to report a high score problem with dangerous terminal and transitions are roadside and bridge barriers with no breakaway terminals, terminals buried in the ground, roadside barriers not connected, roadside and bridge barriers connected without transitions. In Poland the frequency of highest risk score “2” for these issues is much higher than Italy (17.9% and 20,3% respectively higher in Poland).

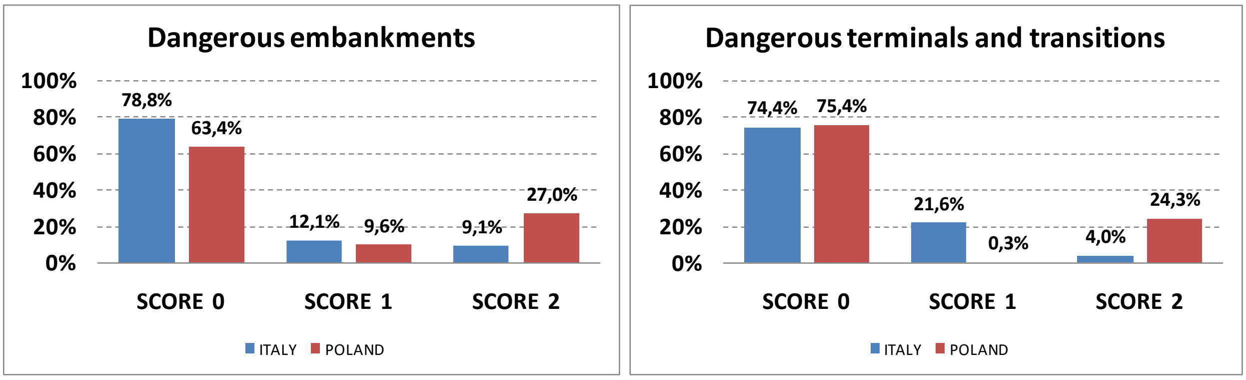

Fig. 4.
Frequency distribution for embankments and terminal and transitions scores in Italy and Poland

Fig. 5.
Poland: dangerous embankments

The situation in which it is advisable to report a high level problem with trees, poles and other obstacles are:

- high diameter trees/poles and concrete utility poles less than 3 m from the roadway;
- rows of trees;
- rigid obstacles with exposed front face or corner less than 3 m from the roadway.

Again, in Poland percentage of trees, utility poles and rigid obstacles with a high score problem (score 2) is higher (+24%) than in Italy (Figure 6).

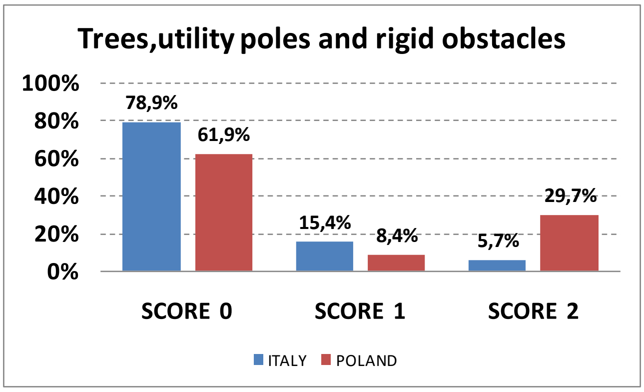

Fig. 6.
Frequency distribution for trees, utility poles and rigid obstacles scores in Italy and Poland

Fig. 7.
Poland: rows of trees

An access is classified at high score problem if located on horizontal curves, on crest curves, on site with poor visibility, close to less than 30 m from the intersections. Low score problems are narrow, not signalized with road markings or delineators, unpaved driveways. In Poland percentage of dangerous access with a high (score 2) and low (score 1) problem are higher than in Italy (Figure 8).

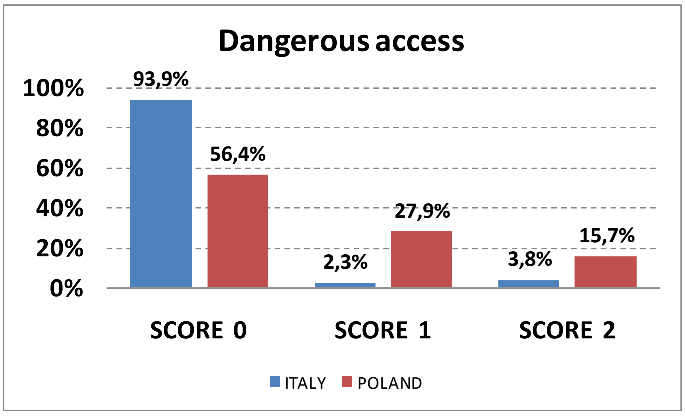

Fig. 8.
Frequency distribution for dangerous access scores in Italy and Poland

Fig. 9.
Poland: unpaved access

A high score problem of inadequate sight distance is:

- for on horizontal curves, less than 50 m due to the presence of obstacles along the whole inside of the curve;
- for vertical curves, less than 50 m due to the presence of a crest.

For these issues (Figure 10), in Poland the percentages are higher than Italy (+14,7% for horizontal and +8,1% for vertical sight distance).

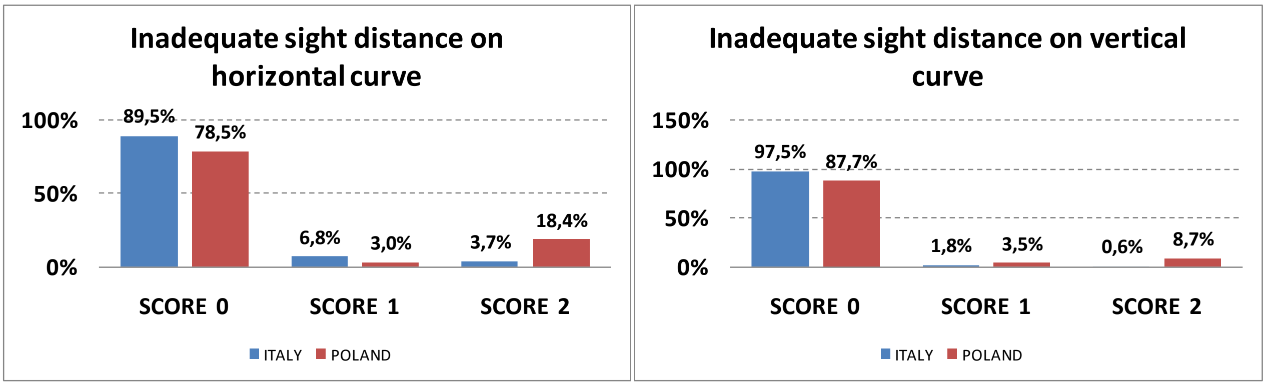

Fig. 10.
Frequency distribution for inadequate sight distance on horizontal and vertical curve scores in Italy and Poland

Fig. 11.
Poland: inadequate sight distance on horizontal curve

For edge lines, the situations in which it is advisable to report a high score problem are missing or very faded edge lines; for centre line, these situations are missing or very faced centre lines and discontinuous line with no overtaking sight distance. Unlike the other cases, in Italy the percentages for high score problem are higher than Poland (+47.4% for edge lines and +62.4% for centre lines more in Italy) (Figure 12).

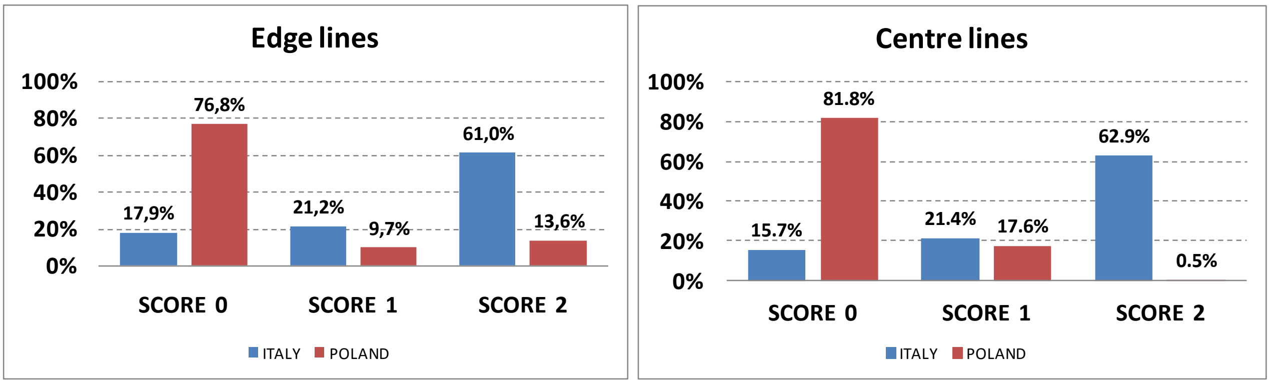

Fig. 12.
Frequency distribution for edge and centre lines scores in Italy and Poland

Finally, for cross section, the checklist for road safety inspections considers lane width and shoulder width, as well. A lane width of less than 2,75 m has to be classified as a high score problem, as well as a lane width more than 4,50 m. There is a low problem if the width is between 2,75 m and 3,25 m.
A shoulder width of less than 0,30 m is considered as a high score problem, while a width of between 0,30 m and 1,00 m is a low score problem. In Poland, the percentage of lane width at low score is higher than Italy (67,5%) while there is a higher percentage of shoulder width is high score (98,1%) (Figure 13).

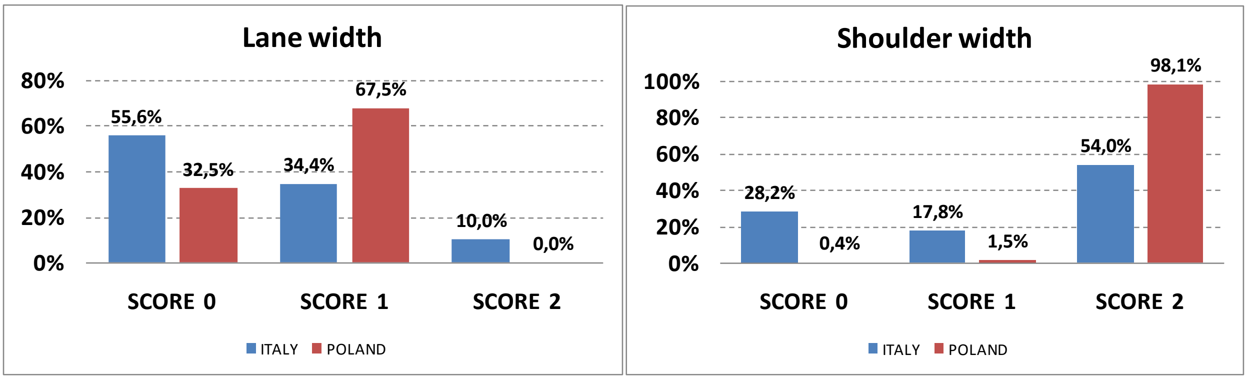

Fig. 13.
Frequency distribution for lane and shoulder width scores in Italy and Poland

Fig. 14.
Poland: inadequate shoulder width

The Chi-Square test of independence was further used to check the statistical significance of the differences in the proportions between the two samples. Results reported in table 1 figure out that all the previous differences between the proportion of score 2 safety issues, are significant, as well.

Table 1
Chi-Square test for comparison of Italian and Polish safety issues at score 2

5. Conclusion

Based on the conducted comparison and analysis of the results of the road safety inspection performed on regional roads in Poland and Italy it can be concluded that:

- The results (in Italy and Poland) are promising for the international transferability of the IASP Safety Inspections procedures and tools.
- It is possible to apply the IASP method and equipment to carry out Safety Inspections in Poland, which would comply with the Polish guidelines.
- To ensure efficiency of the Safety Inspections, it is necessary to limit the number of issues and classes of risk in Polish checklist, which should be identified during the inspection. To this aim, checklist developed in the present paper could be considered.
- The proposed procedure and tools can improve effectiveness of the Safety Inspections process and its usability in Poland and Italy, as well.
- From the point of view of road network features and management, limiting the discussion to the two samples of roads in Italy and Poland, results pointed out as the lack of maintenance for marking and sign are more relevant on Italian roads, Polish rural roads are more effected by structural deficiencies related to roadside protection, alignment and cross section.

SESSION 12: ROADS: PLANNING, DESIGN AND CONSTRUCTION ISSUES

RURAL ARTERIAL ROAD PLANNING AND DESIGN STEPS

Müge Özgenel[1]
[1] *Department of Highway Project Design - BOTEK Bosphorus Technical Consulting Corp., Turkey*

Abstract: This paper highlights road design stages for low volume roads in Turkey. Starting from tendering procedures (e.g. General Directorate of Highways) brief explanations regarding planning, design with supporting information of transportation design criteria. In Section 1, tendering and proposal preparation stage is explained. Following this section; in section 2 design of the alignment and important considerations given in detail. In Section 3, roles and usage of surveying, catchment basin, geological and geotechnical issues are explained. In Section 4, design of intersections / interchange and engineering structures along with their link to the alignment are explained. Landscaping, drainage and traffic project design briefly explained in Section 5. And finally in Section 6, project delivery documents are given and explanations are made just before work completion is made.

Keywords: low volume road, Turkey, General Directorate of Highways.

1. Tendering and proposal preparation

In this article starting from Rural Arterial Road Project tendering stage, preliminary design, final project stages of Malkara-Hayrabolu-Alpullu-D100 State Road in Turkey is explained. Malkara-Hayrabolu-Alpullu-D100 State Road is approximately 72 kilometer in length, starting from Malkara on Tekirdağ-Çanakkale D110 State Road, passing near Hayrabolu and Alpullu and connecting to Lüleburgaz-Babaeski D100 State Road.

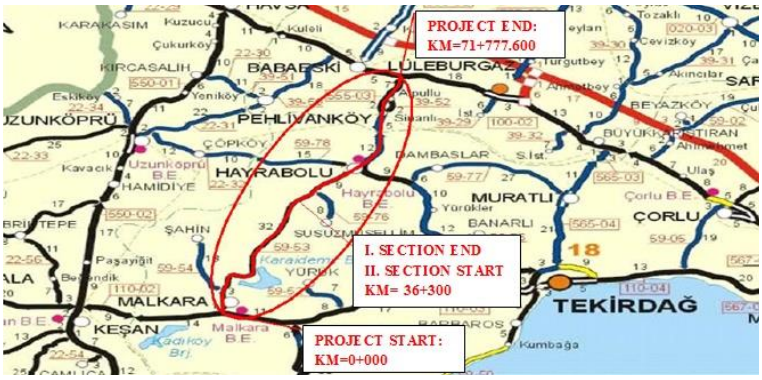

Fig. 1.
Project area

1.1. Tendering

Projects announced by General Directorate of Highways (GDH), starts with a call for tender and publishing the required documents and interested companies apply to purchase tender documents.

1.2. Expression of interest

Initially at the first stage, an expression of interest phase take place for the companies who are willing to participate and win the project. In this Expression of Interest Stage following information are required for the company wishing to participate:

- Company information, Trade Registry Gazette, ISO Certificate, Company Turnover, Letter of Application, Relevant Experiences, Offered Staff List and CV's.

Purpose of the EOI stage is to identify the companies willing to enter the tendering stage and control if the company satisfies the conditions of the GDH and have the capability to carry out project activities.
Required documents in a dossier is delievered to the Client, before or on the date and the hour stated in the tender notice.
As EOI stage finalizes and results come out, companies are invited for the proposal stage.

[1] Corresponding author: muge.ozgenel@botek.info

1.3. Tender preparation

Companies invited for the tender submit their Technical and Financial Offers on seperate envolopes and finally wrapped all together in a single package based on; Administrative Specifications, Technical Specifications, Plan and Unit Price Tables (If the Tender is according to Unit Price) or Lump Sum Rate Letter of Tender.

For Malkara-Hayrabolu-Alpullu-D100 Road the Financial Offer is on Lump Sum Rate.

Technical Offer consists of:

- General information of the region (population, climate, seismicity, cultural, touristic aspects)
- 1/25000 scaled plan and profiles and explanations
- Field visit report
- Geological report along the alignment
- Proposed staff list, CV's, diplommas, social insurance contribution indications
- Related references and work completion certificate.

Financial Offer consists of:

- If the proposal is according to Unit Price; every service is given in unit price, additionally a financial proposal letter is also presented.
- If the proposal is according to Lump Sum; a Lump Sum Rate Letter of Tender is submitted.

Proposal is delivered to the Client, before or on the date and hour stated in the tender notice.

In the evaluation stage, initally Technical and afterwords Financial Proposal Envolopes is opened. The company which gets the highest score from overall Technical and Financial Proposal entitled to win the tender, inorder to accept the project and sign the contract meet with the Client on the date and hour stated to the company with a letter after the announcement of the results.

The winner company start the studies with the guidance of the Specifications given by the GDH to the Selected Companies to carry out the project in appropriate standards.

The standards found within the project cd which was presented to the interested companies at the tendering stage are:

- Highways Final and Preliminary Design Engineering Services Technical Specification
- Investigation Engineering Services Technical Specification
- Highway Flexible Pavement Design Manuel
- Highway Tunnel As Built Project (Final Design) Technical Specification
- Technical Specification Consisting of Detail and Feature Catalogue, National Data Exchange Format, Map Particular Signs and Classes, Point, Facility, Plan, Chart, Canvas, Sheet and Sheet Classification Examples
- Highway Geodetic and Photogrammetric Map Engineering Service Works Technical Specification
- Large Scale Map and Map Information Production Regulations
- Environmental Effect Evaluation- Consultancy Services Technical Specification for Project Introduction Report Preparation
- Bridge Project-Traffic Marking-Road Lighting-Landscape Project Specifications

2. Design of the road geometry

Designing a particular road consists of two main stages; Preliminary Design and Final Design.

In Preliminary Design Stage, the winner company decides with the opinions of the Client whether to go along with the alignment and profile (1/25000 scaled) proposed in the tendering stage. During the investigation of the corridor, on 1/25000 scaled maps, Road Design Engineers determine the most suitable alternative in terms of technical and economic aspects, and transfer information to Google Earth to obtain KMZ files and get up-to-date information about the region. Residential areas, archeological sites, touristic facilities, industrial and military facilities, cemeteries, power transfer lines, natural gas pipe lines, current and planned infrastructure facilities are considered.

After the requirements of the Client understood well enough, the designer presents an alignment. The Consultants Design Team design the Alignment in coordination with the current terrain and road profile is drawn accordingly. The design should consider geographic conditions and be in accordance with the geometric standards. (Highway Design Manual, April, 2005)

Following the completion of the alignment and profile design, appropriate cross section selection is made for the special regions and along the road alignment.

For intersecting roads and roads connecting residential areas, the accessibility is provided by areas possible and suitable for intersection design after detailed consultations with GDH experts and key experts within the company.

The data required for Road Design is given by GDH, including Road Data Table.

Summary information extracted from Road Data Table for Malkara-Hayrabolu-Alpullu-D100 State Road which is given by GDH is as follows:

Table 1
Road data table

Horizontal Alignment Design	R > 600 m for 2x1, 2x2 Road with V=100 km/h	R > 380 m for 2x1, 2x2 Road with V=80 km/h
Vertical Alignment Design	**Sag Vertical Curve;** Max 500 m,	**Crest Vertical Curve;** Max 600 m
Maximum Longitudinal Slope	%4 - %6 2x1 and 2x2 Roads with V = 110 km/h, 90 km/h	
Maximum Superelevation	%4, %6, %7, %8	
Lane Width	3,5 m	
Central Median Width	4 m	
Shoulder Width	Inner; 1 m	Outer; 2.5 m.
Total Platform Width	27,5 m	

The standards are important for level of service, comfort, drainage, aesthetic, car headlamp visibility range etc.
Road Design Engineers work on alternative alignment at the initial stage of the project. Alternative Alignments are studied on 1/5000 scaled base maps. The widths of the maps are determined accurately by the Client, covering 1-4 km width strip area. Possible alignment or alternative options for slope plan and profiles are shown in the same project sheet in 1/5000 scale.
Considering the approved Location Plan, Project Alignment is determined consisting of 1/1000 scaled Horizontal and 1/100 – 1/1000 scaled vertical alignment at the Final Project Stage.
When presenting the studied and designed project to GDH following information is deem important.
Critical sections, large scale engineering structures and special locations requiring geological precautions, intersection type connection points and side road lines are drawn into same project sheets or on separate plan-profile sheets. Detail project sheet of intersection is given separately.
In order to make earthwork calculations and detect the locations of the structures for the designed and approved alignment plan and profile, cross sections in critical regions with 100 meter intervals are taken from the numerical model in Autocad Civil 3D Environment (1/200 – 1/400 scaled)
Preliminary Project Report is also a part of the design and presented with the project. Additional to the project report Preliminary Project BOQ is also submitted.
After the approval of the Preliminary Project Design, Engineers prepare Final project.
At this stage following Projects and Reports are prepared.
Project Geometric Elements and Report Preparation

a) Horizontal Alignment
b) Vertical Alignment
c) Superelevation, Cross Section and Detail Project Sheets
d) Side Roads and Connection Roads
e) Alternative and Relocation

Drawing Project Volumetric Elements and Calculations

a) Drawing Clearance Height and Cross Section Sheets
b) Cubage Calculations
c) Bruckner Calculations
d) Preparation of Bill of Quantities (BOQ)

Project Sheets and BOQ Report Preparation

a) Head and Type Sheets, Plan Profile Sheets
b) Engineering Structures and Road Work BOQ

Current linear Structures Displacement and Service Facilities is also designed by Road Design Engineers at this stage.
At last Final Project Report is presented to Client for examination and approval.

3. Surveying, catchment basin, geology, geotechnical issues and pavement

3.1. Surveying

Surveying takes place after an alignment has been agreed with the Client. Approximate required mapping area stated before at the tables given in Financial Proposal forms by the Client. Winner Company provides detailed mapping data for the alignment and start working on the alignment and profile.
Required surveying area stated in the Technical Specification during tendering stage. To give an example, In Highway Final and Preliminary Design Engineering Services Technical Specification 1 kilometer corridor (corridor width is 200 m) 20 Hectare is required to be obtained by the Consultant.
1/25000 scaled maps are used at both tendering stage and preliminary corridor study stage. After careful considerations engineers pass through the next step and start working on 1/1000 scaled maps.

Following this, after site investigations and detailed observations made by experienced engineers and consultation with GDH experts, the limits and borders of the required survey area frames are defined.
The required measurements of surveying for the alignment is made and transferred to computer as numerical data in Autocad Civil 3D Environment to form the surface area for our project alignment as a map base.
Surface area is the first step to obtain detailed information about alignment geometry and to analyze road alignment and road profile in detail.

3.2. Catchment basin

Catchment Basin is an important piece of the Road Design puzzle. Drainage is a must for Road Design as to prevent road from distortion during and after 20 years maintenance time.
At the initial stage of the project, flows and catchment basin are drawn on 1/100.000 or 1/ 25.000 scaled maps in order to make an analysis of the existing conditions. Areas of the catchment basin and locations of the required culvert and river bridges is determined by Environmental Engineers. At the end of this stage with a calculation report, road alignment hydrological analysis is presented.
For Final Projects, Hydraulic and Hydrologic Studies is performed according to approved Preliminary Studies.

3.3. Geology

In tendering stage, geology experts conduct a site visit for the mentioned alignment and make investigations accordingly to acquire Geological Conditions of the region. Report including important landmarks and special conditions is written on site visit report for further studies.
After detailed investigation of the current Geological Condition, slope gradient are determined by Geology Engineers.
Required geological preventions are determined by Geology Engineers according to conditions.
All together with site investigations, laboratory results and studies performed inclination of the slopes is obtained.
Cut Slope ratio and bench requirement is determined according to Soil Investigation Report, in cuts located on soil ground, cut slope used is 2:1 and on high cut areas Bench design is constituted.
For Fill Slopes the following inclinations will be used after geological and geotechnical investigations.

- $0 < h < 1.50$ m; 4:1 (4 horizontal: 1 vertical),
- 1.50 m $< h < 2.00$ m; 3:1 (3 horizontal: 1 vertical),
- 2.00 m $< h < 5.00$ m; 2:1 (2 horizontal: 1 vertical),
- $h > 5.00$ m; slope inclination is determined according to material used to make fill slopes,
- $h > 8.00$ m; for this condition, stability analysis for fill slopes are made.

Before geological and geotechnical investigations finalization, 2:1 slope inclinations are used both in fill and cut slopes.
With the approved Preliminary Project, Geological and Geotechnical Studies is prepared for the Final Project.

3.4. Geotechnical

Geotechnical Engineers analyzes the conditions and as a result determine appropriate solutions; eg. Walls,
Seismicity and Natural Risk Analysis, Bearing Capacity Calculations, Settlement Calculations, Stability Analysis for critical fill sections and required precautions are presented in Geotechnical Report.
At Final Project stage, Projects of Sheet Wall, Retaining Wall and prevention structures on sea, riverside and streambed is designed by Geotechnical Engineers.

3.5. Pavement

In addition to the design of the road geometry, Pavement Engineer determines the pavement structure.
In this case, flexible pavement is used for our project. Flexible Pavement is designed by Pavement Engineer considering; CBR, Mr values of the samples taken from the soil along the alignment, Traffic Composition and Traffic Volume, Rainfall, Climatic Conditions of the Region etc.
For our project and in general pavement structure consists of the following layers:

- Wearing Course (5 cm)
- Binder Course (6 cm)
- Bituminous Base Course (8 cm)
- Plant Mix Base Course (15 cm)
- Broken Stone Subgrade (15 cm)

Pavement Thickness selected from the table in Highway Flexible Pavement Design Manual according to Traffic Categories.

4. Intersection / interchange design and engineering structures

4.1. Intersection / Interchange design

Main purpose of an intersection design is to provide continuous flow for main and side roads, to increase safety, control speed, reduce delay due to deceleration and stopping actions, to provide adequate level of service.
An intersection is designed as at grade junction or grade seperated junction; considering conditions of the terrain, traffic volume and safety.
Mandatory conditions for an intersection design are; Safety, Adequate Level of Service, Economy and Aestehetic Issues.
In an intersection design, the designer requires the following data and made design accordingly:

Regional Data:

- Topographical conditions, maps and dimensional drawing of the intersection region
- Vertical and horizontal geometry, cross sections, pavement conditions of the intersecting roads.
- Conditions bringing limitations on cultural, historical, physical, legal topics within the intersection effect region
- Current soil and drainage system
- Local, zoning roads, current or planned intersection category and types within the intersection region
- Current zoning road and expropriation borders
- Demand of the related local authority and institutions
- Location of special facilities and authorities

Interchange Signalization Projects are presented to the Client at the Final Design Stage.

Traffic Data:

- Traffic survey of main and side roads (according to vehicle class and hour, day, average annual daily traffic)
- Peak hour values
- Vehicle characteristics and class
- Vehicle speed for all intersecting roads.
- Passenger count and movement; expecially on urban transitions
- Accident reports, analysis and statistics
- Capacity analysis of the current intersections / interchanges
- Capacity analysis of the planned intersections / interchanges

Considering all the listed data, by determining intersections /interchanges and connection roads, Slope Plan and Profiles are prepared.
Intersection projects are submitted to GDH with an offical writing, and comment received afterwards from the experts.
After the receipt of the comments from GDH, Road Desing Engineers immediately make revisions, finalize and submit to GDH.
At final design stage, an intersection report and final project of the choosen intersection alternative is submitted to the Client.

4.2. Engineering structures

Road Design Engineers determine the location and scale of small and large scaled engineering structures; bridges, tunnels, and viaducts.
Revisions of the engineering structures are made after presenting the proposed engineering structures and receipt of comments from GDH.
After acceptance take place, Road Design Engineers transfer information to Structural Design Engineers to analyze the structures in detail, make calculations, prepare project sheets and calculation reports.
Additionally, location and dimensions of overpasses and underpasses, including pedestrian passes are determined by Road Design Engineers in consultation with Structural Design Engineers.
After the location has been finalized Structural Design Engineers prepare Detail Design Sheets.
For Final Design:

a) Small Scale Engineering Structures (Transmission Structures)
b) Large Scale Engineering Structures (Bridges, Viaducts)
c) Tunnels

are presented to the views of the Client and for approval stage.

5. Landscape, drainage and traffic

5.1. Landscape

At the preliminary stage of landscape project, considering road area data requirement, programme is created. Planning and project area work recommendations, environment interaction values, economic and other aspects (technical), comparisons are made accordingly and following this landscape project sheets are prepared.
In addition to the project sheets submitted, a report is presented. Landscape Project Report covers the following topics; topography, geology, drainage, soil properties, climate, regional characteristics, water existence, fauna, vegetation, historical and cultural values.
With the approved Preliminary Landscape Project and Report, depending on planning and size of the project area, Final Projects are drawn on 1/1000 scaled Project Sheets.
These Final Landscape Projects are used as a base for As-Built-Projects.
In general, purpose of Landscape in Road Design, is to prevent headlamp light to reach drivers eye coming from the opposite direction, in terms of aesthetic means, to provide prevention from noise and dust and to be in harmony with the present environment that our road alignment passes through.
The project that are presented on Final Project stage are; Landscape and Irrigation Projects.

5.2. Drainage

Catchment Basin Studies highlights the path for drainage as pre-studies for culvert design is made during this stage. In general Road Drainage branches into two parts;

- Surface Drainage Structures
  Drainage Trench, Culverts, Kerb, Vertical Drains, Collectors
- Subsurface Drainage Structures
  Stabilization Ditch, Horizontal Drains, Vertical Sand Drains, Stone Drains, Drainage Gallery (Culvert) are done according to Geotechnical Investigation Report.

Environmental Design Engineer further study on Culverts, Drainage Trench, Kerb, Vertical Drains, Collectors and present a Hydraulic Report consisting of these structures along with their calculations. For Final Design stage, revisions of the approved Preliminary Projects and Drainage Projects are prepared.

5.3. Traffic sign and safety project

Traffic Sign and Safety Project sheets include; traffic control elements, horizontal, vertical, traffic signal and control region signs.
The projects are designed to provide traffic safety and studies are made accordingly.
Main Sources to be used in Project Sheet Preparation are:

1. Highway Traffic Law and Specifications published
2. Traffic Signs Manual I, II
3. Highway Technical Specification
4. Highway Traffic Safety Control Manuel
5. Highway Design Manual
6. Client Certified Guardrail Publication
7. Signalized Traffic Sign Technical Specification
8. Related Publications, Standards and Specifications of GDH
9. Related Turkish Standard Institute Standards (TS 498, TS 500 etc.)

Considering above Specifications, 1/1000 scaled Traffic Project Sheets are prepared.
Traffic control elements (horizontal, vertical and traffic signal etc.) are shown more significant with respect to road structure and other information on the project.
Project Sheet Details can be found in Traffic Sign and Safety Project Specification.
Guardrail List and Sign List are presented along with foundation and steel construction static calculations, other required calculations within the context of Traffic Sign and Safety Project and presented in A4 format hardcover.
Documents to be submitted for this section are given in detail on Traffic Sign and Safety Project Specifications.
At the Final Project stage, Traffic Safety and Marking Projects are prepared by Road Design Engineers.

6. Project delivery and conclusion

Final Project is delivered to GDH in format and details stated in the Technical Specifications.
Documents submitted to the Client are;

- Project horizontal alignment and 1/1000 scaled map on which intersections / interchanges marked and same with the slope plan within the project
- Project vertical alignment
- Coordinate table of project horizontal alignment (in ITRF96 system and conversion parameter is stated)

- Original drawings of the dimensional drawings
- Cross section drawings (in digital environment)
- Project design sheets (including intersections / interchanges) printed onto the polyester (in the project design sheet bags)
- 2 copy of the complete project in original size and blueprint copy (hardcover or hold and boxed)
- Small sized album (A3 sized); 3 copies
- Original bruckner roll and carriage table
- Assembly, bill of quantities and drawings obtained from other institutions
- Cubage table
- Bill of quantities detail file
- Road work engineering structure quantities table
- Road work quantities table (3 copies)
- CD including grade and coordinate list of slope stake
- Plan and profiles of the displacements
- Satellite file of the alignment
- Scanned copies of the approved design sheets and project report
- Project CD including; digital map, surface information, each document given within the Project.
  2 Copies to the General Directorate, 2 Copies to the Regional Directorate.

Project Design Sheets will be in A1 format polyester and other documents in A4 format. All documents is presented in Turkish unless indicated otherwise by the Client.
In conclusion, after the delivery of the Project and reports with an official letter addressed to GDH, acceptance is presented by the Client and the Work Completion Certificate will be received.

ESTIMATION OF START-UP LOST TIME AND AMBER TIME UTILIZATION FOR SIGNAL TIMING

Stamenka Stanković[1], Nikola Čelar[2], Jelena Kajalić[3]
[1,2,3] University of Belgrade - Faculty of Transport and Traffic Engineering, Vojvode Stepe 305, 11000 Belgrade, Serbia

Abstract: The main purpose of urban traffic management is an effective allocation of capacity, by using traffic signals. Lane capacity at signalized intersections is determined by saturation flow value and effective green time. Effective green time duration depends on actual green time, start-up lost time and amber time utilization. Therefore, the accurate determination of effective green is important for intersection performance estimation. The main objective of this paper is to analyze the influence of traffic signal parameters and traffic flow conditions on the value of the start-up lost time and amber time utilization. The research was conducted on more than 300 lanes at 40 main intersections in Belgrade. These intersections operate close to their capacity and therefore an accurate effective green time determination is crucial for system operation. Results have shown that average values of start-up lost time is about 2 s, while amber time utilization vary from 0.3 to 2.5 s depending on different parameters. Considering the number of intersections in the research, it is possible to draw a general conclusion to be used in estimating the traffic signal performance at the same intersection types.

Keywords: signalized intersection, capacity, start-up lost time, amber time utilization.

1. Introduction

Urban networks have a constant lack of capacity, due to disproportion between traffic demands and actual capacity. The problem is most evident at intersections that represent the bottlenecks of the system. Capacity distribution at network nodes is usually preformed by traffic signals. The primary objective of signal timing optimization is to provide the maximum use of intersection capacity, with acceptable level of service. Lane capacity is defined as a maximum number of vehicles that can be served at intersection during one hour. It depends on the queue discharge process during green phase, saturation flow value and effective green time. The capacity of a given lane group may be stated as shown (Webster and Cobbe, 1966):

$$K = \frac{g_e \cdot S}{C} \tag{1}$$

Where: K: lane capacity (veh/h), g_e: effective green time (s), S: saturation flow (veh/h), C: cycle length (s).

Saturation flow is the most important parameter for signal timing optimization. Its value can be determined on the field or estimated using analytical models. Saturation flow models differ in base values, number of adjustment factors and level of their influence. As adjustment factors are used: lane type, adjustment for turn movements, pedestrians, parking maneuvers, heavy vehicles, area type, etc. (Akçelik, 1981; HCM 2010; Webster and Cobbe, 1966).

If the saturation flow value for a specific traffic lane at intersection is considered constant, the capacity value depends exclusively on the effective green time. The effective green time is defined as part of green time during which the vehicles are passing the intersection, and saturation flow has a constant maximum value.

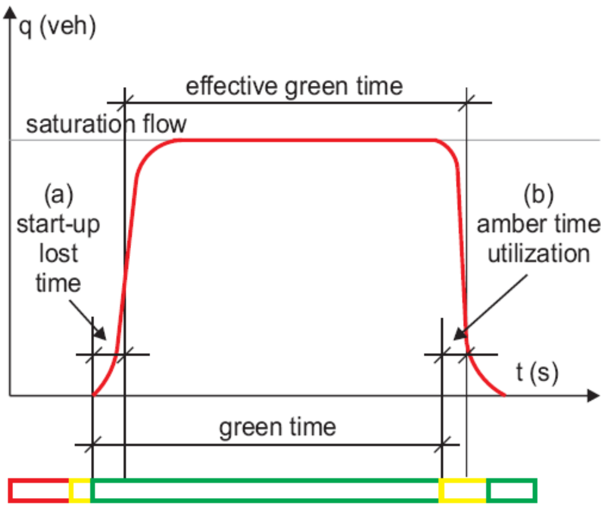

Fig. 1.
Effective green time
Source: Webster and Cobbe, 1966

[1] Corresponding author: s.stankovic@sf.bg.ac.rs

The effective green time is translationally shifted on the time scale relatively to the green time. Mathematically, it differentiates form the green time by the value of start-up lost time and amber time utilization (HCM 2010):

$$g_e = G - a + b \, (\mathrm{s}) \tag{2}$$

Where: g_e: effective green time, G: green time, a: start-up lost time, b: amber time utilization .

Effective green time, as a result of driver's reaction to signal change, depends on several factors: driver’s forcefulness, vehicle characteristics, trip purpose, individual vehicle delay, visibility of traffic signals, intersection geometry, prevailing conditions at intersection and its environment etc.

In theory, the length of effective green time can be shorter, equal or longer than the green time. In signal timing optimization is often assumed that these two variables are numerically equal.

Queue discharge process in a single cycle can be performed in unsaturated and saturated conditions. However, considering a larger number of cycles, queue discharge can be realized in a series of unsaturated cycles, series of saturated cycles or in their combination. Basic assumption of this paper is that the value of effective green time varies depending on traffic flow conditions. Therefore, traffic flow conditions can influence driver’s behavior to a better use of green time, lower start-up lost time and better amber time utilization. This leads to an increase of lane capacity at signalized intersections. The increase of lane capacity can also be affected by signal timing parameters. The assumption is that for traffic flows with lower G/C ratio, a lower start-up lost time and greater amber time utilization are achieved.

2. Literature review

In signalized intersection capacity analysis, researchers were mostly focused on a saturation flow value, rather than on the start-up lost time and amber time utilization. In general, *Highway Capacity Manual* (HCM, 2010) recommends 2 seconds as a default value of the start-up lost time. However, different authors considered the influence of various factors on the start-up lost time over the past few decades. Agent and Crabtree (1983) analyzed the factors related to start-up lost time and lost time at the end of the phase (or unutilized part of amber plus all-red), including the following: city size, location in a city, cycle length and the length of green, speed limit, gradient, vehicle type and turning maneuver, turning radius, distance from stop bar to intersection, and flow conditions. They found a strong correlation between start-up lost time and cycle length. For longer cycle lengths, start-up lost time tended to be much lower. Start-up lost time for longer cycle lengths was 40% lower than for shorter cycle lengths, from 1.42 to 0.85 s. In their study, the increased green time resulted in decreased start-up lost time, with approximately 50% difference between the longer and shorter green time, from 1.72 to 1.05 s. Their recommended base value for start-up lost time was 1.40 seconds with correction factors. In addition, a significant difference in start-up lost time in relation to flow conditions, was not detected. By analyzing the impact of various factors on the unutilized part of amber the authors concluded that lost time decreased as the cycle length increased (from 2.09 to 1.29), also with the increase of green time the unutilized part of amber decreased (from 1.94 to 1.35). They proposed the base value for ending lost time of 1.67 seconds, with adjustment factors. Both cycle length and green time summaries show that lost time decreases with the increase of time a driver must wait if he stops at the yellow light (Agent and Crabtree, 1983).

Bonneson (1993) realized that traffic pressure, measured by traffic volume per cycle had a statistically significant effect on discharge headway. An increase in traffic pressure resulted in a decrease in discharge headway, and therefore the start-up lost time. Bonneson (1993) also discovered a linear correlation between traffic pressure and start-up lost time. The author presented the average start-up lost time values, depending on the maneuver, 2.71 s for left and 2.13 s for right movement, based on research conducted at two intersections. Zhao et al. (2015) also determined that start-up lost time was correlated with queue length. For example, start-up lost time is 1.7 s and 3 s for queues with only 5 and 7 vehicles, respectively.

Recently, researches of amber time utilization are mostly oriented towards the red-light violation and traffic safety. Also, studies focus on defining the amber light dilemma zone, by analyzing the factors affecting it, and by defining the amber time duration. Modest number of authors has conducted research of amber time utilization in relation of signalized intersection capacity.

Agent and Crabtree (1983) concluded that green time and cycle length are actually related, but they weren’t able to determine which of the two was more accountable for start-up lost time variations. For this reason, the authors of this study have observed the effect of the *G/C* ratio on the start-up lost time and amber time utilization.

3. Data collection

The research of real start-up lost time and amber time utilization were carried out at 40 main intersections in Belgrade, with 300 lanes in total. The methodology was based on recording the time components of the queue discharge process in a period of one hour.

The following conditions are fulfilled in the research:

- Presence of the initial vehicle queue in each cycle,

- Uninterrupted queue discharge process,
- Different conditions of queue discharge in the research period,
- Standard traffic flow structure (commercial vehicle up to 10%),
- Standard intersection geometry.

Field data were collected by developed Android application for smart phones. For each cycle the following data were recorded:

- Start of a new cycle (the end of red for the observed flow),
- Moment of the first vehicle rear end passing over the stop bar,
- Moment of last vehicle rear end passing over the stop bar, and,
- Vehicle class.

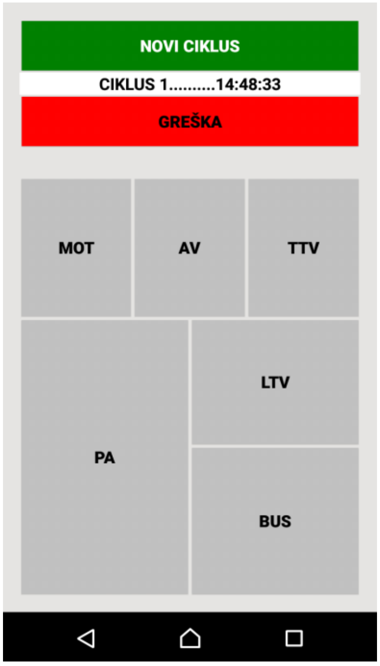

Fig. 2.
Developed Android application for field data collection
Source: Made by authors

Generated database for individual flow includes:

- Average start-up lost time

$$a = \frac{1}{n}\sum_{i=1}^{n} T1_i - \left(ER_i + ra\right) \tag{3}$$

- Average amber time utilization

$$b = \frac{1}{m}\sum_{i=1}^{m} T2_i - \left(ER_i + ra + Z_i\right) \tag{4}$$

- Green time share in the cycle

$$\lambda = \frac{G}{C} \tag{5}$$

- Saturated cycle share in the total number of cycles

$$X_c = \frac{m}{n} \tag{6}$$

Where: a: start-up lost time, b: amber time utilization, n: number of cycles, m: number of saturated cycles, ER: starting moment of red/amber, $T1$: moment of the first vehicle passing, $T2$: moment of the last vehicle passing, ra: red/amber duration (2 s).

4. Results

4.1. The influence of traffic flow conditions on the queue discharge process

To analyze the impact of flow conditions on the queue discharge process, traffic flows were classified by the ratio of saturated cycles in the total number of cycles X_c. Table 1 shows the average values of start-up lost time and amber utilization depending on X_c class. Start-up lost time declines from 1.98 s, when the saturated cycle ratio is lower than 10%, to 1.78 s when the ratio exceeds 90%. However, flow conditions have a greater impact on amber utilization, which increases from 0.31 s to a maximum 2.23 s. Figure 3b shows that amber time utilization reaches its maximum at X_c of 0.7-0.8, and then rapidly decreases. The reason for decline of amber time utilization at high levels of X_c can be explained by driver's assumption that congestion in the intersection's exit leg could provoke his staying in the conflict area of the intersection.
At higher X_c values, effective green time is greater than green time. The opposite can be concluded for lower values of X_c. The results show that effective green in comparison to green time varies in the range of -1.67 to +0.38 s.

Table 1
Effect of flow conditions on start-up lost time and amber utilization

X_c	<0.1	0.1-0.2	0.2-0.3	0.3-0.4	0.4-0.5	0.5-0.6	0.6-0.7	0.7-0.8	0.8-0.9	0.9-1
a **(s)**	1.98	1.94	1.84	1.90	1.77	1.80	no data	1.85	1.76	1.78
b **(s)**	0.31	1.05	1.11	1.36	1.20	1.61	1.75	2.23	1.71	1.35

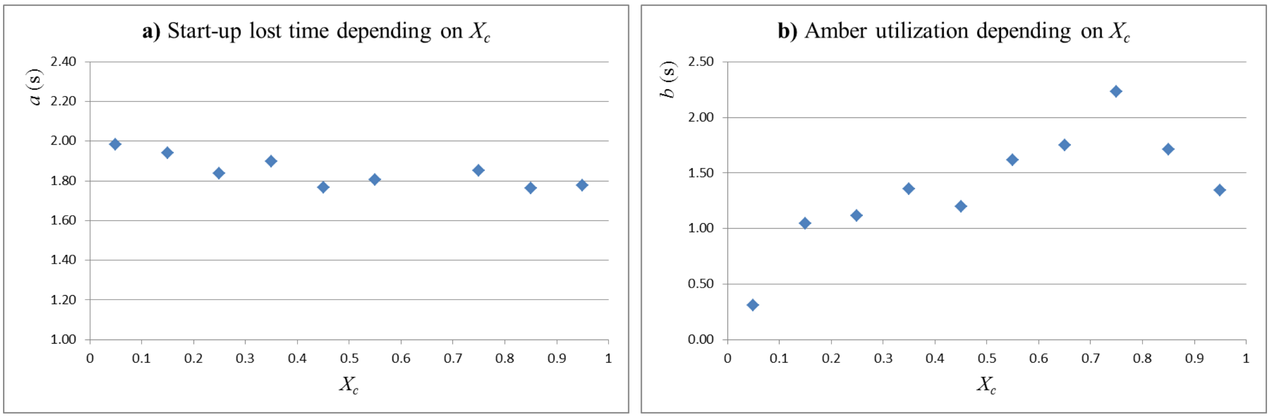

Fig. 3.
Effect of flow conditions on a) start-up lost time and b) amber time utilization

4.2. The effect of signal timing parameters on queue discharge process

In this part the influence of *G/C* ratio, the parameter with largest effect on the lane capacity is discussed. Start-up lost time and amber time utilization are analyzed up to a value of *G/C* = 0.6. The *G/C* values higher than 0.6 occur in a small sample, so they are removed from further consideration.
As Table 2 shows, start-up lost time value increase rapidly to *G/C* = 0.3, followed by its relatively constant value. The increase of *G/C* ratio (Figure 4b) causes the reduction of amber time utilization, in the range of 2.26 s to 0.45 s. The highest amber time utilization is for *G/C* up to 0.1. In the next class (*G/C* 0.1-0.2) the value of amber time utilization rapidly decreases (1.35 s). With further increase of *G/C* occurs a constant, small decrease of the analyzed parameter.

Table 2
Effect of G/C on start-up lost time and amber time utilization

G/C	<0.1	0.1-0.2	0.2-0.3	0.3-0.4	0.4-0.5	0.5-0.6
a **(s)**	1.64	1.76	2.03	2.05	2.02	1.89
b **(s)**	2.26	1.35	1.30	0.69	1.00	0.45

5. Conclusions

The quality of signal timing optimization depends on the accuracy of input data, primarily saturation flow value and effective green time. This paper researches the effect of traffic flow conditions and signal timing parameters on start-up lost time and amber utilization. The research included 40 main intersections in Belgrade.
Based on results, a conclusion can be drown that start-up lost time is realized in a defined range (1.7 to 2.0 s), which corresponds to a value proposed by HCM 2010. Also, it was noticed that *G/C* ratio has larger impact on start-up lost time, especially for $G/C < 0.2$. The start-up lost time values for different X_c are relatively constant. However, the amber time utilization significantly depends on both analyzed parameters. At high X_c value (0.7-0.8) the amber time utilization is 2.25 seconds. The similar result is also obtained for the short green time duration ($G/C < 0.1$).
The difference between green and effective green is variable and depends on both observed parameters. In conditions in which $X_c > 0.7$, as well as for short green time duration, the effective green time can be larger than green, up to 0.5 s. For other combinations of values, the effective green is always smaller than green, up to 1.5 seconds. Therefore, it can be concluded that in signal timing optimization, traffic flows could be treated separately depending on degree of saturation and *G/C* ratio. For the flows with lower X_c and larger *G/C*, the effective green time value of up to 2 s lower in comparison to green time, should be adopted, and for the ones with higher X_c and lower *G/C*, the effective green time of up to 1 s higher. Precise determination of effective green time is particularly important for capacity estimation and signal timing optimization in saturated conditions.
Further research will be oriented towards the influence of driver behavior on start-up lost time and the impact of the start-up lost time on the queue discharge process, ie the saturated flow value. The future research should also analyze the combined impact of saturation flow and effective green on signalized intersection capacity variation.

ESTIMATION OF TURBO-ROUNDABOUT CAPACITY

Janusz Chodur[1], **Mariusz Kiec**[2]
[1,2] Institute of Road and Railway Engineering, Cracow University of Technology, Poland

Abstract: In recent years, a new estimation method of lane capacity at turbo-roundabouts entries in various countries has been developed. It can be shown that methods developed under different assumptions and taking into account various factors determining capacity give significantly different results. Different approaches to the estimation of capacity are used, i.e.: stream conflict models (regression models) and gap acceptance models with behavioural parameters. The values of parameters in models reflect local research conditions. Therefore, the direct application of empirical findings on another area (country) may cause an unspecified inaccuracy. The authors conducted a comparison of capacity estimation models, i.e.: those developed by Fortuijn and Harte, HCM-2010 Hagring and Fisk, and Brilon and Wu, in order to indicate differences of estimated capacity. The paper also presents research conducted in Poland, including: parameters of the gap acceptance capacity model (critical headway, follow-up headway) as well as characteristics of a roundabout circulating stream. These parameters were used in a comparative study of models which are used in various countries to estimate the capacity of roundabout entries. The main aim of this research is the development of an estimation capacity method for practical applications in Poland. The findings and analyses are promising, but they indicate a need for continued research, in particular in behavioural parameters of the gap acceptance model.

Keywords: capacity, turbo roundabout, gap acceptance model, critical headway, follow-up headway.

1. Introduction

Turbo roundabouts are a relatively new form of intersections. They are characterised by the ability to direct different traffic routes through the intersection, using more than one lane. The vehicles in the particular movements pass through the intersection without having to change lanes. Cross-sections of the roadway of a roundabout, which can have between one and three lanes in various places, are adapted to the traffic volume of each movement. Spiral marking can be seen on the roadway of the roundabout, often accompanied by a physical separation of traffic lanes by means of raised dividers. It is supposed to rule out the unnecessary changing of lanes on the roundabout's roadway which increases the traffic safety hazards. The edges of the central island and of the traffic lanes on the roundabout's roadway are shaped using sections of a circle, the Archimedean spiral or an ellipse (Giuffre et al. 2009; Royal Haskoning DHV, 2009).

Due to the lack of Polish design guidelines for turbo-roundabouts in Poland, they are designed using foreign legislation and guidelines (Royal Haskoning DHV, 2009; Brilon, 2014; Haller, 2015). This results in a diversity of solutions used in different regions of the country. One of the problems related to implementation is the need to use foreign methods of assessing performance, which do not take into account the behaviours of Polish drivers. Polish methods of calculating the capacity of intersections including roundabouts, do not cover turbo-roundabouts due to the period of their development between 2001 and 2004 (Tracz et al. 2004). It can easily be demonstrated that foreign methods of assessing traffic performance, developed with different assumptions and taking into account determining various factors, yield significantly different results. The parameters of the gap acceptance capacity model in the circulating flow rate have values representing the area of study. Thus, the direct application of a selected method in conditions other than those in the test area, may be subject to an undefined inaccuracy. In the recent years, empirical studies have been undertaken in Poland, mainly focusing on behavioural parameters for the turbo-roundabout entry capacity estimation models (Macioszek, 2013; Chodur and Ostrowski, 2015). These studies and the conducted comparative analyses of different models have allowed for the development of hints for estimating the capacity of turbo-roundabouts.

2. Capacity models of turbo-roundabouts

Models used to calculate the capacity of turbo-roundabouts can be divided into three types: models of conflicting streams, gap acceptance models and simulation models. Models of conflicting streams are also known as empirical models. The linear or exponential relationship between the capacity of entries and traffic volume on the roadway of a roundabout is determined based on observations. The advantages of these models are: the ability of direct application of the results of the measurements carried out in the conditions of saturated traffic, and taking into account the so-called pseudo-conflict in the calculation (the impact of vehicles non conflicting – leaving the roundabout – with the stream of vehicles entering the roundabout on the capacity of the entry). Among the disadvantages of this method one can name: its inability to identify the relationship between traffic volume on entries and traffic volume on the roadway of a roundabout when there is no saturated traffic, as well as the ability to estimate only a simple relationship between the capacity of entries and traffic in the roundabout. The first model allowing to estimate the capacity of entries in turbo-roundabouts was the model of Fortuijn and Harte based on a modification on Bovy's model, and it was designed to estimate the capacity of one- and two-lane roundabouts (Fortuijn, 2009).

$$C_{El} = C_{0l} - b_{\min} \cdot Q_{R,\min} - b_{\max} \cdot Q_{R,\max} - a_{lu} \cdot Q_{Su} \tag{1}$$

[1] Corresponding author: jchodur@pk.edu.pl

$$C_{Er} = C_{0r} - b_{ru} \cdot Q_{Ru} - a_{ru} \cdot Q_{Su} \tag{2}$$

where:

- C_{El}, C_{Er} – capacity of left/right entry lane [pcu/h],
- C_{0l}, C_{0r} – capacity of left entry lane (left/right) without traffic on circulating lane [pcu/h]
- $Q_{R,\min}$, $Q_{R,\max}$ – circulating traffic volume on lane with the lower/higher traffic volume [pcu/h],
- Q_{Su} – exiting traffic volume [pcu/h],
- a_{lu}, a_{ru} – effect of exiting traffic on the capacity of the left/right entry lane [-]
- $b_{\min}$, b_{max} – effect of roundabout lane with the lower/higher traffic volume on the capacity of left entry lane [-]; b_{min}=0.68
- b_u – effect of outer roundabout lane on the capacity of right entry lane.

Another example of the empirical model is the exponential relation between the capacity of the lane on the entry and the traffic volume of the roundabout roadway as applied in HCM 2010 method.

$$C_j = A \cdot e^{-B \cdot Q_R} \tag{3}$$

where:

- C_j – capacity of j entry lane [pcu/h],
- A – capacity of entry lane without traffic on circulating lane [pcu/h],
- B – impact of the lane configuration on the roundabout inlet and roadway,
- Q_R – conflicting flow rate [pcu/h].

With the most extended theoretical and empirical background, gap acceptance models have recently been most often applied. Their theoretical rudiments are based on the analysis of driver behaviours entering to the conflicting flow rate from the conficting stream. Apart from the circulating traffic volume (on the roundabout roadway) Q_R, other key variables, which constitute this type of models, include: critical headways for circulatory lane t_c and follow-up time for queuing vehicles t_f, which indicate drivers' behaviour when entering the roundabout and the minimum distance between vehicles on the roadway of a roundabout t_m.

Gap acceptance models include a model designed by Hagring in 1998, constituting the extension of the earlier model by Troutbeck (1986) modified then by Fisk (1989) (Fortuijn, 2009).

The conversion of these models gave rise to the Brilon-Wu model enabling the calculation of a two-lane roundabout capacity; presently the model is used as part of a practical method of calculating the capacity of turbo-roundabouts in the following form (Haller, 2015):

$$C_j = \frac{3600}{t_f} \cdot \left(1 - \frac{t_m \cdot Q_{Ru}}{3600}\right) \cdot \left(1 - \frac{t_m \cdot Q_{Ri}}{3600}\right) \cdot exp\left(-\frac{Q_{Ru} + Q_{Ri}}{3600} \cdot \left(t_c - \frac{t_f}{2} - t_m\right)\right) \tag{4}$$

where:

- C_j – capacity of j entry lane (PCU/h),
- Q_{Ri}, Q_{Ru} – circulating traffic volume on inner/outer lane [PCU/h],
- t_c – critical gap for vehicles entering circulatory lane j [s],
- t_f – follow-up time, depending on which circulatory lane j entering vehicle has to merge into [s],
- t_m – minimum gap between vehicles in major circulating traffic [s],

Based on empirical studies conducted in Poland (Macioszek, 2013), a model of entry capacity was developed for different configurations of turbo-roundabout lanes. Below there is a formula for the left lane of a two-lane entry of a turbo-roundabout with two priority lanes:

$$C_{El} = \begin{cases} \dfrac{a \cdot 3600}{t_f} & \text{for} \quad Q_R = 0 \text{ pcu/h} \\[2ex] \dfrac{a \cdot 3600 \cdot e^{-\left(\frac{Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}} + \frac{Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right) \cdot (t_{cl} - t_{mi})} \cdot \left(\frac{Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}} + \frac{Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right)}{\left(1 - e^{-t_{fl} \cdot \left(\frac{Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}} + \frac{Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right)}\right) \cdot \left(1 + \frac{t_{mi} \cdot Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}}\right) \cdot \left(1 + \frac{t_{mu} \cdot Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right)} & \text{for} \quad 1 < Q_R \leq 100 \text{ pcu/h} \\[2ex] \dfrac{a \cdot 3600 \cdot \phi_i \cdot \phi_u \cdot e^{-\left(\frac{\phi_i \cdot Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}} + \frac{\phi_u \cdot Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right) \cdot (t_{cl} - t_{mi})} \cdot \left(\frac{\phi_i \cdot Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}} + \frac{\phi_u \cdot Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right)}{\left(1 - e^{-t_{fl} \cdot \left(\frac{\phi_i \cdot Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}} + \frac{\phi_u \cdot Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right)}\right) \cdot \left(\phi_i + \frac{\phi_i \cdot t_{mi} \cdot Q_{Ri} \cdot}{3600 - Q_{Ri} \cdot t_{mi}}\right) \cdot \left(\phi_u + \frac{\phi_u \cdot t_{mu} \cdot Q_{Ru} \cdot}{3600 - Q_{Ru} \cdot t_{mu}}\right)} & \text{for } Q_R > 100 \text{ pcu/h } \wedge Q_R < C_R \\[2ex] \cong 0 \text{ pcu/h} & \text{for} \quad Q_R \cong C_R \end{cases} \tag{5}$$

where:

- C_{El} – base capacity for left lane on entry [pcu/h],

Φ – share of vehicles in free flow speed [-],
a – a parameter depending on the configuration of the traffic lanes and the presence of separators [-]
i, u – indices for the circulatory lanes; inner/outer,
– other markings as in the formula (4).

In the above model, behavioural parameters t_c and t_f depend on the average speed on the roundabout roadway and this is, in turn, a function of the base radius of the roundabout roadway, R_1 (Giuffrè et al. 2009). The minimum headway t_m between vehicles on the roundabout roadway depends on the traffic volume on this lane as well as the share of vehicles in free flow speed ϕ.
The values of parameters t_c, t_f and t_m depend in general on the configuration of lanes on the roundabout entry and on the roundabout roadway by the entry. In addition to the circulating traffic volume, provided it is properly determined and recognised by the model (the share of vehicles in free flow or non free flow and the distribution of headways), the above parameters are of key importance in the process of determining the correct estimation for the capacity of a roundabout entry lane.
Figure 1 shows a comparison between the capacity of a left lane on a two-lane roundabout entry with two priority lanes determined based on models (1), (3), (4) and (5). The following data have been taken into account in the calculations:
model (1) - $Q_{Ri} = Q_{RU} = 0.5\ Q_R$, $a_{lwl} = 0.21$, $a_{pwl} = 0.14$, $b = 0.68$, $b_{\max} = 0.82$; a) traffic volume of the stream leaving the roundabout $Q_{Su} = 0.4\ Q_R$, b) the stream leaving the roundabout has been omitted.
model (3) - $A = 1130$ pcu/h, $B = 0.75{\cdot}10^{-3}$,
model (4) - $Q_{Ri} = Q_{RU} = 0.5\ Q_R$, $t_c = 4.0$ s, $t_f = 2.6$ s, $t = 1.9$ s,
model (5) - $Q_{Ri} = Q_{RU} = 0.5$, $\phi_{Rl} = \varphi_{Ru} = 1.0$ - 0,64 $R_1 = 20$ m; (a) with dividers $v = 31{,}9$ km/h, $t_c = 4{,}2$ s, $t_f = 3{,}3$ s, $a = 1.02$; (b) without dividers $v = 33{,}5$ km/h, $t_c = 3{,}9$ s, $t_f = 2{,}9$ s, $a = 1{,}01$

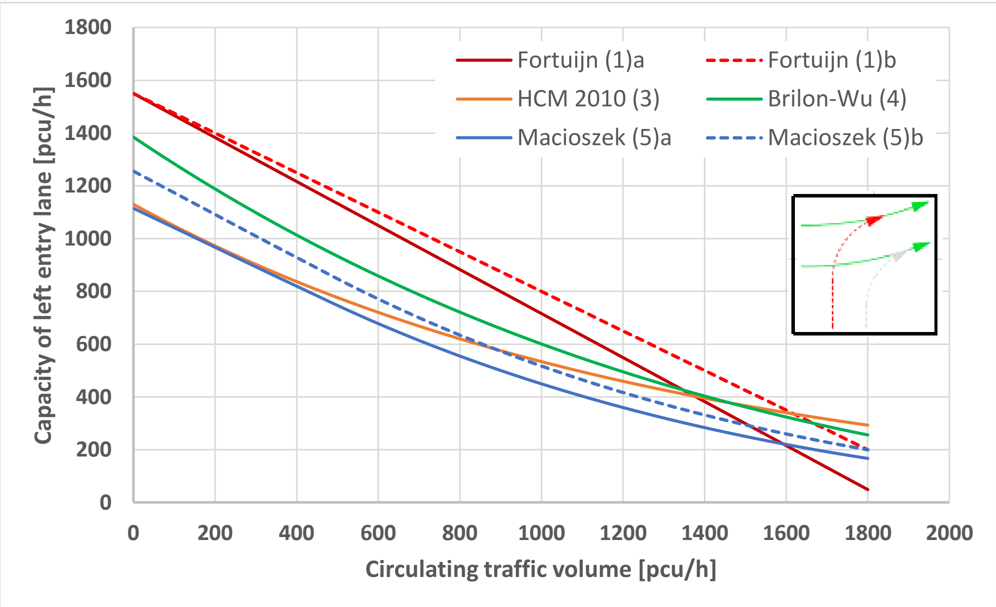

Fig. 1.
Comparison of the left lane inlet capacity on a turbo-roundabout based on various models

The graph shows the extent of diversification of capacity values estimated using various methods. The straight-line graph representing the capacity estimation based on model (1) stands out from the rest. It should be noted that the rate of the decline in capacity depends in this case not only on the traffic volume on the roundabout, but also on the traffic volume of the stream leaving the roundabout roadway (lines (1)a and (1)b). A similar shape of curves was generated by the gap acceptance capacity model in conflicting flow rate (4) and (5), although model (4) and parameters determined in Germany offer greater values of capacity. According to (Macioszek, 2013) research, model (5), using dividers significantly reduces the speed of vehicles on a roundabout roadway and decreases the capacity of the entry (curves (5)a and (5)b).

3. The research on the parameters in models estimating turbo-roundabout capacity

In gap acceptance models, there are assumptions and parameters which are significant for the correct mapping of this process. These assumptions relate mainly to the representation of the circulating flow, primarily the distribution of headways with the appropriate parameters, and, in addition, in some models involving vehicles moving in free and non free flows. The parameters describing the behaviour of traffic participants who join or intersect the circulating flow constitute a separate group. The distributions of headways in the flow on the roundabout roadway are often modelled using the exponential distribution, shifted exponential distribution and Cowan's M3 distribution, or spline functions from several distributions. The simplest exponential distribution, with one parameter, can be used to describe headways on a single lane only at low traffic volumes and to describe a complex major stream, for example, on two lanes of the roadway jointly. The shifted exponential distribution, with an additional parameter, which is the minimum headway, eliminates from the model very small, unrealistic headways on a single lane that can occur when using exponential distribution. At higher traffic volumes, not all vehicles moving in free flow (randomly), so it is advisable to distinct the free and non free parts of the traffic. This entails the need to define an additional parameter, which is the share of vehicles in free flow (Cowan's distribution) or of additional parameters (e.g. minimum headways) for the description of free and non-free parts (complex distributions, e.g. Hyper-Erlang distribution) (Chodur 2007, Macioszek, 2013). Research and analyses concerning the description of the flow of vehicles on the roadway of various types of roundabouts are described in the work (Macioszek, 2013; Brilon and Geppert, 2014).

The approval process model requires the specification of two parameters, i.e the critical headways t_c, which is the minimum time interval between vehicles in the circulating flow, which can be used by the average (in the statistical sense) driver from minor entry for the intended manoeuvre, and the follow-up time t_f, with which vehicles from the queue at the minor entry enter the intersection one by one when the headways in the circulating flow allows more than one vehicle to enter. Research and analyses of these parameters were carried out in recent years, among others at the Cracow University of Technology. Research was carried out on eight roundabouts (19 entries) with the use of the video registration technique. The values for critical headway t_c were determined using the method of maximum likelihood (Brilon et al. 1997; Brilon and Geppert, 2014) based on a set of pairs of values of headways between vehicles in the major flow: the used one and the largest discarded one for each vehicle which stopped at the entry and then pulled into the roundabout roadway. The values of follow-up headway t_f have been designated as the arithmetic mean of the registered headways from the queue at the entry entering the roundabout roadway when the headways in circulating flow allowed more than one vehicle from the queue to enter. Most often, the test results of these parameters are aggregated to the individual configurations of the traffic lanes on the entries of turbo-roundabouts. They can also be dependent on geometric features of a given roundabout. An example of such a relation is the model listed in (Macioszek, 2013):

Table 1

t_c and t_f models for two-lane entry with two priority lanes (Macioszek, 2013)

Diagram	Lane	Critical headway t_c (s)	Follow-up headway t_f (s)
	Roundabout with dividers		
	Left lane	$-0.0002\bar{V}^2 - 0.032\bar{V} + 5.3795$	$-0.0003\bar{V}^2 - 0.1346\bar{V} + 7.8901$
	Right lane	$-0.0003\bar{V}^2 - 0.0045\bar{V} + 4.5601$	$-0.0007\bar{V}^2 - 0.0974\bar{V} + 6.9869$
	where: $\bar{V} = -0.001R_1^2 + 0.7622R_1 + 17.038$ [km/h] speed on the roundabout roadway		
	Roundabout without lane dividers		
	Left lane	$-0.0001\bar{V}^2 - 0.0297\bar{V} + 5.0352$	$-0.0001\bar{V}^2 - 0.1154\bar{V} + 6.8691$
	Right lane	$-0.0004\bar{V}^2 - 0.0034\bar{V} + 4.5492$	$-0.0004\bar{V}^2 - 0,0813\bar{V} + 5.8799$
	where: $\bar{V} = -0.001R_1^2 + 0.8672R_1 + 16.521$ [km/h] speed on the roundabout roadway		

In that model, the base radius of the turbo-roundabout R_1 (Macioszek, 2013) determines the average speed on the roundabout roadway $\bar{V}$, which, in turn, determines both parameters of the gap acceptance process t_c and t_f.

An example list of the obtained values of parameters t_c and t_f is presented in Table 2. The values of critical headways t_c obtained from the measurements conducted by the authors turned out to be larger than the values calculated from the relations provided in (Macioszek, 2013) (Table 2). This is mainly due to the applied method of determining t_c. In own studies, it was the method of maximum likelihood, while in (Macioszek, 2013) these were much earlier methods of cumulative curves for accepted and rejected headways, and the acceptance curve method. Critical headways determined by different methods differ by more than 1 second (Patil and Pawar, 2014).

Table 2
Critical headways t_c and follow-up times t_f obtained from own studies (CUT) and calculated according to relations provided in (Macioszek, 2013)

As is apparent from the values in Table 3, the Polish research featured a larger range of variability both in the values of t_c and t_f obtained on particular roundabouts. Based on the German and Polish research, the recommended values of t_f differ by up to 0.3 s, while for the left lane of the E2 configuration a larger value was obtained in the Polish research, whereas for the E4 configuration – a smaller value was obtained. This gives a difference in capacity of around 150 pcu/h with Q_R = 0 pcu/h. The diversity of t_f can also be influenced by such factors as the radius of the entry, the vehicles leaving the roundabout (especially with a high proportion of heavy vehicles) and weather conditions (Fortuijn, 2009).

With regard to t_c, the recommended values differ by up to 0.9 s and this applies to the left lane at the entry to a roundabout with E2 configuration. When it comes to the German results, what is interesting is that t_c for the left lane of E1 configuration equals 4.5 s, while for E2 configuration it equals 4.0 s. In the first case, the vehicles of the entry cross only the circulating flow, while in the second case they cross the stream on the outer lane and merge into the stream on the inner lane of the roundabout roadway. In the Polish studies the obtained values were, respectively, 4.7 s (E1) and 4.9 s (E2). The diversity of values of t_c for the right lane of configurations E1 and E2 in the Polish research can be explained by the influence of vehicles in the inner lane of the roundabout roadway on the vehicles merging into the stream on the outer lane (pseudo-conflict) with E2 configuration.

4. The choice of models for practical applications

The gap acceptance capacity models in the circulating flow have often been used in various applications. They are easily adaptable due to the selection of appropriate parameters and their calibration. Numerous varieties of acceptance models, with more or less complex description of the circulating flow, enable the adaptation of the already existing models to current solutions, especially where the implementation of the research programme on intersection capacity requires a longer time. The research projects carried out by the Cracow University of Technology in the period of 2013 – 2016 included the study of behavioural parameters as well as the research on the turbo-roundabout entry capacity. The maximum number of vehicles (capacity) entering the roundabout from a given entry lane on the roundabout roadway can be determined during the periods of traffic saturation (the period when vehicles queue before entering the roundabout). Due to the adaptation to the needs of traffic as well as their traffic performance, turbo-roundabouts have no queues in the area of entries. Queues forming by entries are usually short-term. This entails the need to count vehicles with a right of way as well as entering the roundabout in short intervals. Of course this implies a significant dispersion of values in the capacity of recalculated within an hour. An interval assumed in the reaserch carried out by Cracow University of Technology amounted to 30 s. The same interval was applied in descriptive studies presented in (Brilon and Geppert, 2014).
Figure 2 shows the average values of the left lane capacity on the entry with E2 configuration based on observations in 30 s intervals. The dependence of the capacity on the major traffic volume on the roundabout roadway has been represented in the figure by a broken line (exponential function).

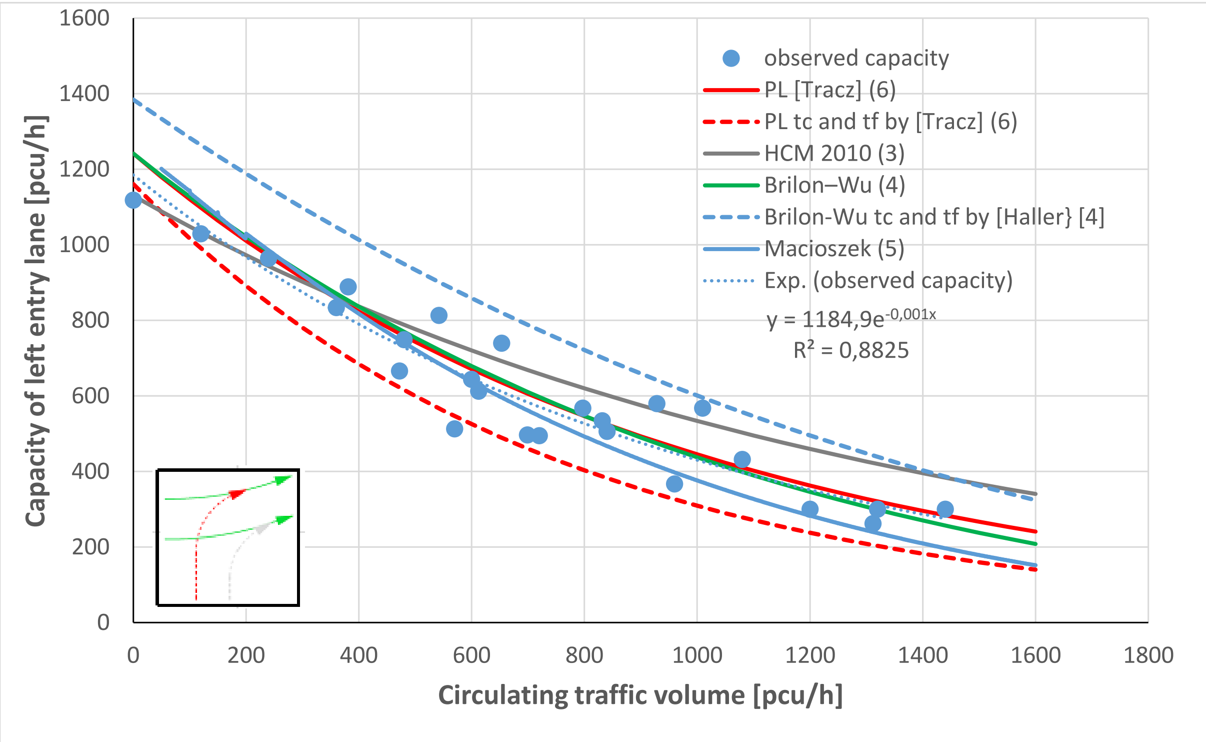

Fig. 2.
Empirical capacities for the left lane on E2 turbo-roundabout inlet and capacity curves according to various models

Also the capacity model for the intersection entry without traffic lights is possible to applying for describing the dependence between the capacity of the left lane and traffic volume on the roundabout roadway (Tracz et al. 2004). In the case of an intersection with the right of way, the equivalent of the analysed relation of the left two-lane E2 turbo-roundabout entry is the movement of turning left from the minor entry. In both cases the analysed movement crosses the priority lane and joins in the traffic on the other lane. The difference in operation for these two cases concerns traffic directions on the road with the right of way and the perception of the flow of vehicles with the right of way.

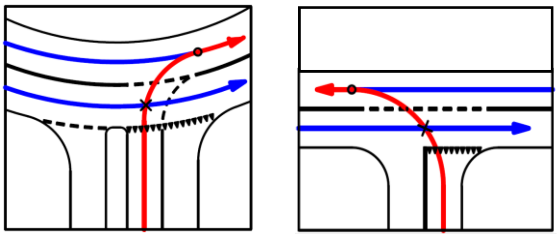

Fig. 3.
Analogical manoeuvres on the roundabout and three-inlet intersection with the right of way

The capacity model in the method (Tracz et al. 2004) is represented as follows:

$$C_l = \frac{3600}{t_f} \cdot e^{-1{,}07 \cdot \frac{Q_R}{3600} \cdot \left(t_c - \frac{t_f}{2}\right)} \quad \text{[pcu/h]} \tag{6}$$

symbols as in previous formulas.

In all capacity estimation models compared with empirical data, the values of parametres t_c and t_f were determined in own research (table 3 – t_c = 4,9 s, t_f = 2.9 s). For the remaining parameters, the values recommended for particular methods were assumed (description before Figure 1). The distribution of traffic on the roundabout lanes was assumed to equal 50%. The matching of particular curves to empirical capacity (Figure 2) was assessed with the help of the root mean square error – RMSE).

Table 4
Root mean square error values for capacity estimation using various methods

Method	**Polish (Tracz et al. 2004) (6)**	**Brilon–Wu (4)**	**Macioszek (5)**	**HCM 2010 (3)**
RMSE [pcu/h]	78.9	80.6	179.4	105.5

As evidenced by results, models (6) and (4) show the best match, with an almost identical error. It should be noted that model (6) is applied in the method of calculating capacity of intersections with a right of way and it is for those intersections that it was calibrated. The application of this model with parameters t_c and t_f determined for turbo-roundabouts yielded a positive result. For comparative purposes, the graph (Figure 2) also includes curves (broken lines) according to models (6) and (4) with values of parameters t_c and t_f recommended, respectively, in the Polish method: for a left turn from the minor entry of an intersection situated in a small locality (t_c=6.3 s and t_f=3.2 s), and in the German method: for a left lane of a two-lane entry of a turbo-roundabout with two priority lanes (E2). In this case, the Polish method gives a significantly lower lane capacity, while the German one gives a significantly higher one.

5. Conclusions

Capacity models for entry lanes on turbo-roundabouts which have been designed and applied in various countries make use of a different number of parameters (from 2 – (6) model, to 6 – (5) model). This diversity and parameter values determined in a given country yield a relatively large scope of estimated capacities for a given entry configuration and determined circulating traffic volume. A direct use of a given method in different conditions (in a different country) may lead to unspecified inaccuracies in capacity estimations.

Thanks to the authors' research it was possible to determine empirical capacity and values of key parameters t_c and t_f of the gap acceptance model for different configurations of turbo- roundabout entries in Poland. The values t_c and t_f differ from those established in German studies (Brilon and Geppert, 2014; Haller, 2015). It is down to specific behavioural patterns of drivers using turbo-roundabouts in these two countries. Polish drivers are usually very cautious while entering such intersections. Turbo-roundabouts are not yet a common type of an intersection, and traffic rules are quite different from those on single or two-lane roundabouts.

The reference to the estimated capacity with the use of various models dedicated to turbo-roundabouts as well as the model designed for intersections with the right of way, showed that it is possible to use for calculation both Brilon-Wu (4) model as well as the Polish one (6) (Tracz et al. 2004), provided that they assume behavioural parameters indicated in the authors' own analyses. These findings are related to the left lane on two-lane turbo-roundabout entry with two priority lanes presented in this article. Further research and analysis should enable the equivalent calculations for every individual lane and entry configurations.

EVALUTION OF THE EFFECT ON THE LAYER THICKNESS OF DIFFERENT LAYER DESIGNS

Ahmet Ünal[1], Muhammed Yasin Çodur [2], Merve Gülfer Özcan[3]
[1,2,3] Erzurum Technical University, Engineering and Architecture Faculty, Department of Civil Engineering, Erzurum, Turkey

Abstract: Road pavement design is carried out by estimating the expected traffic density during the project. According to these estimations material properties of the layer and layer thickness are determined. Pavement project should be carried out so as not to allow the formation of cracks and large deformation beyond permissible limits. Road pavement consists of gravel with asphalt concrete and base layer thickness. In case of undesired deformations pavement cracks occur in the pavement design and implementation of the scientific method. In this study layer thickness calculation and selection of material properties belonging to the layers used in Erzurum South Ring Road that was built in respect to American Association of State Highway and Transport Officials (AASHTO-86) were analysed. Other pavement designs that could be alternative to the same road were investigated in terms of layer thickness and economic analyses.

Keywords: AASHTO-86 method, flexible pavement, layer thickness.

1. Introduction

Road body consists of two main parts which include infrastructure and superstructure. Infrastructure is called as a term between constructions completed on leveling a road surface and the natural ground line. Road infrastructure provides a smooth surface elevation and loads from the infrastructure layer are built to be spread over a larger area (Saltan et al. 2002). The road superstructure provides vehicles with smooth rolling surface and is built to transfer loads from superstructure to the infrastructure. Road superstructure consists of three parts which are surface, base and subbase layers (Pavement Interactive, 2008).
The main purpose of the pavement design is to predict from traffic loads stress and to reduce limit value of infrastructure capacity. Moreover, it is important that design of layer thickness should not allow to any deformation. There are 3 different flexible design method which are empirical, analytical and empirical-analytic method (Kok, 2008). In our country, American Association of State Highway and Transport Officials (AASHTO-86) method is used which are based partly empirical partly by the analytical methods of layer thickness of road is designed length of service and economic efficiency of the road, subgrade bearing capacity and are designed using passed over to the amount of traffic and axle loads.

2. Literature review

Before the 1920s, pavement design mainly consisted of defining thicknesses of layered materials that would provide strength and protection to a soft, weak subgrade. Pavements were designed against subgrade shear failure. Engineers used their experience based on successes and failures of previous projects. As experience evolved, several pavement design methods based on subgrade shear strength were developed. The Asphalt Institute (AI) Method (Asphalt Institute, 1982, 1991) and the Shell Method (Claussen et al., 1977; Shook et al., 1982) are samples of procedures based on asphalt concrete's fatigue cracking and plastic deformation failure modes. These methods were the first to use linear-elastic theory of mechanics to compute structural responses (in this case strains) in combination with empirical models to estimate number of loads to failure for flexible pavements. The American Association of State Highway Officials (AASHO) Road Test in 1960s was a seminal experiment from which the AASHTO design guide was developed.
New design criteria were required to incorporate such failure mechanisms (e.g., fatigue cracking and permanent deformation in the case of asphalt concrete). The Asphalt Institute Method (Asphalt Institute, 1982, 1991) and The Shell Method (Claussen et al., 1977; Shook et al., 1982) are samples of procedures based on asphalt concrete's fatigue cracking and plastic deformation failure modes. These methods were the first to use linear-elastic theory of mechanics to calculate structural responses (in this case strains) in combination with empirical models to estimate number of loads to failure for flexible pavements.
The first empirical methods for flexible pavement design date to the mid-1920s when the first soil categorization were enhanced. One of the first to be published was the Public Roads (PR) soil classification system (Huang, 2004). In 1929, the California Highway Department improved a method using the California Bearing Ratio (CBR) strength test (Huang, 2004). The California Bearing Ratio (CBR) method related the material's CBR value to the required thickness to provide protection against subgrade shear failure. The thickness computed was described for the standard crushed stone used in the definition of the CBR test. Several methods based on subgrade shear failure criteria were enhanced after the CBR method. Huang used Terzaghi's bearing capacity formula to calculate pavement thickness, while he applied logarithmic spirals to specify bearing capacity of pavements. Regression equations can also be enhanced using performance data from existing pavements (Huang, 2004). Examples contain the COPES (Darter et al., 1985) and EXPEAR (Hall et al., 1989) systems. Although these models can represent and clarify the effects of specific factors on

[1] Corresponding author: ahmet.unal@erzurum.edu.tr

pavement performance, their limited consideration of materials and construction data result in wide scatter and many uncertainties.

Mechanistic-empirical (M-E) methods represent one step forward from empirical methods. Kerkhoven and Dormon first recommended the use of vertical compressive strain on the top of subgrade as a failure criterion to decrease plastic deformation (Kerkhoven and Dormon, 1953). Saal and Pell published the use of horizontal tensile strain at the bottom of asphalt layer to minimize fatigue cracking. Dormon and Metcalf first used these concepts for pavement design (Saal and Pell, 1960). The Shell Method (Claussen et al., 1977) and the Asphalt Institute Method (Shook et al., 1982; AI, 1992) combined strain-based criteria in their mechanistic-empirical procedures.

In this study, the construction which was completed in 1999 in Erzurum South Ring Road was investigated. Existing superstructure section was examined and this superstructure section are determined that it could be an alternative to the existing superstructure section. Considering that according to the specified conditions in the drainage section of the superstructure design methods of AASHTO-86 was calculated layer thicknesses. The cost calculation was made of existing superstructure section and could be an alternative to the existing superstructure section.

3. Material methods

In this study, the South Ring Road of Erzurum which is built according to AASHTO-86 pavement design method examined. This superstructure layer is determined as will be alternative sections. Erzurum South Ring Road to the top of the existing structure section is given in Table 1. Superstructure section is shown in the Figure 1 used in general.

Table 1
Erzurum South Ring Road existing superstructure section

Type A	
Wearing Course	5 cm
Binder Course	8 cm
Asphalt Base Course	10cm
Road Base Course	20 cm
Plentmix Subbase Course	20 cm
Total Thickness	**63 cm**

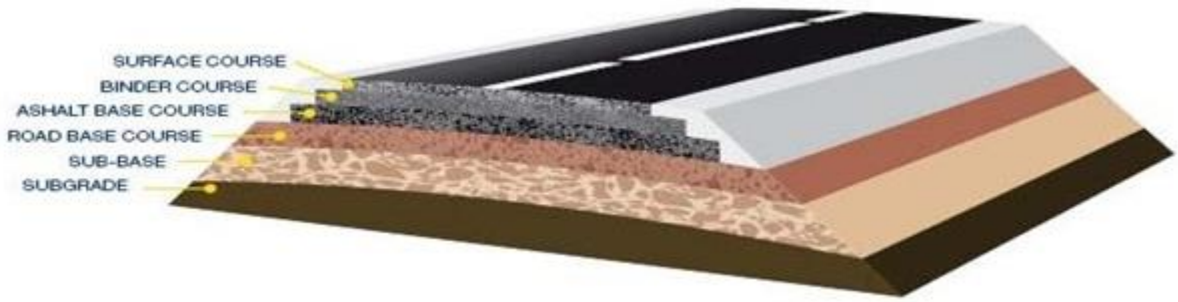

Fig. 1.
Commonly used superstructure section

In the second part of the study alternative superstructure sections were examined and the effects of this on the layer thickness for different superstructure design were investigated. Comparison of selected superstructure sections was calculated according to the AASHTO-86 method and has is given in Equation (2, 3, 4, 5, 6). Undoubtedly, ground bearing capacity values that are used in the calculation show the changing values along the path of a road. The ground bearing capacity value in the calculations was taken as 10.000 psi. The total number of replicates required to drop the end of the service capabilities of the superstructure in the calculation of the different types of pavement sections is defined as $W_{8.2}$=37.178.900 standard axles / project duration.

The design of layers thickness;

Z_r =-1.037, S_0 = 0.45, P_0 = 4.5, P_t= 2.5, M_R = 10.000 psi, has been taken as in calculations.

$$LogW_{8.2} = Z_r \times S_0 + 9{,}36 \times Log(SN+1) - 0{,}20 + \frac{Log\left(\frac{P_0 - P_t}{4{,}2-1{,}5}\right)}{0{,}40 + \frac{1094}{(SN+1)^{5{,}19}}} + 2{,}32 \times Log(M_R) - 8{,}07 \quad (1)$$

where W $_{8,2t}$ is predicted number of 8,2 tones equivalent single axle load applications, Z_r is standard normal deviate, S_0 is combined standard error of the traffic prediction and performance prediction, M_r is resilient modulus, SN is structural number.

Crushed stone subbase M_r value 18.834 psi and the basis of the M_r value is used as plentmix 33.266 psi.

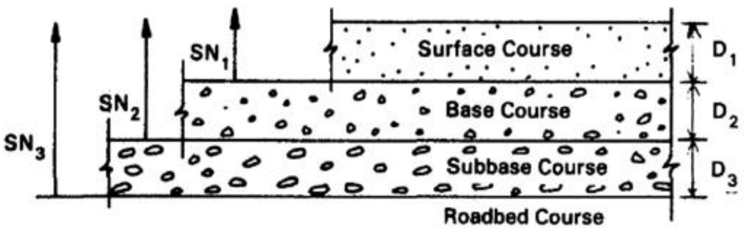

Fig. 2.
Procedure for determining thickness of layers using a layered analysis approach
Source: AASHTO 93 Pavement Structures Design Guide

$$D_1^* \geq \frac{SN_1}{a_1} \quad (2)$$
$$SN_1^* = a_1 D_1^* \geq SN_1 \quad (3)$$
$$D_2^* \geq \frac{SN_2 - SN_1^*}{a_2 m_2} \quad (4)$$
$$SN_1^* + SN_2^* \geq SN_2 \quad (5)$$
$$D_3^* \geq \frac{SN_3 - (SN_1^* + SN_2^*)}{a_3 m_3} \quad (6)$$

SN value is multiplied by the relative coefficients of resistance layer with layer thicknesses (Equation 7).

$$SN = a_1 D_1 + a_2 D_2 + a_3 D_3 m_3 \quad (7)$$

where a is the relative strength coefficient, d layer thickness, m refers to the drainage coefficient.
Asphalt concrete wearing course is the layer that is constructed on binder layer and contacts directly to the traffic load. To form a uniform and smooth rolling surface for the wear layer, the flow of the traffic is organized accordingly. Laying uniformly the surface of the bituminous mixture made series of pavers can be ensured. The bituminous binder course on basic or applied as a granular base asphalt. The thickness of the binder course by the amount of traffic varies from 6 to 12 cm.
The most difference between superstructure sections is the base material that is predicted to be used as an alternative material. Crushed stone and fine material consist of a mixture obtained by mixing in a mechanical plant fine material. Subbase layer according to the criteria set out in the specifications laid with pavers is obtained by mixing with water. The fact that the available grounds do not have sufficient transport capacity strength is applied in the circumstances in which the ground should be strengthened. The occurrence of hot mix of living, depending on the underlying floor of asphalt to be applied for the application of plentmix base is a very likely situation. After completion of earthworks disrupted traffic achieved under the platforms. Various distortions occur due to seasonal conditions. Basic material or basic necessaries, making a kind of coating to avoid this situation has necessitated the need. For this reason, stabilizing is performed based application.
Accounts and other alternative body sections with the AASHTO-86 method is used on pavement design is given Table 2.

Table 2
Alternative superstructure sections

Alternative Superstructure Sections					
Type B		**Type C**		**Type D**	
Wearing Course	5 cm	Wearing Course	9 cm	Wearing Course	9 cm
Binder Course	8 cm	Binder Course	12 cm	Binder Course	12 cm
Bituminous Base Course	10 cm	Plentmix Base Course	28 cm	Stabilizing Base Course	60 cm
Plentmix Base Course	20 cm				
Subbase Course	20 cm				
Total Thickness	**63 cm**	**Total Thickness**	**49 cm**	**Total Thickness**	**81 cm**

The unit prices of each layer is taken from the General Directorate of Highways. Unit price list is given in Table 3.

Table 3
The unit prices of the layers

The Unit Price of the Layers	Cost
1 cm thick stuck in 1 m^2 of asphalt concrete base made of hot bituminous	0,405 \$/ m^2
1 cm thick stuck in 1 m^2 of asphalt concrete wearing surface	0,516 \$/ m^2
1 cm thick stuck in 1 m^2 of asphalt concrete binder base	0,430 \$/m^2
To make plentmix base	10,21 \$/ ton
To make with sifted gravel subbase material	2,97 \$/ m^3

Cost accounts for different body types are shown in Table 4. The cost calculation is taken as the road width of 18 meters and road length as 1 km. As a result of the calculations, the cost of superstructure types is calculated.

Table 4
The total price of section types

Section Type	Cost ($/km)
A	132.709
B	85.006
C	119.822
D	102.003

4. Conclusion

Stabilizing the basis of relative strength coefficient is taken as 0,08 in Type D. Relative strength coefficients of the layers in the other superstructure sections as calculated for wearing course 0,44, binder course 0,40, bituminous course 0,36, plentmix course 0,15 and subbase course 0,13.

Layer thicknesses of the alternative superstructure sections is given in Table 2. The main factor of existing different superstructure is used different base materials. Another factor in the calculations of the layer thickness being different is different coefficient of strength of the layer.

Ton price of basic materials have been translated into cubic unit price multiplied by the coefficient of 1,6.

Erzurum South Ring Road of the superstructure section is given in Table 1. As a result of the calculations, the cost of existing pavement section was calculated as 132.709$/km. It was determined that Type B could be as an alternative of Type A. Reasons for the emergence of low cost of the B section is the use of a lower cost material as the base material. Type B superstructure does not have any disadvantages in terms of technique.

When we compared type C with type D, it was calculated that base course of type C must be thicker than type D. This condition is not desirable in terms of technical. When compared in terms of cost, it seems to be making sense of type C.

EFFECTS OF THE PEDESTRIAN PAVEMENT NETWORK AND ILLUMINATION ON ACCESSIBILITY ON PUBLIC PARKS IN SOUTH AFRICAN CITIES

Dillip Kumar Das[1], James Honiball[2]
[1,2] *Department of Civil Engineering, Central University of Technology, Free State, 20 President Street, Bloemfontein, South Africa, 9300*

Abstract: Public parks are integral elements of residential areas of cities. It is well established that public parks have a positive influence on the social and physical health of the people who have access to them. The public parks despite being seemingly planned according to urban planning guidelines and are located appropriately in the neighbourhoods of the cities of South Africa, they are observed to be highly underutilised. Many social and physical factors that include location, accessibility, crime or fear of crime, life style, and lack of time are generally attributed for such a scenario. However, explicit studies on the factors that influence- and their relationships with the use of public parks by people, particularly in the residential areas of cities are limited. Therore, the objective of this study is to explore how pedestian movement network in the neighbourhoods and illumination levels in the public parks influence the utilization of public parks in the residential areas of South African cities. Blomefontein city of South Africa was taken as a case study, and a survey research method for data collection, subsequent statistical analyses and development of empirical models were follwed. Data were collected through park user survey conducted by using random sampling process, and household survey through startified random sampling by using pre tested questionaires. Besides, physical park utlisation survey was conducted by using continous time lapse digital photography and videograpgy of the public parks. The study revealed that more people use the public parks during evening hours. Higher artificial illumination and availability of quality pedestrian pavement netwoks are the two important factors, which influence public park use, although they do not necessarily influence each other. However, the combination of availability of both factors would enhance the utlisation of public parks significantly.

Keywords: accessibility, illumination, public parks, pavements, road network, residential areas.

1. Introduction

Public parks (PPs) and recreational facilities (RFs) offer people the opportunities for a wide range of leisure, sport and recreational activities. They are crucial for the social and economic health of the cities and towns (Sallis, Frank, Saelens, & Kraft, 2004). It is observed that the habitation areas including residential areas of South Africa in general and in the cities in particular have been going through transformations since the establishment of its new constitution in the year 1994. In the process transformations in urban functions and consequent land uses are observed in many cities of the country. Consequently a hierarchical change in the pattern of residential areas in urban areas has been experienced (Spocter, 2004). For instance, the residential areas have been expanded to develop suburban areas. The suburban areas, which were essentially started for residential purposes, gradually incorporated other urban functions such as commercial, civic and recreational activities. Besides, a stress was laid upon to create organized open spaces including public parks and open recreational facilities in the residential areas of the cities. They become one of the core land uses in the city development plan offering urban social and recreational functions. Although, a number of such public parks and recreational facilities have been developed in most of the South African cities, it is observed that except a few major and organized ones, majority of the public parks in residential areas scarcely utilized. The reason of underutilization these public parks are attributed to many factors that includes lack of amenities, inappropriate location, lack of attractiveness, lack of accessibility, behavioural issues like lack of time and life style, social issues like crime or fear of crime to name a few. However, accessibility to public parks particularly in sub urban residential areas is a crucial challenge. Therefore, the objective of the of study is to explore how two imporatnt accessibility parameters such as illumination levels in the public parks and pedestraian network facilitiess (with respect to road network facilities) influence the accessibility and consequent utilisation of public parks in the residential areas of South African cities. However, other social, cultural, and other physical, visual and symbolic accessibility factors have been kept out of the scope of the paper as they also warrant specific investigation.

The study was conducted by using Bloemfontein city of South Africa as a case study. A survey research method and empirical modelling were used for the purpose. Two hypotheses that (1) availability of improved level of artificial illumination in the public parks; and (2) complete pedestrian facilities along the road networks in residential areas of cities, will improve the utilisation of public parks" are tested. Findings suggest that majority of the people use the parks during evening hours. Artificial illumination is one of the most important factors that influences accessibility of the public parks, and utilisation of the public parks increases with higher level of artificial illumination. Besides, it is also found that more complete the pedestrain facilitiy network along the roads leading to public parks, higher is the urtilisation of the parks.

2. Literature review

2.1. Role and indicators of success of public parks

Public parks have crucial roles to play in cities. Some of the important roles they play are that they offer open recreational facilities to people, bring people together, increases social bonding, make intergenerational interaction, develop contact with nature (especially if it is natural green spaces), compliment the architectural articulation of the surrounding built areas, improve the value and desirability of the surrounding residential areas, and create an area for people to orientate themselves with the greater part of the city or town (Dempsey, 2012). Public parks have many design aspects, which positively contribute to the well-being and value of the surrounding spaces. Properly planned and designed open green spaces (OGSs) and public parks greatly add to the aesthetic quality of the surrounding areas and satisfaction inhabitants around them. Also, they create a restorative environment, which cannot be neglected as they positively influence the inhabitant's well-being and health (Ariane, Bedimo-Rung, Andrew, Mowen, Deborah, Cohen, 2005).

The project for public spaces (PPS, 2011) evaluated thousands of public spaces around the world and has found that successful public parks and recreational facilities have four key qualities. Firstly, they are accessible; secondly, people are engaged in activities there; thirdly, the space is comfortable and has a good image; and lastly, it is a sociable place where people meet each other and take people with them when they come to visit (PPS, 2011). Based on such studies, a tool called "The Place Diagram (Figure 1)" was developed to aid people to judge whether any public place is good or bad. One of the important aspects, which have been emphasized in it is the access and linkages of parks and recreational facilities, which essentially influence the success of the public parks and open recreational areas PPS, 2011).

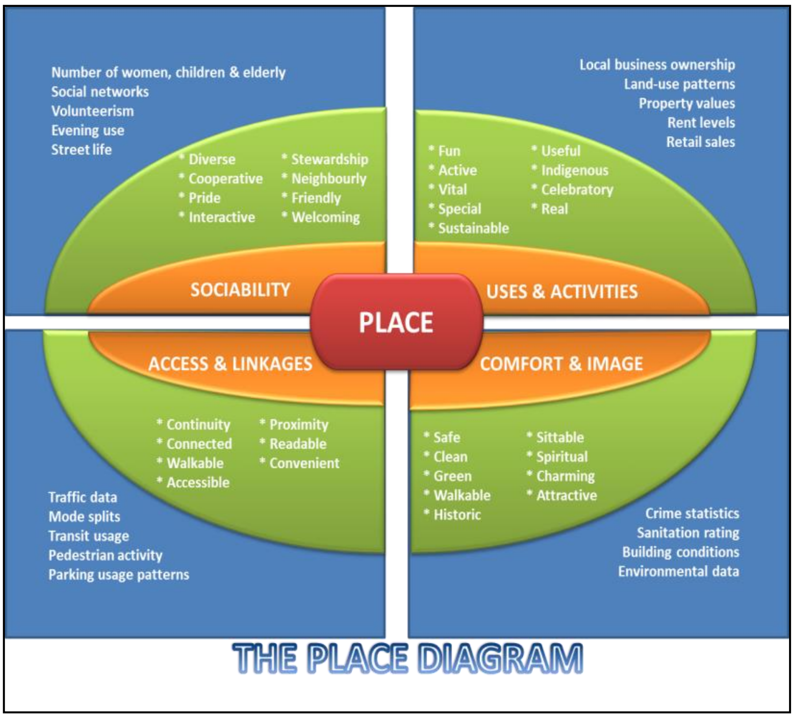

Fig. 1.
The Place diagram for public parks

2.2. Forms of accessibility to public parks

The accessibility of public parks is related to the ability of people to reach the space by means of public transport, private transport or pedestrian infrastructures. Accessibility is often considered as a crucial factor to make a public park function as purposed. For instance, a public park that is set on a busy road may draw more people that are passing by as well as people using services and facilities that are nearby (Dempsey, 2012). Although, there is no unanimity on the definition of accessibility of public parks because of the various roles it plays and its effect on the vibrancy and usefulness of public parks, it can be categorized into three forms such as, physical access, visual access, and symbolic access (Sendi and Golicˇnik Marusˇic, 2012).

2.2.1. Physical access

Physical access to public parks requires the space to have proper linkage from neigbouring spaces as well as no barriers preventing pedestrians to enter the space. According to Sendi and Golicˇnik Marusˇic, (2012) physical access to public parks should be easy for children and elderly people to make use of. Houses and residential areas next to the public parks should also have relatively easy access to the space. Physical access is hampered by vehicular movements around the public parks. Also, the type, quality and continuity of the pavements of the pedestrian facilities are factors that encourage or discourage people to visit the parks at the neighbourhood or residential area level (Dell'Acqua, Mario, Russo, 2012; Žilionienė, Mario, Russo, 2013). The physical accessibility of parks is also influenced by the density of the neighbourhood which surrounds it, and perhaps by the shape of the park. Besides, convenient access for physically challenged people is an essential element of the physical access of the public parks (Dempsey, 2012).

2.2.2. Visual access

The visual access of a public park refers to the visual connection a user would have with the park they are heading towards. Visual access contributes to the safety of the user due to the proper visibility needed to safely navigate to the park. Not only must a public park be easily visible to its users, it must also ensure that the users are visible when accessing as well as when using the parks (Sendi and Golicˇnik Marusˇic, 2012). According to Peña-García, Hurtado, & Aguilar-Luzón, (2015), artificial illumination of a public park is a key element in making sure that the visual access of a public park is adequate.

2.2.3. Symbolic access

Symbolic access to public parks is becoming more and more important in defining the full accessibility and vibrancy of the public parks. Symbolic access can be defined by the level and quality of signs and marks that share information to prospective users on who or what is welcome and who or what is not in the areas and territories of the space. These markings and signs can also be elements like structures, landmarks, monuments, sculptures, etc. Public display areas and programs, such as, pavilions, galleries, and other theme objects can also be seen as features contributing to symbolic access. Users such as groups (teenagers, small children, dog walkers, etc.), maintenance workers, and security staff visible in the public parks are also contributors to the symbolic access of the public parks (Sendi and Golicˇnik Marusˇic, 2012).

2.3. Issues of accessibility and use of public parks

The issue of accessibility to the public parks is becoming more and more debated with regards to sustainable urban planning. Accessibility to the public parks is essential for the health, well-being and cultural equality of the societies. This awareness can mainly be attributed to the awareness about the health and well-being benefits that are gained from the successful use of the public parks (Thomson, Aspinall, & Roe, 2014). Access to the public parks is particularly useful to children, lower socioeconomic group, and people with physical/mental disabilities (La Rosa, 2014).

Challenges of accessibility to public parks vary according to the different access needs people. If accessibility to the public parks is considered as the degree of ease at which a user can reach their destination, then fully determining the factors and variables affecting the accessibility of public parks should be a pre- requisite for further analysis on planning for vibrant and sufficient public parks (La Rosa, 2014; Sendi and Golicˇnik Marusˇic, 2012).

In addition to the spatial accessibility of public parks, Weiss et al., (2011) suggests that there are many other variables of the environment that might negatively affect the use and accessibility of the public parks. In this regard, the research conducted in the perspective of environmental justice highlights the linkage between the inequalities in the spatial distribution of public parks and natural hazards in the environment. For example communities with less or limited accessibility to public parks face exposure to environmental ailments such as air pollutions (Evcil, 2012). Besides, it is also found that fear of crime or concerns for personal safety limits the accessibility of the parks as it discourages the users to make use of the available modes of access to the public parks. For instance, these fears and concerns may lead users to rather seek out other recreational facilities, which are perceived to be safer to access (Weiss et al., 2011). However, Painter (1996) observed that adequate levels of illumination in public parks are often a deterrent for crime and inadequate levels of illumination in the parks are often a deterrent for potential users of the parks.

Evidence from the literature suggests that most of the researches on the accessibility to public parks that have been carried out until now are mostly on industrialized nations, which have well-established infrastructure. However, on the contrary very little is known about accessibility of public parks, particularly the influence of illumination level in the parks and availability of pedestrian facility network on the park use, in fast growing cities of developing countries (Wright, Zarger, & Mihelcic, 2012). Therefore, an effort has been made in this study to understand the relationship between illumination and pedestrian facility network leading to the parks and the use of public parks in a city of a developing country.

3. Study Area

Bloemfontein city of South Africa is used as a case study for this investigation. It is comprised of 35 suburban residential areas. The city has an adequate number of hierarchical public parks and recreational facilities, which includes central park and stadiums at the city level, public parks at the neighbourhood level and residential area level. However, most of the parks in the residential areas are observed to be lacking in vibrancy and more so found to be underutilized. Accessibility, perception of safety, actual safety, lack of entertainment amenities, lack of maintenance, and lack of comfort are some of the suggested factors, which discourage the higher use of these parks. Therefore, it was felt relevant to explore the relevant accessibility factors such as illumination and pedestrian facilities that influence the utilisation of the public parks in the city.

4. Research methodology

The investigation followed a survey research methodology and development of empirical models. Data was collected through household survey and physical and park use surveys. The surveys were conducted in four representative suburbs of the city such as Universitas (South-Western part of Bloemfontein), Langenhovenpark (Western part of Bloemfontein), Batho (Eastern part of Bloemfontein), and Lourier Park (Southern part of Bloemfontein). The suburbs were selected on the basis of a set of selection criteria such as, geographic location, population, social demographic condition, availability of number and type public parks, type of accessibility through road network, and size. These selected suburban residential areas vary from each other in terms of its diverse demographics, size, location, and accessibility via road networks. Household survey with a sample size of 208 was conducted by using systematic stratified random sampling process through semi-structured interviews. Physical and park use survey were conducted by using continuous digital photography and videography. Twenty four public parks located in the four selected residential areas were identified for the physical and park user survey. For this purpose a camera was set up at each of the identified public parks, which filmed the park for 7 days non-stop to monitor the daily use of each parks and various accessibility issues.

Physical accessibility was evaluated based on the availability of pedestrian facilities and road network leading to the parks. Pedestrian facilities include properly maintained paved pathways along the roads without obstructions/barriers/encroachments/gaps. The road network includes the local roads and access streets passing through the residential areas. While analysing the accessibility factors with regards to pedestrian facilities the ratio of length pedestrian facilities to length road network was considered as the relevant parameter for the convenience of analysis as both are dependent on each other. Similarly lighting facilities and their intensity in lux in the evening times was taken as the level of illumination in the parks. The analysis was conducted by use of statistical methods such as correlation, significance tests and trend analysis by developing empirical models.

5. Findings and discussion

Table 1 presents the correlation coefficients between parks use and illumination level, and park use and pedestrian facility network leading to the parks as well as significance test results between park use and accessibility parameters. A correlation between the average number of users and recorded level of illumination was conducted and it is found that illumination level in parks and use of parks are highly correlated (cc=0.84). The high correlation coefficient suggests that higher the illumination levels of the public parks, the higher will be the average number monthly users of the public parks. The high correlation between the average number public parks users per month and the pedestrian facility network to road network ratio (cc=0.82) means that the more complete the pedestrian facility network in the service areas, the higher will be the average number of public parks users per month. Besides, the significance test results show that p values (both single tailed ad two tailed) for each variable are <0.05 for $\alpha <0.05$. This establishes that there are significant relationships exist between the accessibility variables such as pedestrian facility network to road network ratio, and illumination level of parks in evenings with the park uses in Bloemfontein, thus establishing the two hypotheses envisaged that (1) availability of improved level of artificial illumination in the public parks; and (2) complete pedestrian facilities along the road networks in residential areas of cities, will improve the utilisation of public parks.

Table 1
Correlation and significance test results

Accessibility Parameter	**Decadent parameter**	**Correlation coefficient (cc)**	**r^2**	**T value**	**df**	**p***	**p****
Illumination level of parks in the evening	Park use	0.84	0.92	6.82	40	0.0000003	0.0000006
Pedestrian facility network to road network ratio	Park use	0.82	0.92	7.40	32	0.00000001	0.00000002

*Note: *single tailed; ** two tailed p values for α <0.05*

5.1. Influence of the level of illumination in public parks in the evenings on the number of users of public parks in the study area

Figure 2 presents the relationship between the illumination levels in the evenings and the average number of monthly users of the public parks in the study area. The relationship is presented in the equation 1 (Eq.1).

$$Y_1 = 37.585X_1 + 89.75 \tag{1}$$

$r^2 = 0.92$

Y_1 = Number of public park users per month; X_1= Illumination level in parks in lux

The relationship proves that a linear relationship exists between illumination level and number of park uses. It is observed that parks with very low illumination (<3 lux) experience very few visitors and more people use parks where illumination level is high (>10 lux). However, majority of the parks have illumination level less than 20lux recommended by the Encyclopedia of Occupational Health and Safety. Thus, as per the trend analysis the average number of monthly park users increases significantly along with an increase in the level of illumination of the public parks in the evenings. So, significant improvement in the illumination in the public parks during evening is essential to improve the uses of public parks in the study area.

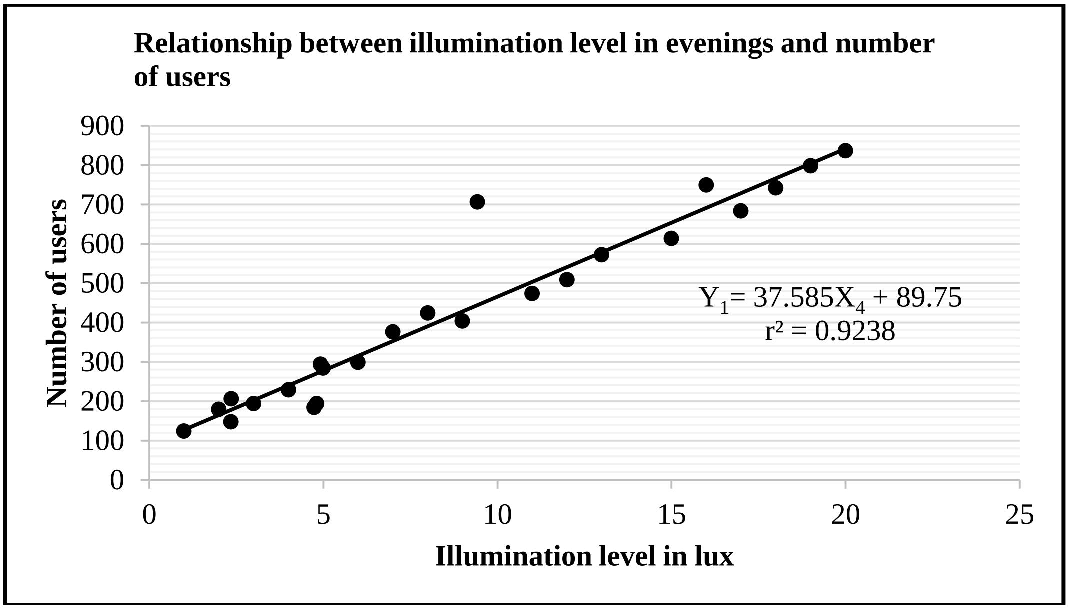

Fig. 2.
Influence of the level of illumination in public parks in the evening on the number of users of public parks

5.2. Influence of pedestrian facility network to road network ratio on the number of users of public parks in the study area

Figure 3 shows the relation between the pedestrian pavement network to road network ratio and the average number monthly users of the public parks in the study area. The relationship is presented in the equation 2 (Eq.2).

$$Y_1 = 2.032e^{5.9542X_1} \tag{2}$$

$r^2 = 0.92$
Y_1 = Number of public park users per month; X_1= Pavement network to road network ratio

The trend analysis from Figure 3 revealed that the average number of monthly users increases gradually (non-linearly) as the pedestrian facility to road network ratio increases up to 0.85; however, it increases exponentially as the ratio improves beyond 0.85. This indicates that if the pedestrian facilities are not available commensurate to the road network, it will act as a barrier for the people to use the parks, however, more number of people use parks where the pedestrian facility network is more complete, i.e., if the pedestrian facilities are almost provided along all the roads leading to the parks without much obstructions.

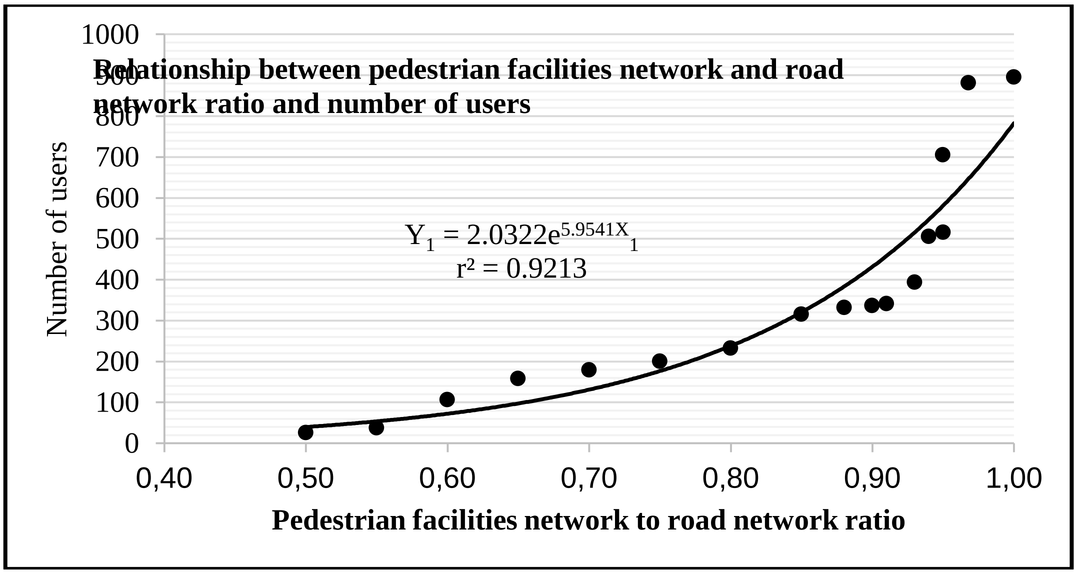

Fig. 3.
Influence of pedestrian facilities network to road network ratio on the number of users of public parks

6. Conclusion and further research

Accessibility of public parks in residential areas in the South Africa cities is a challenge. This study revealed that illumination and pedestrian facility network along the roads leading to the public parks are two major parameters, which influence the accessibility and consequent use of the parks. The relationship between the illumination and use of parks, and pedestrian facility network and use of public parks, are established by empirical models as well as by significance tests. It is found that number of users of the public pars increases with the increase in illumination and pedestrian facility. However, there are various other factors, such as physical access, social and cultural issues, which also influence use of public parks, which is the further scope of the research. Nevertheless, at its current state, it is revealed that there is a need to improve the artificial lighting infrastructure in the public parks and to make provision for complete pedestrian facilities along the roads leading to the public parks in residential of Bloemfontein city in order to improve their use.

MODELING OPERATING SPEED USING ARTIFICIAL COMPUTATIONAL INTELLIGENCE ON LOW-VOLUME ROADS

Mario De Luca[1], Francesco Abbondati[2], Francesco Saverio Capaldo[3], Salvatore Antonio Biancardo[4], Daiva Žilionienė[5]
[1,2,3,4] Department of Civil, Architectural and Environmental Engineering (DICEA), University of NaplesFederico II, Italy
[5] Department of Roads, Vilnius Gediminas Technical University, Lithuania

Abstract: In recent years, Artificial-Computational Intelligence (ACI) have found increasing applications in management of transportation infrastructures. Examples of ACI applications can be found in highway management however, compared to transportation planning, research of ACI methods applied to infrastructure management has been relatively limited. In this study was used artificial intelligence ANN (Artificial Neural Network). In particular the objective of the research study is to compare the predicted operating speed on tangents and circular curves for low-volume roads by using two different statistical approaches.The starting point was to predict the operating speed on investigated tangents and circular curves elements by using four regression equations developed using a traditional ordinary–least-squares method (OLS) as shown in a previous work of the authors. Then, the same database was used to calibrate new operating speed models by using ANN procedure. The results have shown that ANN models offer more reliable results in terms of predicted operating speed than those returned by OLS method on all circular curves and on tangents lengths greater than 500m. For tangents length less than 500 m, OLS method is to be preferred to ANN procedure.

Keywords: artificial-computational intelligence, data mining, artificial neural network, operating speed, multivariate regression.

1. Introduction

In recent years, Artificial-Computational Intelligence (ACI) have found increasing applications in management of transportation infrastructures. Many researchers, in particular, have employed Artificial Neural Network (ANN) procedures to analyze factors related to data processing. In the scientific literature, many research works have dealt with the road safety issues, driver speed behavior, traffic flow. The comparison of results coming from ordinary simulation method and ANN procedure is often carried on.

Satish et al. (2007) estimated the annual average daily traffic (AADT) for low-volume roads. Artificial neural networks are compared with the traditional factor approach for estimating AADT from short-period traffic counts. The neural network approach can be particularly suitable for estimating AADT from two 48-h counts taken at different times during the counting season. In fact, the 95th percentile error values of about 25 percent as obtained in this study for the neural network models compare favorably with the values reported in the literature for low-volume roads using the traditional factor approach.

Faghri and Aneja (1996) proposed and examined alternative methodology for trip prediction by using artificial neural network (ANN) concepts and techniques. The data base used was made available by the Delaware Department of Transportation. The data were collected for 60 sites throughout Delaware between 1970 and 1974 and are based on field counts and home interviews. Twenty-six regression models were calibrated on these data. In addition, 18 ANN architectures were developed, and their predictions were compared with those from regression models. Comparisons indicate that the ANNs have the capability to represent the relationship between the trip production rate and the independent variables more accurately than regression analysis at no additional cost of increasing the data base.

Saito and Fan (1999) analyzed the effects of architecture, learning mode, and learning rate on the performance of a level-of-service (LOS) analysis model by using an artificial neural network (ANN). Multilayer LOSANN models demonstrated improved quality of learning and testing over single layered models in evaluating level of service of signalized intersections given geometric, traffic, and traffic signal control data.

Hassan and Mohamed (2007) focused on accident location with respect to the plaza structure (before, at, after plaza) and driver injury severity (no injury, possible, evident, severe injuries). Two well-known artificial neural network (ANN) paradigms were investigated: the Multi-Layer Perceptron and Radial Basis Functions neural networks. The performance of ANN was compared with calibrated logit models. Modeling results showed that vehicles equipped with ETC devices, especially medium/heavy-duty trucks, have higher risk of being involved in accidents at the toll plaza structure.

Mohammadian et al. (2007) used the nested logit model and the multilayer perceptron artificial neural network to investigate the household vehicle choice problem in terms of their applicability. Both methods generated strong results, although the multilayer perceptron artificial neural network yielded better predictive potential.

Douglas et. al (2007) used speed profile models as a diagnostic tool for highway engineers. Previous work investigated relationships between operating speed and geometric roadway elements for permanent roadway conditions on predominantly two-lane rural roads. However, little research of this type has been directed specifically toward construction work zones. In this study, a speed profile model for construction work zones on high speed highways was developed using artificial neural networks. The model inputs include horizontal and vertical alignment variables, cross section dimensions and traffic control features. A linear reference system is used for model input and output. Three categories of vehicles-cars, trucks, and all vehicles-were used in this study. Models for the 15th percentile speed, mean

[2] Corresponding author: francesco.abbondati@unina.it

speed, and 85th percentile speedwere developed.
Ismail (2010) developed methods for obtaining maps to determine traffic Hot Spots in Konya, Turkey, by applying linear analysis supported by a Geographical Information Systems (GIS). In this research, a GIS system was used to organize geometry, traffic, environmental conditions and accident data. Subsequently, the data contained in the GIS were processed using two different techniques of analysis: "non-linear multiple regression" and "artificial neural networks". In particular, the second technique, used in this field for about 10 years, is gaining growing consensus for the construction of predictive accident models.
Abdel-Aty and Abdelwahab (2002) investigated the use of two well-known artificial neural network (ANN) paradigms: the multilayer perceptron (MLP) and fuzzy adaptive resonance theory (ART) neural networks for analyzing the severity of driver injury. The objective of this study was to investigate the viability and potential benefits of using ANN to predict driver injury severity if a crash occurs. ANN performance was compared with a calibrated ordered probit model. Modeling results showed that testing classification accuracy was 73.5% for MLP, 70.6% for fuzzy ARTMAP, and 61.7% for the ordered probit model. This result indicates more accurate injury severity prediction capability for the ANN (particularly MLP) compared with other traditional methods.
This study is part of a wide research program (Capaldo, 2004a; Capaldo, 2004b; Dell'Acqua and Russo, 2010). In particular is a continuation of a research project (Dell'Acqua and Russo, 2011) that developed four operating speed prediction models for horizontal curves and tangents on low-volume roads: a) 2 models on tangents were associated with the segment length (the first one can be applied on the tangents with a length of less than 500 meters and the second one on tangents with a length greater than 500 meters); b) 2 models on the circular elements were associated to a mean CCR (Curvature Change Rate) value of the roadway segment to which the curve belonged (the first one can be applied on the curves with a CCR value of less than 240grad/km and the second one with a CCR value greater than 240 grad/km). The objective of this research is to compare the predicted operating speed on tangents and circular curves for low-volume roads by using two different statistical approaches: Artificial Neural Network (ANN) versus Least-Square Model (OLS).

2. Operating speed prediction models by least-square model (OLS) method

Four prediction models were developed by the authors in a previous work (Dell'Acqua and Russo, 2011) for the analyzed roadways: two models on tangents and two models on the circular curves. Speed observations on the circular curves with a radius greater than 500 meters were included in the same database of tangents because drivers' behavior is very similar to that adopted on the tangent segments. The models were created using the statistics software. All parameters included in the models are significant with a 95% confidence level. The best specification of the ordinary - least-square model (OLS) of operating speeds on tangents, in kilometers per hour, with a length greater than 500 meters is as follows with adjusted coefficient of determination (ρ^2) of the model equal to 0.83:

$$V_{85T} = 79.67 + 2.8 \cdot 10^{-3} \cdot L + 0.011 \cdot R_{PC}^{3/2} - 0.23 \cdot R_{PC} + 0.15 \cdot V_{85PC} - 2.40 \cdot INT - 4.94 \cdot PD \tag{1}$$

The best specification of the OLS model for operating speeds on the tangents with a length of less than 500 meters, in kilometers per hour, is as follows with adjusted coefficient for the determination (ρ2) equal to 0.89:

$$V_{85T} = 61.56 + 2.4 \cdot 10^{-4} \cdot R_{PC}^2 - 0.11 \cdot R_{PC} + 0.017 \cdot D - 3.29 \cdot INT + 0.30 \cdot V_{85PC} - 3.41 \cdot PD \tag{2}$$

The best specification of the OLS model for operating speeds on horizontal curves with a mean CCR value of less than 240grad/km, in kilometers per hour, is as follows with adjusted coefficient for the determination (ρ^2) equal to 0.81:

$$V_{85C} = 55.74 + 5.57 \cdot W - 0.038 \cdot CCR_S + 10^{-5} \cdot CCR_S^{\,2} - 0.03 \cdot L - 0.48 \cdot RES - 4.65 \cdot INT + 7.3 \cdot 10^{-4} \cdot L_{PT} - 0.064 \cdot CCR - 0.30 \cdot PD \tag{3}$$

The best specification of the OLS model for operating speeds on horizontal curves with a mean CCR value greater than 240 grad/km, in kilometers per hour, is as follows with adjusted coefficient for the determination (ρ2) equal to 0.72:

$$V_{85C} = 59.16 + 0.20 \cdot W^2 - 0.023 \cdot CCR_S + 10^{-5} \cdot CCR_S^{\,2} - 0.69 \cdot RES + 8.8 \cdot 10^{-2} \cdot R_{PC} - 3.5 \cdot 10^{-4} \cdot R^2{}_{PC} - 2.63 \cdot PD \tag{4}$$

where:

- V_{85T} = predicted operating speed value on tangent segment (km/h);
- L= total tangent length (m);
- RPC= radius of the preceding curve (m);
- V_{85PC}= operating speed in the middle section of the preceding curve (km/h);
- INT= intersection indicator, which is equal to 1 if the intersection is located 150 m before or after the surveyed location and 0 otherwise;
- PD= pavement distress indicator, which is equal to 0 if pavement distress is absent, which means that the pavement condition does not influence the driver free-speed behavior, and which is greater than 0 if the level of pavement distress is not low and this condition negatively influences the driver speed behavior, causing a speed decrease (1 if the distress is low, 2 if the distress is high, and 3 if the distress is very high);
- D= distance from the survey point from the end section of the preceding horizontal curve (in meters);
- V_{85C}= predicted operating speed on horizontal circular curve (km/h);
- W= width of travel lanes plus shoulders (m);
- RES= number of residential driveways per kilometer;
- LPT= length of preceding tangent (m).

3. Techniques used in data analysis

3.1. The ANN (Artificial Neural Network) multilayer approach

Inspiration for the structure of the ANN is taken from the structure and operating principles of the human brain. It is made up of neurons linked by connections that represent the connections between the biological synoptic neurons. The function of a biological neuron is to add its input and produce an output. This output is transmitted to subsequent neurons, through the synoptic joints, only if the transmitted signal is high (i.e., greater than a predetermined value), otherwise, the signal is not transmitted to the next neuron. In the network, therefore, a neuron calculates the weighted sum, by using Equ.5 (considering the input xi and weights wi) and compares it with a threshold value; if the sum is greater than the "threshold" value, the neuron "lights up" and the signal is transmitted. Otherwise, the neuron does not turn on and the flow stops.

$$I = \sum_{i=1}^{n} w_i \cdot x_i \tag{5}$$

The activation value "u_i" rather than "u_j", connected to weight W_{ij}, is a function of the weighted sum of the input. This function may take various forms. In this study, a function of type Equ.6 was used.

$$u_j = \frac{1}{1+e^{-(\Sigma(i) w_{ij} uj + \vartheta j)}} \tag{6}$$

where θ_j is the bias unit u_j (i.e. the degree of sensitivity of u_j when it receives an input signal from u_i).

3.2. Multi Layer Perceptron (MLP) and the Back Propagation (BP) algorithm

In this study, a neural network with MLP architecture was used. Training was carried out using the Back Propagation (BP) algorithm. The neurons (or units) that comprise this type of network are organized into layers: an input layer, an output and a number of intermediate layers between input and output referred to as hidden, defined by the user. Initially the weights are assigned random values normalized in the range [0,1] or [-0.5, +0.5] and initially there is a pattern "p" input to the network: Xp = (X0, X1, X2, ..., Xn-1) with X0 = 1 and a vector consisting of the output values Tp = (T0, T1, T2, ..., Tm-1). In this way, the network will consist of (n-1) input neurons and (m-1) output neurons. The "weighted sum of the inputs" for each layer is calculated using equation 5, and its value of activation, i.e. output, using equation 6. Then, the weights must be changed so that the output of the network (i.e. the output of the last layer of neurons) increasingly approximates the target set by the user. We defined a function error Equ.7 proportional to the square of the difference between the output and target for all output neurons:

$$E_p = \frac{1}{2}\sum_j (T_{pj} - O_{pj})^2 \tag{7}$$

Subsequently, Back Propagation is applied i.e. the weights are varied so that error Ep tends towards zero (starting from the last layer to the first). We define, for the current pattern p, a variation Δw_{ij} of weight w_{ij} between the neuron i and j that given by Equ.8.

$$\Delta_p w_{ij} = -\alpha \frac{\partial E_p}{\partial w_{ij}} + \beta \Delta_{p-1} w_{ij} \tag{8}$$

where α is the learning coefficient (learning rate), β is momentum, and Δp-1wij is the variation of the same weight calculated according to the previous model. The new weights are given by Equ.9.

$$w_{ij}{}^{new} = w_{ij}{}^{old} + \Delta_p w_{ij} \tag{9}$$

The variation of the weights is calculated starting from the layer of output neurons and backward toward the first hidden layer. The derivatives can be calculated using equations 10.

$$\Delta_p w \ = \alpha A_i \delta_j + \beta \Delta_{p-1} w_{ij} \tag{10}$$

where Ai is the value of the i-th neuron of the layer being considered; δj is given by Equ.11 if we are considering the output layer.

$$\delta_j = (T_j - O_j) O_j (1 - O_j) \tag{11}$$

It is given by Eq.12 for all other intermediate layers.

$$\delta_j = I_j (1 - I_j) \sum_k w_{jk} \delta_k \tag{12}$$

To train a network, this process must be run many times (at least 1,000) with different patterns, each of which features a different weight. This process is performed until the error is less than a predetermined value (the value is set by the user). When the process converges, the network is ready to classify a new input with an unknown target. The parameters α and β are chosen by the user with values between 0 and 1; in the present study α was assumed equal to 0.5 and β equal to 0.4. In particular, α is linked to the convergence of the network.

4. Data collection

The collection of speed data was carried out in 2009 on dry roads and during daylight hours. The measurements were conducted by using a light detection and ranging KV laser (LIDAR gun). The analyzed roadways fall within the Salerno Province network (southern Italy): low-volume roads SP 30, SP 52, SP 312, SP 135, SP 262, SS 166, SS 103, and SS 426, located partly in the region of Piana del Sele and partly in the region of Vallo di Diano. The parameters (Discetti et al., 2011; Esposito et al., 2011) observed for each roadway section are speed values, roadway features [width of the lane, radius of the horizontal curve, the curvature change rate (CCR) of the homogeneous segment, CCR of a single circular curve (CCRS), and tangent and curve lengths], the presence of intersections, the number of residential driveways per kilometer, and pavement distress. The geometric elements used to study driver speed behavior (Dell'Acqua et al., 2013c; Esposito et al., 2012) included 80 tangent segments, 40 circular elements, and 70 tangent–curve–tangent transitions to study deceleration and acceleration actions.

5. Results and discussion: ANN applications

5.1. ANN application

ANN models (See Figure 1 and Table 1) were obtained by using Artificial Neural Network technique shown in the previous section. The variables in ANN models are shown in Table 2 and only 70% of whole database was used in the calibration phase and the remaining data for verification. Different configurations were considered for the architecture of the neural network. The best architecture of ANN network is shown for each model in Figure 1. Moreover, Table 1 shows ANN.

5.2. ANN and empirical model comparison

Figures 2 shows the comparison of the plotted profiles for V_{85} values by using the corresponding ANN models/OLS methods related to geometric features and observed V_{85} values (De Luca and Dell'Acqua, 2012). The profiles show that ANN models offer more reliable results in terms of predicted operating speed than those returned by OLS method on all circular curves and on tangents lengths greater than 500m. For tangents length less than 500 m, OLS method is to be preferred to ANN procedure.

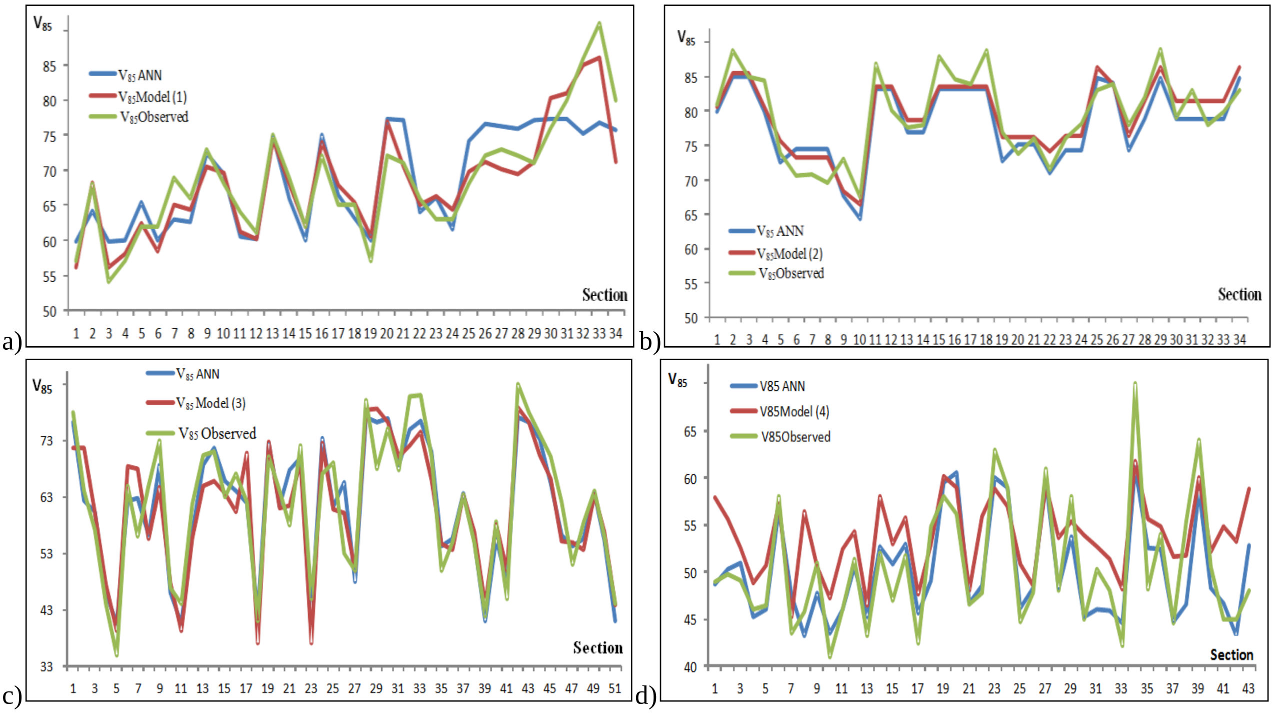

Fig. 2.
Comparing models
a) Tangent Length>500m; b) Tangent Length <500m; c) CCR>240 grad/km; d) CCR<240 grad/km

Table 2 returns a comparison between residuals (difference between Predicted and observed V_{85}) returned by ANN procedure and OLS method for predicting operating speed values.

Table 2
Residuals analysis of predicted operating speed values

Case	ANN Residual	OLS Residual	Mean observed V_{85}	V_{85} Dev. Std.
L>500m	307.0	319.3	77.5	9.03
L<500m	126.5	71.4	68.6	8.13
CCR>240	101.2	200.8	50.4	6.54
CCR<240	171.0	221.2	61.6	11.93

6. Conclusions

The study has shown ANN procedure for calibrating operating speed (V_{85}) prediction models on tangent segments and circular curves on two-lane rural roads in low-volume conditions located in Southern Italy. Predicted V_{85} values coming from ANN procedure and OLS method used in a previous research work of the authors were compared on the same study road network. Two V_{85} prediction models for tangents (greater than and of less than 500 meters) were calibrated, and two V_{85} prediction models on circular curves (curves with a mean CCR value of less than and greater than 240grad/km) were calibrated.The results have shown that the residuals of ANN procedure are in general lower than those calculated by using OLS method for predicting V_{85} value on tangent segments and circular curves with CCR>240grad/km. In particular, it was observed that ANN procedure reaches more consistency than OLS method particularly when the observed speeds present a standard deviation of less than 10 km/h. Future developments are addressed to improve the variables type and to increase the number of study two-lane rural roads in low-volume conditions to give more reliability (Capaldo and Biggiero, 2014; Russo et al., 2013) and effectiveness (Dell'Acqua et al., 2016; De Luca, 2015; Russo et al., 2015) of statistical results.

SPEED DIAGRAMS: AN UPDATED RELATIONSHIP FOR V_{85}

[2] *University of Calabria, Rende, Italy*

Abstract: Speed diagrams of rural roads are an essential tool for the good geometric road design, for the control, in existing roads, of the geometrical layout characteristics (visibility distances, coordination between successive elements, the climbing lane for the heavy vehicles). Again they can be used, with information to vehicle weights, to improve sizing of safety barriers. These operations can be successfully performed if it will increase the knowledge of the speed characteristics in road sections with greater accident risk.
There are many studies realized on driver speed, in the last two decades; the resulting values and relationships are different from each other. Every Country has an its own relationship that characterizes the behavior of drivers in road environment: it is not possible to define a single formula for different situations and different drivers. In the paper, in particular, it describes an experimental relationship obtained of the distributions of running speeds of vehicles recorded, in significant periods of time, in different conditions of geometric path and different provinces. The surveys were conducted on various two-lane roads and have allowed to identify a good relationship for the dependence of the operating speed of the layout geometrical elements not only with the free flow speed (FFS, 85th-percentile) and the CCR (curvature change rate), but also with the road longitudinal gradient. It has used the measurements over 40 sections of rural roads with two-lane single carriageway, width greater than 7 meters, long straights and curvature radii greater than 100 meters. The roads are located in Italy, in the provinces of Grosseto, Caserta, Benevento, Cosenza and Naples, with different plan and elevation views of alignment. The environmental conditions of surveys have always been clear weather and daylight. The values obtained were interpolated with different relations and the results were compared with those obtained from other authors in the same geometric conditions.

Keywords: operating speed, prediction models, speed diagrams, driver behavior, infrastructure design, road safety.

1. Introduction

High speed is a major problem in road safety (Benedetto et al., 2004; Capaldo and Nasti, 2012; Dell'Acqua, 2011a; De Luca et al., 2011). The main benefit of high speed traffic flow is that the cost attributed to travel time is reduced, despite higher running costs together with the associated higher environmental costs. The improvements of vehicle performance and road standards promote even higher speeds. The impacts at high speed, however, have a higher kinetic energy and this contributes to increase the severity for the consequences of road accidents.
The driver adopts a behavior that is the compromise between the conditioning due to a number of external factors (road conditions, environmental conditions, etc.) and a series of ability, motivation, internal stimuli (attention, driving ability both physical and mental, etc.). The result of this workload is the spot speed of the vehicle driving: in some favorable conditions, the speed coincides with the desired one; in other cases driver proceeds at a slower speed. Such behavior is always characterized by a series of identifiable factors that allow the study.
In a road section, the value of free flow speed measured fluctuate randomly around a reference value which is constant for all the time in which the environmental conditions (flow, lighting, weather) remain constant. If a parity of every other condition, observation section is changed and it changes on a section with different geometric characteristics, also changes the characteristic value of the measured speed. In the speed realized by drivers (a measure of user behavior) it can be distinguished a systematic component and a random component. The systematic component (the average or an appropriate percentile of speed distributions) varies as function of environmental conditions while the random value varies among the drivers. Still it can distinguish two ways to vary the systematic speed component when varying environmental conditions: in a section, with similar layout conditions, the reference value of the distribution of the instantaneous speed will be a function of traffic flow; along a road path, with a steady flow and not very high, with constant condition of weather and lighting, the changes in instantaneous speed will be related to the geometry of the road. The used value to measure the systematic component of recorded speeds is the 85th-percentile speed, defined as that speed below which 85% of vehicles operate under free flow conditions, on clean, dry road surfaces.
So speed and behavioral study are part of a wide research program that the DICEA is conducting for many years (Capaldo et al., 1997; Capaldo, 2004a; Capaldo, 2004b; Dell'Acqua and Russo, 2010).
The studies that are being carried out on the one hand consider regression models (Ordinary Least-Square Model, OLS) such as the proposed one and the others already mentioned, and on the other consider models based on Artificial Intelligence Computational methods (ACI). In recent years, ACI methods have found Increasing applications in the management of transportation infrastructures. For example many researchers have employed ANN procedures to analyze factors related to data processing. In the scientific papers, many research works have regarded the road safety issues, driver speed behavior or traffic flows. Often on safety procedures is carried an comparison between results coming from ordinary simulation method and/or ANN.
But compare the predicted operating speed on tangents and circular curves for low-volume roads by using two different statistical approaches (ANN versus Ordinary Least-Square Model, OLS) is topic for another paper.

[1] Corresponding author: fcapaldo@unina.it

In this paper shows the results of a never interrupted survey project (Capaldo et al., 1998;) that developed an operating speed prediction models for horizontal curves and tangents on low-volume roads: speed model is associated with the CCR (Curvature Change Rate) value of the curve and with the absolute value of road longitudinal gradient (slope). This relationship has maintained a good validity in time and is now has been revised with new surveys and a more extensive database.

2. Operating speed prediction models

There are many surveys realized on speed, in the last two decades; the resulting values and relationships are different from each other. Every Country has an its own relationship that characterizes the behavior of drivers in the road environment: it is not possible to define a single formula for different situations and different drivers. In the paper, in particular, it describes an experimental relationship obtained of the distributions of running speeds of vehicles recorded, in significant periods of time, in different conditions of geometric path.
Many studies have recorded values for speed on tangents and circular curves. Rather than referring to the simple curve radius, it is preferred to consider the CCR. The *CCR* (Curvature Change Rate) is defined as curvature change rate of the single circular curve with transition curves (clothoids or Euler's spirals). Furthermore, this design parameter includes the influence of the transition curves (in front of and behind the circular curve), and regards the overall length and the deflection angle at the curved sites. CCR, whose analytical value is given by the ratio between the total angular deviation in gon (grads), and the overall length of the curvilinear section, is calculated from the following formula (1):

$$CCR = \frac{Lcl1/2R + Lc/R + Lcl2/2R}{L} * \frac{200}{\pi} * 1000 \approx \frac{Lcl1/2R + Lc/R + Lcl2/2R}{L} * 63700 \quad (1)$$

where:

- *CCR* [gon/km]: Curvature Change Rate;
- *R* [m]: Radius of circular curve;
- L_{cl1} e L_{cl2} [m]: Length of clothoids in front and behind;
- L_c [m]: Length of circular curve;
- L [km] = $L_{cl1} + L_c + L_{cl2}$: Length of curve.

Without regarding transition curves, the formula reads: *CCR* = 63700/R

In order to determine operating speeds, expressed herein by the 85th-percentile speeds, with respect to the curvature change rate of the single circular curve with transition curves (CCR), some known operating speed backgrounds for a number of Countries are given in Table 1.

Table 1
Some empirical relationship of operative speed for rural roads with two bidirectional lanes for a number of countries and their speed limits

Country	Speed Limit	V_{85}	*Coefficient of determination* R^2	
Germany	100	$10^6/(8270+8.01\bullet CCR)$	0.73	(2)
USA	90	$103.04-0.053\bullet CCR$	0.80	(3)
Grece	110	$10^6/(10150.1+8.529\bullet CCR)$	0.81	(4)
France	90	$102/\left[1+346/(63700/CCR)^{1.5}\right]$	-	(5)
Italy	90	$(118-1.8\lvert i\%\rvert)\bullet(1-34.61/R)$ $(118-1.8\lvert i\%\rvert)\bullet(1-CCR/1870)^2$	0.91, (Capaldo et. al., 1998)	(6)
		$93.96-57.3\bullet CCR+20\bullet CCR^2$	0.86, (IASPIS, 2001)	(7)
Lebanon	90	$91.03-0.056\bullet CCR$	0.81	
Australia	90	$101.2-0.075\bullet CCR$	0.87	(8)

Adapted from Lamm et al. (1999)

In Table 1 only the relationship (6) considers the speed change due to *R* or *CCR* and also to the absolute value of the longitudinal slope (|*i%*|).
Four prediction models were later developed by Ordinary Least-Square Model (OLS) Method (Dell'Acqua and Russo,

[2] Relationship shows in this form (with CCR) for the first time since its publication.

2011) for the analyzed roadways: two models on tangents and two models on the circular curves. Speed observations on the circular curves with a radius greater than 500 meters were included in the same database of tangents because drivers' behavior is very similar to that adopted on the tangent segments. The models were created using multiple correlations. All parameters included in the models are significant with a 95% confidence level. The best specification of the OLS model of operating speeds on tangents, in kilometers per hour, with a length greater than 500 meters is as follows with adjusted coefficient of determination (R^2) of the model equal to 0.83:

$$V_{85T} = 59.16 + 0.20 \cdot W^2 - 0.023 \cdot CCR_S + 10^{-5} \cdot {CCR_S}^2 - 0.69 \cdot RES + 8.8 \cdot 10^{-2} \cdot R_{PC} - 3.5 \cdot 10^{-4} \cdot R_{PC}^2 - 2.63 \cdot PD \tag{9}$$

The best specification of the OLS model for operating speeds on the tangents with a length of less than 500 meters, in kilometers per hour, is as follows with R^2 equal to 0.89:

$$V_{85T} = 61.56 + 2.4 \cdot 10^{-4} \cdot R_{PC}^2 - 0.11 \cdot R_{PC} + 0.017 \cdot D - 3.29 \cdot INT + 0.30 \cdot V_{85PC} - 3.41 \cdot PD \tag{10}$$

The best specification of the OLS model for operating speeds on horizontal curves with a mean CCR value of less than 240gon/km, in kilometers per hour, is as follows with R^2 equal to 0.81:

$$V_{85C} = 55.74 + 5.57 \cdot W - 0.038 \cdot CCR_S + 10^{-5} \cdot {CCR_S}^2 - 0.03 \cdot L - 0.48 \cdot RES - 4.65 \cdot INT + 7.3 \cdot 10^{-4} \cdot L_{PT} - 0.064 \cdot CCR - 0.30 \cdot PD \tag{11}$$

The best specification of the OLS model for operating speeds on horizontal curves with a mean CCR value greater than 240 gon/km, in kilometers per hour, is as follows with R^2 equal to 0.72:

$$V_{85C} = 59.16 + 0.20 \cdot W^2 - 0.023 \cdot CCR_S + 10^{-5} \cdot {CCR_S}^2 - 0.69 \cdot RES + 8.8 \cdot 10^{-2} \cdot R_{PC} - 3.5 \cdot 10^{-4} \cdot R^2{}_{PC} - 2.63 \cdot PD \tag{12}$$

where:

- V_{85T} = predicted operating speed value on tangent segment (km/h);
- L= total tangent length (m);
- R_{PC}= radius of the preceding curve (m);
- V_{85PC}= operating speed in the middle section of the preceding curve (km/h);
- INT= intersection indicator, which is equal to 1 if the intersection is located 150 m before or after the surveyed location and 0 otherwise;
- PD= pavement distress indicator, which is equal to 0 if pavement distress is absent, which means that the pavement condition does not influence the driver free-speed behavior, and which is greater than 0 if the level of pavement distress is not low and this condition negatively influences the driver speed behavior, causing a speed decrease (1 if the distress is low, 2 if the distress is high, and 3 if the distress is very high);
- D= distance from the survey point from the end section of the preceding horizontal curve (in meters);
- V_{85C}= predicted operating speed on horizontal circular curve (km/h);
- W= width of travel lanes plus shoulders (m);
- RES= number of residential driveways per kilometer;
- LPT= length of preceding tangent (m).

The relationship (6) shown in Table 1 was proposed already in the late '90. This had a good R^2 (0.91) among all other correlations but the data base on which had been validated consisted of 16 velocity distributions recorded on 6 low-volume roads with carriageway width more than 7 m, with radii not less than 200 m and longitudinal gradients not more than 7%. The survey sections were all far from intersections and on paths with tangents of at least 500 m. The good correlation was obtained with an essential formulation which had consider only two parameters. The project was never abandoned and it was consistently increased the data base and carried out sample verifies in order to possible corrections on older speed distributions.

In this note it proposes latest revision of this relationship in function of a series of new surveys that have led to over 40 of the data recording sections.

3. Data acquisition, analysis and relationship structure

The experimental survey of this study started out as one of the principle objectives in amplifying the samples of available data relative to the speed analysis. The acquisition of the necessary data, if it do not have specific devices to automatic recording, is an intensive work in terms of time. The measurements were made using videos shot with cameras on sections of low-volume roads with two-lane, single carriageway and using measured bases. The system remains preferable to others because it allows possible control of numerical faults through a repeat of the analysis of recorded images.

For each survey beforehand were known the geometrical characteristics of the paths of which the sections were elements. During the video taking it has always had the attention of hide the devices to prevent drivers could exchange

these as approved speed detectors (radar type, speed cameras and the like). Video devices was positioned always sideways and out of to the road.
The new surveys available were 43 and were carried out on sections of state roads in the provinces of Benevento, Caserta, Cosenza, Grosseto and Naples, with different horizontal and vertical layout characteristics. All measurements were made in clear weather and daylight. In Fig. 1 and 2 two images of the SS 88 about to 82 km in the travel direction from Campobasso to Benevento.

Fig. 1.
SS 88 at km 82.650 in the direction from Campobasso to Benevento

Fig. 2.
SS 88 at km 82.450 in the direction from Campobasso to Benevento

The tangent sections were 26, horizontal curves with constant radius 17 with a minimum radius of 90 m and a maximum of 800 m. The flat sections were 21, those with some longitudinal slope were 22, with a maximum of 7%. The road width was always greater than about 8 m (7.80 m).
For each of the investigated sections and for each vehicle it have been recorded transit times between the delimiting sights on the measured basis, obtaining the following data: type of vehicle, direction of origin, transit time on the first relative sight, speed, distance from the vehicle preceding.
Given that it is always worked with bases measured between 20 and 30 m, the recorded speed can be considered instantaneous. To compare the speed measurements it is always referred to measurements carried out in low traffic conditions using the flow diagrams, with the flow rates expressed in equivalent cars per hour.
The flow diagrams representing the relation between flows and speeds in a road section: when traffic conditions changing (flow rate) it records the corresponding speed variations. Is possible to obtain a diagram in which the flow rates are constituted only by «passenger cars» if calculates a coefficient of equivalence for the commercial means (heavy). Working, then, with the flow-speed diagrams and with capacity expressed in equivalent cars/hours, it has eliminated the interferences due to the various traffic flows and their heterogeneous composition (passenger cars and trucks).

4. Data analysis, relationship structure and results

The surveyed data were necessary to search a relation between the geometric road characteristics and the so-called operating speed (FFS or maximum 85th-percentile value of the speeds surveyed on long tangents), because it represents «the speed which drivers tend to go at when they are not conditioned by traffic or by horizontal alignment».
This parameter of the velocity distributions was evaluated using the CCR and road longitudinal gradient (slope).
Compared to the original formulation (Capaldo et al., 1997) it is preferred to leave the old parameter R and to privilege the most diffused JRC, recalling the perfect equivalence (less than some scale factors) between the two parameters if there are no clothoids on the circular curves.

Table 2
Correlations of V_{85} with other recorded data as the roadway width, the absolute value of the longitudinal slope, the CCR and also intersections/km or intersection factor

	V_{85}	Road. Width	|i%|	CCR	Int./km	Int. Factor
V_{85}	1					
Road. Width	-0,22885	1				
|i%|	-0,32958	0,331712	1			
CCR	-0,88427	0,158298	0,072008	1		
Int./km	-0,27383	-0,128760	-0,013150	0,214628	1	
Int. Factor	-0,20146	-0,093530	0,127715	0,154211	0,750982	1

The recorded data include for each section: 85th-percentile value of the speeds, the width of the roadway, the absolute value of the longitudinal slope, the CCR. It has also recorded information on interference to the uninterrupted flows by intersections as the number of them or another correlated value for km. In Table 2 are shown the correlations of all these factors registered.

The carriageway width, as also indicated various works, influence the speed only if it is clearly less than 7 m. At this point of the investigation, the correlations with intersection data, or with a value related, appear be as little significant. It remains to investigate the correlation between the absolute value of the longitudinal slope and the CCR.

By multiple regressions of speed on the absolute value of the longitudinal slope and the CCR have been obtained coefficients for the relationship:

$$V_{85} = a_0 + a_1 * |i\%| + a_2 * CCR \tag{13}$$

$$V_{85} = 119.20 + 1.33 * |i\%| - 0.057 * CCR \tag{14}$$

Where a_0 is the running speed on a flat tangent; $|i\%|$ is the absolute value of the longitudinal slope. The analysis has furnished for the relationship (14) the coefficient of determination R^2 of 0.853 (Fig. 3). The basic structure of the interpolation relationship has been modified in the form the (15) to considering that the running speed in a curved section is a function not only of the radius of curvature but also of the approach speed to the curve itself which generally is a function of the characteristics of the path.

$$V_{85} = (a_0 + a_1 * |i\%|) + (a_0 + a_1 * |i\%|) * a_3 * CCR = (a_0 + a_1 * |i\%|) + (1 + CCR/a_3) \tag{15}$$

$$V_{85} = (119.20 - 1.33 * |i\%|) + (1 - CCR/2034) \tag{16}$$

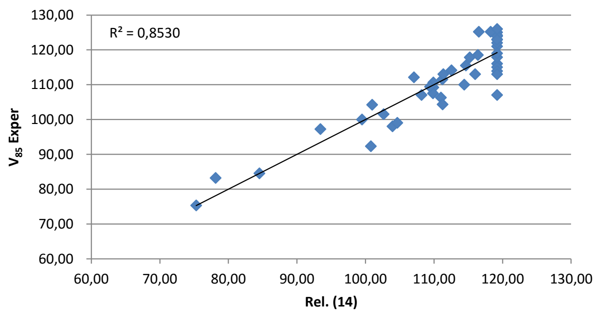

Fig. 3.
Experimental speed versus the calculated speed with the report (14) and coefficient of determination (R^2)

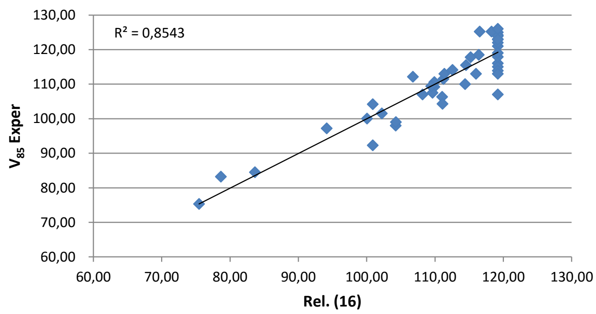

Fig. 4.
Experimental speed versus the calculated speed with the report (16) and coefficient of determination (R^2)

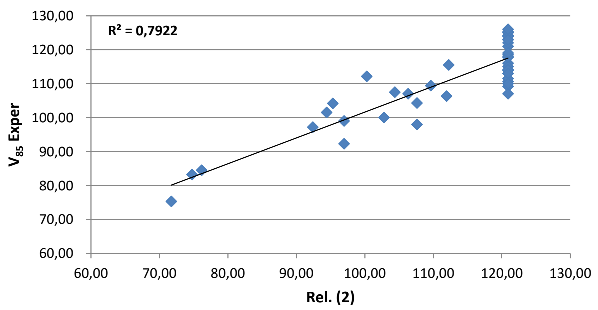

Fig. 5.
Experimental speed versus the calculated speed with the report (2) and coefficient of determination (R^2)

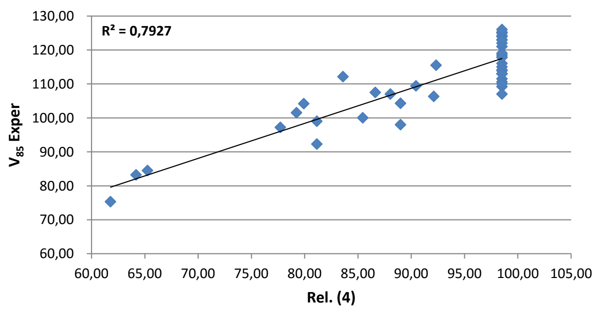

Fig. 6.
Experimental speed versus the calculated speed with the report (4) and coefficient of determination (R^2)

The coefficient a_3 of the (15) is equal to 2034 in the (16). It was obtained by making minimum the sum of the differences squares of the experimental speed values on curve and those obtained from the (16). For this latter relationship is obtained a coefficient of determination R^2 0.854 (Fig. 4).

5. Results comparison

The relation (16) has a best fit to the experimental data. It requires little information to provide a very reliable value of the desired speed. It would be interesting to operate also a comparison with the results of the shows relationships from (9) to (12) but they need a larger number of parameters which were not available by surveys made, or, at least, they were only partly.

It was decided to compare the experimental surveying data with some more similar relationship, and it chose to utilize, among those including in Table 1, the relations (2) and (4) relating to two Countries such as Germany and Greece. The Table 3 shows some examples between the compared values and, in the ending rows, they are summarized the minimum, maximum and average of the absolute values of the percentage differences between the experimental and data calculated with the corresponding relationship. The two Fig. 5 and Fig. 6 show the complete graphs of the values calculated with the two cited relationship and those of the starting experimental data, They indicate a good degree of adaptation of the two relation to the data, although much lower than that of the report (16).

Table 3

Where: Exp. V_{85}: 85th percentile of measured experimental speed (km/h); Rel. (xx): resulted speed form relationship (xx); Diff% (XX): percentage difference between the calculated value with the relationship (XX) that of the experimental V_{85}; Diff% min, max, average: minimum, maximum and average of the absolute values of percentage difference.

4. Some considerations

The regression analysis was conducted only on specified parameters. To make the speeds analysis independent by traffic flows it has worked with the flow diagrams made for each survey. It may be noted that the speed of certain sections were different from those which might have been expected under the same geometric conditions. The drivers proceeded more slowly because of the presence of a some number of intersections along the way. It has tried some correlations directly with information as number of intersections per km and/or for the direction of travel, as well as with numeric values that could derive from this basic information. To date the results have not been satisfactory and it must wait for a future survey research in order to investigate this further step.

The wider data base has led to a relationship not too different from that proposed in the past and the relative increase of the interpolation constants was due more to the data increase that the small difference in the control values on old surveys.

5. Conclusion

The study of the relationship between speed and environmental parameters (road, geometric characteristics, lighting, pavement conditions, visibility, etc.) is important to formulate best criteria for the road design and for the verification of existing roads, criteria which are more close to reality. It 'a study necessary but costly, in terms of time, and the results are valid in the territorial areas not too large. The reason that influences the location of the expressions is on the one hand the difference between the methodologies related to construction of the infrastructures , especially, the orography of the various Countries and on the other hand, certainly not secondary factor, is the difference of driver behaviors.
Sure the speed study through an extensive database related on driving events, realize a picture of what can be defined as the product of emotional experiences of drivers which are reflected in the control, or less, of the velocity vector and with this in control of their passenger cars. And for this reason the relationships like the one presented contribute to the provision of this aspect of the driving behavior. Furthermore, through the knowledge of some basic factors (bending radius and longitudinal slope) that have been shown to influence drivers, it can try to intervene to change, to the benefit of safety.

Abstract: Speeding is a general problem in traffic and exploring factors underlying the choice of speed is an important task. The relationship between various measures of traffic speed, under free flow conditions, and speed limits is investigated for two groups of sites in southern Italy. The effect of speed limits on traffic speed is estimated for both groups of sites.

Keywords: driver behavior, design, safety, speed limit.

1. Introduction

High speed is a major problem in road safety (Benedetto et al., 2004; Capaldo and Nasti, 2012; Dell'Acqua, 2011a; De Luca et al., 2011). The main benefit of high speed traffic flow is that the cost attributed to travel time is reduced, despite higher running costs together with the associated higher environmental costs. The improvements of vehicle performance and road standards promote even higher speeds. Increased speeding will likely result in augmenting the number of traffic accidents, as well as the severity of the injuries, resulting from high-speed accidents. Many drivers are aware of the negative effects of speed, exceeding the speed limit is nevertheless one of the most frequent traffic violations. A feature of road safety is that inferences based on statistical information from individual studies are often imprecise. Designers need to take expert judgment and results from similar surveys into account when drawing conclusions. Traditional approaches have many points of weakness connected to the inadequacy of the accident database and to the low reliability of statistical methods for the diagnosis of the cause. Techniques based on artificial intelligence have been investigated (De Luca, 2015; Mauro et al., 2013). Hazard analysis approach has given important, very applicable and reliable results (Russo et al., 2014b; Russo et al., 2016a). The best point estimates for the link between speed and accidents suggest that the number of accidents could be substantially reduced; by either enforcing lower speed limits or at least reducing the spread of vehicle speeds. To determine the attitudes of drivers towards speed limits and understand their behavior, a survey (Figure 1) of Italian drivers was undertaken in two roadway environments.

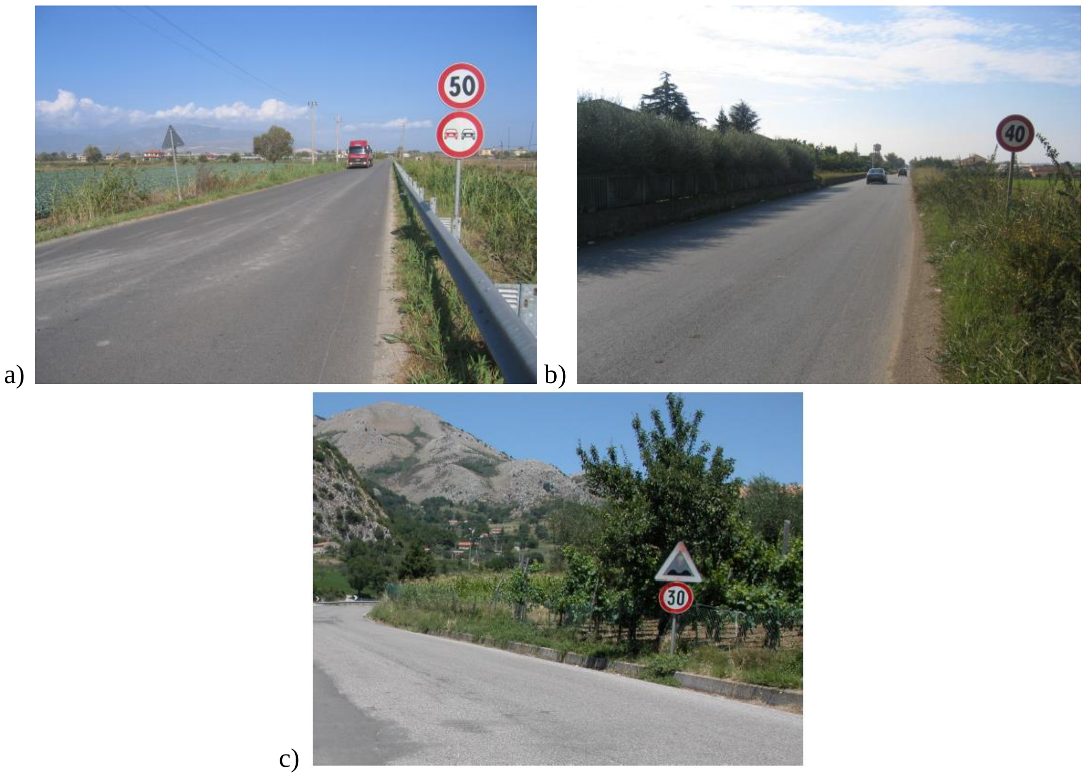

Fig. 1.
a) Posted speed limit on tangent of SP312; b) on tangent of SP30b; c) on curve of SS166

Speed limits are the usual means of controlling vehicle speeds under free flow conditions on high speed road links. Their efficiency depends, partly, on the level of policing and the size of penalties. It is generally acknowledged that

[1] Corresponding author: francesco.abbondati@unina.it

85th percentile operating speeds exceed posted speeds (Fambro et al., 1997; Fitzpatrick et al., 1995; Fitzpatrick et al., 1999; Fitzpatrick et al., 2000; Krammes et al., 1994; Parker, 1997). Bella (2005) in Italy proposed relationships between operating speed and other road features using driving simulator. Many of these reports have also demonstrated, in USA, that the 50th percentile operating speed either is near or exceeds the posted speed limit. The methods used to set speed limits have been reviewed by several authors (Parker, 1985; Parker, 1992). A review was conducted by an Institute of Transportation Engineers Technical Committee (2001) with the following findings. Also, in Sweden, it was found that most of the drivers exceeded the 90 km/h speed limit, a finding that corresponds with previous research (Haglund and Aberg, 2000). The relationship between various measures of traffic speed, under free flow conditions, and accident rate is investigated for two groups of sites, one in the Tyne and Wear County of the UK and the other in Bahrain (Aljanahi et al., 1999). The results suggest that speed limits are a reasonably effective means of reducing traffic speed in free flow conditions. The effects of speed limit (SL), percentage of heavy vehicles (HV), number of lanes (L), trip length (TL) and length of section (LS) were statistically significant despite the small sample sizes.

$$V_{85} = 6.45 + 0.875 \cdot SL - 1.56 \cdot HV + 2.10 \cdot TL + 0.72 \cdot ln(LS) \qquad \rho^2 = 0.699 \tag{1}$$

$$V_{85} = 42.58 + 0.289 \cdot SL - 0.480 \cdot HV + 2.08 \cdot L + 7.45 \cdot TL + 1.64 \cdot ln(LS) \qquad \rho^2 = 0.926 \tag{2}$$

Circular horizontal curves on rural two-lane highways in Nebraska with posted speeds of 88, 96 and 104 km/h were investigated (Schurr et al., 2002) in 40 study sites to determine the relationship between design, operating and posted speeds. The authors found that as the posted speed increases mean speed increases; operating speed on approach curve (V_{85app}) is assumed to have an obvious relationship with posted speed (V_p) and average daily traffic (T_{ADT}):

$$V_{85app} = 70.2 + 0.434 \cdot V_p - 0.001307 \cdot T_{ADT} \qquad \rho^2 = 0.910 \tag{3}$$

Fitzpatrick et al. (2003) noticed that is a common practice setting speed limits (SL) at the 85th percentile of operating speeds (V_{85}). There is a suspicion however that operating and design speeds are often not in agreement. Posting of speed limits based on operating speeds that are inconsistent with design speed can create potential safety problems. Speed limits have been observed to be posted that are higher than the design speed which may also have a safety impact. Therefore, the authors found the next model for tangent sections:

$$V_{85} = 7.675 + 0.980 \cdot SL \qquad \rho^2 = 0.904 \tag{4}$$

A study (Stamtiadis and Gong, 2007a) was performed to examine the relationship among design speeds, operating speeds and speed limits and develop guidelines for selecting the appropriate speeds to minimize any existing discrepancies along these speeds. Roadway sections were selected throughout Kentucky based on the relationship between design speed and posted speed limit and on the number of lanes. The relationship between operating speed and posted speed limit showed a uniform pattern (V_{85} = operating speed, DS = design speed, LC = length of curve, DL = difference between design speed and speed limit, R = radius of curvature):

$$V_{85} = 26.903 + 0.495 \cdot DS + 0.003 \cdot LC - 0.437 \cdot DL - 1633.64 \cdot \frac{1}{R} \qquad \rho^2 = 0.537 \tag{5}$$

In general, these two speed metrics were different and the posted speed limit was lower than the 85th operating speeds. This was true for all groups considered except those where the design speed was lower than the posted speed limit. For those sections, the two speed metrics were not statistically significant. This may indicate that when posted speed limits were higher than design speeds, drivers operated based not on design speed but on posted speed limits. There has been a significant amount of research on the topic of differential speed limits for heavy trucks and automobiles on rural interstate highways; however, the results and conclusions are often conflicting or do not provide definitive conclusions. One of the reasons for the inconsistency of the results is that the research does not address the separate distributions of truck and automobile speeds (Johnson and Pawar, 2007). To determine the attitudes of drivers towards speed limits and understand their behavior, a survey of Greek drivers was undertaken in three roadway environments (Psarianos et al., 2007). The findings from this survey indicate that, in general, drivers do not observe the posted speed limits and feel that they can determine when they can travel at higher or lower speeds. Drivers also feel that the posted speed limits can be exceeded at certain situations and they believe that a range of 10 km/h is an acceptable value. The results of the survey indicate that the roadway environment plays a more important role than the posted speed limit in selecting the appropriate operating speed. This leads to the basic conclusion that often times posted speed limits are placed without the proper considerations and are implemented due to a variety of reasons often unrelated to the roadway environment (Stamatiadis and Gong, 2007b). An Italian research demonstrated that the only simple apposition of a speed limit is not often able to guarantee a good reduction of drivers' speed in safety (Marchionna and Perco, 2006). Also new Italian standards will introduce the practice to set speed limits at the 85th percentile of operating speeds (Ministero delle Infrastrutture e dei Trasporti, 2006).

Given these issues, an experimental investigation was carried out that to examine the relationship between operating speeds and speed limits, and develop models for selecting the appropriate speeds to minimize discrepancies between them.

2. Speed data

2.1. Data collection

For the purpose of this research (Dell'Acqua et al., 2007), we used three traffic counters "KV Laser" made by SODI Scientifica. The operation feature of these devices is endowed with two photocells. It is based on the issue and the receipt of a laser couple beams perpendicularly direct to the road axis. The laser beams are issued to low-power (class 1) and, therefore, harmless for the vehicles occupants. The vehicle speed is inferred by the passage of the vehicle from the first photocell to the second one. The measurer is lodged in fixed posting on an easel or (where possible) in the cabin of a car parked on the margins of the roadway or inside a box in order to protect it from the drivers sight, not to condition its behavior.

Fig. 2.
Traffic counters

The instrument has been fed by a battery (accumulator to the lead) to guarantee the autonomy of its operation, but the low consumption would also have allowed to use the endowments of the support vehicle. The tool is endowed with a hard memory to record data; then all the information can be transferred with the devoted software, on a personal computer through a serial cable. To every vehicular passage the devices have recorded:
- *time* (date, hour, minutes, seconds);
- *vehicle speed* (in km/h);
- *length of vehicle* (in meters);
- *traveling direction* (binary variable: "direction 0" and "direction 1").

The available mass storage has allowed managing an elevated number of transits for long temporal intervals. In the transfer of the data some light anomalies of the system of relief have been managed, relative, for instance, to the case of passages outdistanced less than 0.5 seconds (vehicles traveling in opposite directions that simultaneously pass in front of the laser measurer). Besides the axis of the laser beams couple were projected on surfaces with low reflecting ability and sometimes the axles of the vehicle were not perpendicular to the axis of the roadway. They are other anomalies recorded. The first objective is the debugging of correlations between the operating speeds (V_{85}) and the geometric features of the roads. The first group of investigations 2003-04 observed for twelve hours one or two stations belonging to 63 roads, for a total of 85 stations and over thousand hours of survey. We classified the infrastructures in operation of the vehicle speeds and of the traffic volumes. The purpose is to select the ones characterized by the more elevated operating speeds (73-99 Km/h) and by the lower vehicular flow ($Q < 400$ vehicles/h). The data were collected on 6 highways belonging to road network of the Province of Salerno: SP52, SS166, SS426 in "Vallo di Diano" and SP30b, SP262, SP312 in "Piana del Sele".

2.2. Data analysis

We preventively filtered the data for getting a sample of transits really representative of the passages of cars in freeflow conditions, because the environmental speed is more possible on "faster" layouts and operating speeds is necessarily referred to low traffic conditions. So we enucleated the only transits of vehicles with:
- *length* between 2.5 and 9.0 meters, like to cars for private use;
- *gap* superior to 5 seconds from the preceding vehicle (absence of loan conditioning among the vehicles).

The roads have been qualified with:
- V_{85} (index of the probability of attainment of the environmental speeds V_{env});
- *traffic flow* related to the whole period of survey (12 hours);
- the *hourly volumes* are almost always inferior resulted to the value of threshold individualizes the free flow conditions.

2.3. Statistical analysis

A basic assumption for speeds is that the observations obtained from a normal distribution. This assumption needs to be verified for each site. Moreover, for the sites where few spot speeds were obtained, it was more important to check the normality before using the collected data in the analysis. Insufficient spot speed samples cannot represent the real population, and therefore they will likely produce meaningless results. The normality check procedure includes the Kolmogorov-Smirnov test and probability plotting. It is a non-parametric test for goodness-of-fit. It can be used to test whether the distribution of a sample matches a specific distribution, in this case the normal distribution (Figure 3). If the p-value of the Kolmogorov-Smirnov test is less than the significance level considered, the distribution of the sample is not normal at the significance level. If the p-value is greater than the significance level, a probability plot should be used to determine whether the distribution of a sample is normal or not. The software of Statistical Package for the Social Sciences (SPSS) was used for the Kolmogorov-Smirnov test. In this study, both regression methods were used to develop a prediction model for operating speed of passenger vehicles and speed limit.

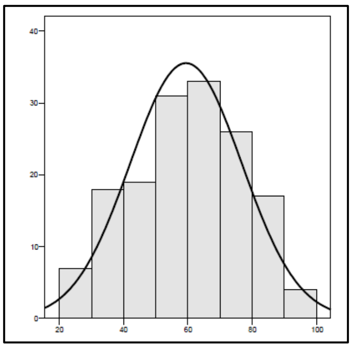

Fig. 3.
Speed frequency on highway SP312 with SPL=50 Km/h

2.4. Results

In this section the relationship among speeds, speed limits and other variables is described.
The use of the speed limit is one of the possible measures for the reduction of the driver speed. This measure has the meaningful advantage to be extremely economic and quick implementation. Nevertheless, the posted speed limit can be not effectiveness to reduce the speed, frustrating the possible safety analysis. There is the possibility to apply a limitation of the speed through opportune signals, because it is not possible to modify operating speed profile intervening on geometric layout (or using other measures that can induce the driver to reduce the speed). Nevertheless, this measure is not always able to get the anticipated effect, particularly when speed limit does not correspond to the speed that driver holds acceptable on the perceived risk. Unfortunately, the limitation of speed is used often in an unsuitable way, more to avoid responsibility for the road administration whether to furnish a useful information to driver. The consequence is that there is a diffused habit to the speed limits and the ones correctly installed do not become effectiveness. To verify the correspondence among the 85th percentile speed and the speed limit the research group surveyed 32 tangents (72 m ≤ L ≤ 4787 m; mean length: L = 2130 m; standard deviation: 1789.8 m) and 15 curves (55 m ≤ R ≤ 280 m; mean radius: R = 149 m; standard deviation: 83.8 m) belonging to 6 double direction one carriageway rural roads on level or hilly terrain, characterized by road width between 5.00 m and 10.00 m (Dell'Acqua et al., 2007). The data collection was held by using traffic counters with infrared rays type active. It was done hiding the equipment and the operator to the traffic to avoid that speeds could be influenced by their presence. The relieves have been conducted in the daytime, with good visibility and dry paving conditions. We surveyed isolated passenger cars (gap 5 seconds) for every study site. The posted speed limit in 47 sites was constituted by the special vertical signal. In the other 7 cases we referred to the generalized speed limit for the local rural roads foreseen by the Italian Road Legislation N.C.d.S. (90 km/h). In Figure 4.a you can see the operating speed on curves and in Figure 4.b the operating speed on tangents in function of the posted speed limit. These two plots clearly show operating speeds are generally superior to the speed limit.

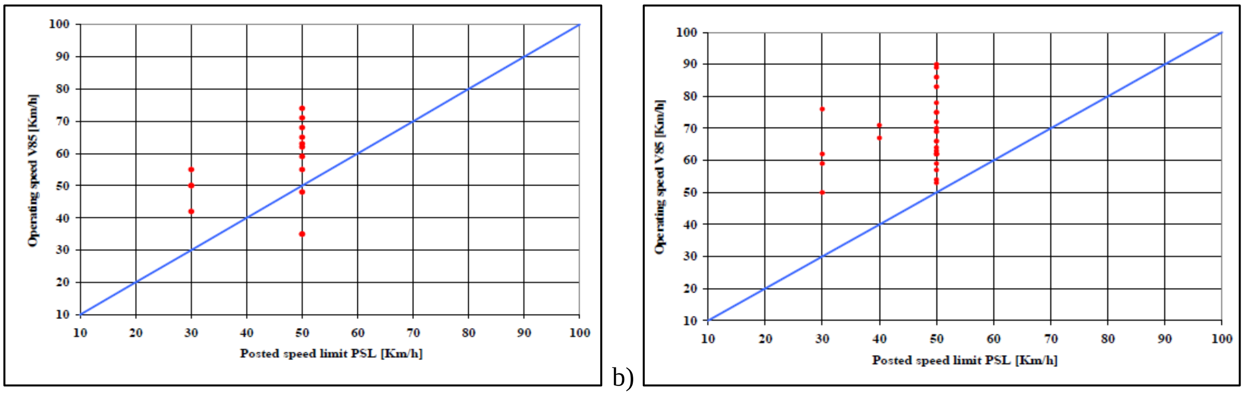

Fig. 4.
a) Operating speed V_{85} versus posted speed limit PSL on curves; b) on tangents

The writing research group calculated $\Delta V_{P,T} = V_{85T} - PSL$ for posted speed limit on tangent, $\Delta V_{P,C} = V_{85C} - PSL$, for posted speed limit on curve and $\Delta V_G = V_{env} - GSL$ for generalized speed limit. Where:
- $\Delta V_{P,T}$ is the difference between operating speed on tangent V_{85T} and posted speed limit *PSL*;
- $\Delta V_{P,C}$ is the difference between operating speed on curve V_{85C} and posted speed limit *PSL*;
- ΔV_G is the difference between environmental speed on homogeneous section V_{env} and generalized speed limit *GSL*.

The environmental speed represent the speed which drivers go when they are conditioned only by the geometry of the single road elements and is defined by the Australian Standards as the maximum speed of the 85th percentile of the speeds surveyed on longer tangents or on curves with a very large radius belonging to a homogenous road section. The geometric feature of every homogenous highway section were characterized with the ratio between the sum of the deflection angles (γi) of successive elements of the horizontal alignment and the length of the homogeneous road section. This parameter is the Curvature Change Rate C.C.R. = Σi|γi|/d [gon/km]. The homogeneous sections are identified by various constant slope interpolating the overall curvature.

Table 1
Surveyed environmental speeds

	Highway	*C.C.R.* [gon/km]	V_{env} [km/h]
1	SS 166	589.264	73
2	SS 426	235.793	83
3	SP 52	159.277	86
4	SP 312	47.156	88
5	SS 426	63.288	96
6	SP 30b	9.601	97
7	SP 262	9.916	103

Table II shows the Mean differences of speed observed, the 85th percentile and the standard deviation SD.

Table 2
Average differences of speeds

	$V_{P,T}$ [km/h]	$V_{P,C}$ [km/h]	V_G [km/h]
Mean	22.34	10.80	-0.57
85^{th}	34.05	20.90	7.60
SD	11.16	12.70	10.08

The average differences of speed observed is 11 km/h and standard deviation is 12.7 km/h on curves; 22 km/h and 11.2 km/h on tangents; -0.57 km/h and 10.1 km/h on homogeneous sections. It is a meaningful value in fact it underlines is not possible to really confuse the speed limit with the practiced speed like in a road safety analysis. The histograms of the distribution of speeds, the posted speed limit, the operating speed and the mean speed are plotted in figures 5, 6 and 7 for some measurement stations on tangents and curves with posted speed limits of 30 and 50 km/h.

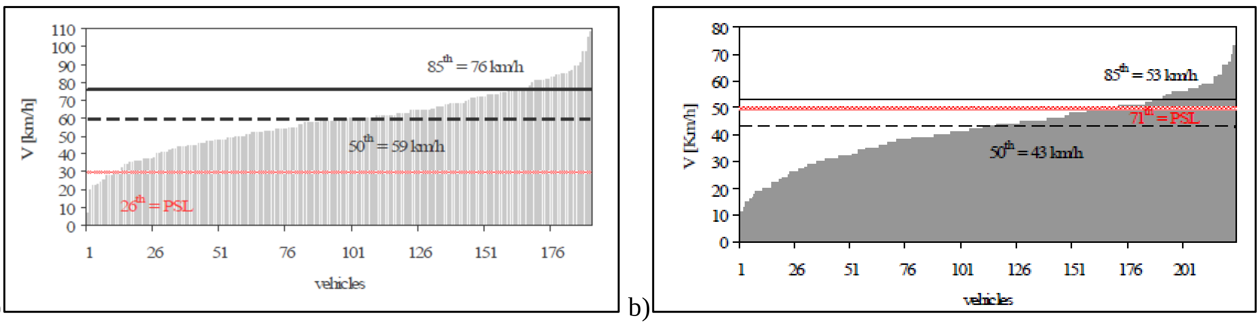

Fig. 5.
a) SS426 Tangent (L= 502 m); b) SP312 Tangent (L= 2908 m)

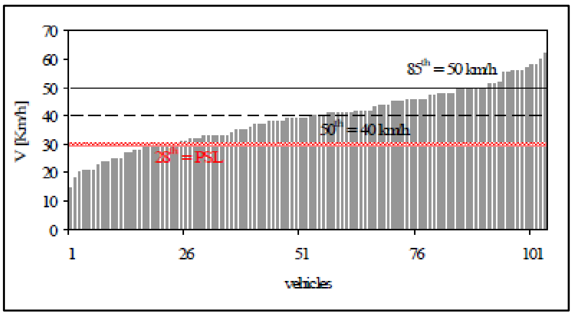

Fig. 6.
SS166 Tangent (L= 76 m)

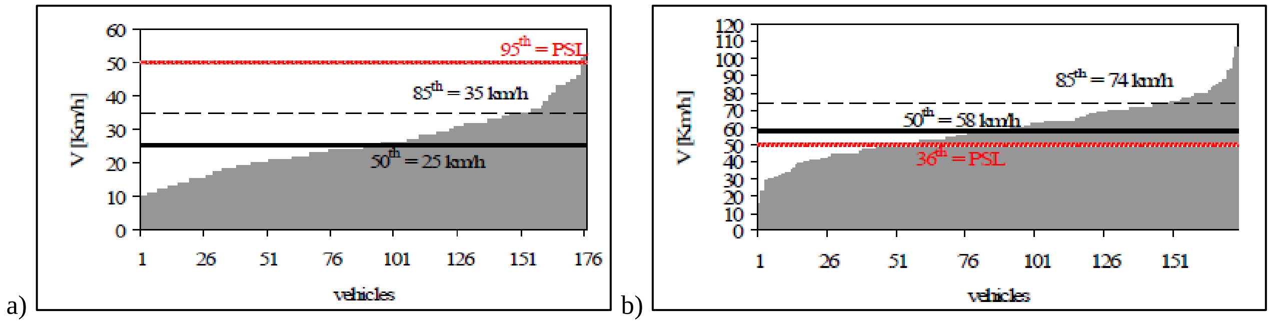

Fig. 7.
a) SP312 Curve (R= 100 m); b) SS426 Curve (R= 240 m)

The database is formed by two groups of study sites for evaluating the effects of the posted speed limits in drivers' behaviour: in the former (32 tangents and 15 curves) there are vertical signals; in the latter (7 homogeneous sections) the generalized speed limit of the highway is considered. We observed the speed differences: $(\Delta V_{P,T})_{max}$ = 46 km/h for tangents with posted speed limit; $(\Delta V_{P,C})_{max}$ = 25 km/h for curve with posted speed limit and $(\Delta V_{G})_{max}$ = 13 km/h for the homogeneous sections with generalized speed limit (Dell'Acqua et al., 2007). This last result depends on the geometric features of roads layout, that meaningfully conditions the driver speed behaviour. As a result the ΔV is greater where the signal is because it is normally inferior to the generalized limit. These results are not generally valid, because the sample is a little numerous. The data are not homogeneous, in fact operating speed is divided among the different limits for the stations with vertical speed limit signal, and instead it refers on generalized limit for the "faster" stations on homogeneous sections. Finally we notice that in both cases the difference of observed values of speeds is greater where the signal is located. Particularly on tangents the geometric features have less influence on the speed in comparison to the curves. It underlines that the posted speed limit is not respected: the mean operating speed on tangents is 70 km/h (49 km/h $\leq V_{85} \leq$ 90 km/h, standard deviation: 10.8 km/h); the mean operating speed on curves is 57 km/h (35 km/h $\leq V_{85} \leq$ 74 km/h, standard deviation: 11.9 km/h); the mean operating speed on homogeneous sections is 92 km/h (83 km/h $\leq V_{85} \leq$ 103 km/h, standard deviation: 7.7 km/h). As a result the speeds are greater where the signal is not, because it is normally inferior to the generalized limit (Dell'Acqua et al., 2007).

3. Conclusions

The existing rural road network is much extended and a wide part of it is represented by one carriageway double direction rural roads in Italy. It requires interventions of adjustment to improve the quality of the offered service and the safety mobility management (Dell'Acqua and Russo, 2011b; Dell'Acqua et al., 2005). These interventions obviously have effected following a sustainable economic approach and it is necessary to make sure that the allocated resource achieves the maximum possible benefits. To guarantee this objective, it is necessary to support the planning of road safety interventions with an analysis able to verify the correctness of the proposals of adjustment by using the most opportune tools (Abbondati et al., 2016; De Luca and Dell'Acqua, 2012). One of the most important tools of this analysis is the diagram of the 85th percentile speed. It allows effecting numerous important verifications because it is able to effectively represent the real speed held by the drivers. The measures that allow to reduce this speed to adjust it to the demands of the intervention of adjustment of roads are different, but everyone characterized by very varying ratio costs/benefits. There is surely the posted speed limit among the most economic feed-forward. To verify the effectiveness of this measure, the writers observed operating speed on 51 study sites and compared the results with the posted speed limit. The analyses clearly suggest that the 85th percentile speed is meaningfully always superior to the posted speed limit. There is also an exception: geometric characteristics influence some sites more than the speed limit. Therefore it should be accompanied to other specific measures, in the cases in which the necessity of this reduction is tightly tied to the safety of the mobility.

SESSION 13: SUSTAINABLE TRANSPORT

HOW TO AVOID ARBITRARY DECISIONS? – ACTUAL VS. TARGET DECISION MAKING

Johannes Kehrer[1]
[1] *TU Vienna, Institute of Transportation, Research Center of Railway Engineering, Traffic Economics and Ropeways, Karlspatz 13/230-2, A-1140 Wien, Austria*

Abstract: Selecting the proper transport system for implementation in urban public transport networks is a complex field of decision-making. In order to achieve rational decision-making, different options have to be compared by uniform decision criteria. This paper gives a brief overview of available transport systems and their characteristics. Subsequently, decision criteria, which are meant to be taken into account in the decision making process are identified. The presented transport systems are investigated for their performance regarding these criteria. Furthermore, the ideal decision making process is defined and tools for comparing different solution alternatives, whilst taking the previously defined criteria into account are investigated. These items are discussed, based on literature review and expert interviews on real and ongoing decision-making processes. The results show that there are many decision criteria that affect third parties who are not directly involved in the decision-making process. These are known as external effects and these criteria are often non-monetary parameters. That is why multi criteria analysis turns out to be the most suitable for comparing solution alternatives since they are not dependent on solely monetary values. A comparison between target and actual decision-making processes shows, that in reality political preferences of decision makers divert actual processes from the "ideal" decision-making process. Therefore the ideal decision-making process is defined in theory and is compared to actual decision making processes, based on two case studies in Austria. A comparison between target and actual decision-making, a discussion of the results and an answer to the posed research question conclude the paper. Finally, an outlook on future questions raised during the work on the paper is given.

Keywords: multiple criteria decision-making, comparison tools, decision criteria for public transport modal choice, impact analysis, benefit analysis, cost-impact analysis, cost-benefit analysis, lifecycle cost analysis, multi criteria analysis.

1. Introduction

Conurbations in central Europe have been growing constantly over the last decades which has led to higher traffic volumes within those metropolitan areas. In order to cope with this increase in traffic volumes, public transportation networks have been extended and improved. Especially the central areas of conurbations have a high building density and organically developed structures which strictly constrain the space available for transportation matters. Therefore, it is essential to find the proper transport system to meet these constraints. Furthermore, aspects like emissions of different kinds as well as efficient building and operation costs have to be taken into account.
This paper focusses on the entire decision making process regarding modal choice for urban transport development. First, the most common transport systems in operation in Europe are selected for further investigation, followed by an overview of key decision criteria. Subsequently the ideal decision making process is defined and the most suitable tool for taking all predefined criteria into account is identified. A key part of this paper is the comparison of actual vs. target decision making in that field. Therefore, two actual decision making processes in Austria, one in Linz and one in Graz, are investigated, based on interviews with involved parties in the process.

2. Transport Systems

Transport Systems can be categorized by different standards. (Vuchic, 2007) identified multiple options for categorizing urban public transport systems, however, the conventional classification , which distinguishes between mixed surface transport (public transport is sharing its way with motorized private transport), accelerated surface transport (level crossings but separation from other transport modes in longitudinal direction) and, rapid transit which is usually entirely independet from other transport modes, is used throughout the paper. Additionally, so-called specialized public transport systems are identified in (Kehrer, 2013). They cannot be classified by conventional standards due to unique constraints. Cablecars, furniculars with its limitations regarding alignment (very steep gradients, but no curves possible) or ferries which can only operate on water surfaces are prime examples for that. Except for cablecars which are getting more and more popular in urban public transport, no specialized public transport system is further regarded in this paper.
Categorized transport modes range from various rail guided systems like trams and light rail systems to heavy rail commuter trains and subways. Conventional bus systems, both as operated in mixed traffic and as stand-alone bus rapid transit systems as well as trolley buses and guided buses are taken into account. The first two columns of Table 1 show the conventional classification of Europe's predominant public transport modes. The list aims to cover all relevant transport systems, with no claim to completeness.

3. Decision criteria

In order to holistically compare different transport systems for a selected case, decision criteria that have to been taken into account have to be determined.
Based on literature review all known impacts on their environment caused by public transport systems are named.
First of all parameters have been divided into two groups. Technical constraints as hard factors on the one hand and other decision criteria that should be taken into account in this field of decision making on the other.

3.1. Hard factors: technical constraints

The following key factors have been identified as hard constraints for public transport systems:

- Maximum capacity,
- Average travel speed,
- Ideal distance between stops,
- Maximum longitudinal gradient,
- Minimum curve radius,
- Track width.

In contrast to „soft factors“, a transport system has to meet the given constraints in order to even be taken into consideration for the decision-making process.
Maximum capacity can be seen as the key constraint for a public transport system. (Anderhub, Dorbritz, & Weidmann, 2008) define capacity as *„the maximum number of passengers per direction and per time unit and is the product of a transport unit's holding capacity and track capacity.“* Since ridership is the main premise for implementing a public transport service, the ex-ante estimated demand is likely to already rule out certain transport systems. For example if a sparsely populated area should be accessed by public transport, a subway with its high capacity will most likely not be taken into consideration. Table 1 shows maximum capacities of the investigated transport systems. The diverging values show that some systems will hardly ever directly compete with each other.
Average travel speed and the transport unit's maximum speed are "benchmarks for the quality of traffic flows" according to (Steierwald, Kühne, & Vogt, 2005). A combination of these two parameters, along with maximum capacity and acceleration performance lead to the **ideal distance between two stops**. Although not really a technical constraint, this parameter along with maximum capacity determines the transport function and capability of a transport system.
Apart from the performance indicators described above, geometrical constraints concerning a transport systems alignment apply. The key parameters in this field have been identified in (Kehrer, 2013) as **maximum longitudinal gradient**, **minimum curve radius** and **track width**. In general, bus systems can climb the steepest gradients and have the minimum curve radiuses compared to rail guided systems. Cable cars are an example for how a specialised transport system can cope with the steepest gradients of all investigated systems of up to 100% but can hardly be designed with curves. They can only be implemented at expensive stations where the cabins do not have to be taken off the rope temporarily.

Table 1
Maximum capacities of the investigated transport systems

Classification	transport system	max. holding capacity [Pers/TU]	max. track capacity [TU/h]	maximum capacity [Pers/h]
Mixed surface transport	Bus	40 - 120	60 - 180	2.400 -6.000
	Tram	100 - 500	60 - 120	4.000 - 15.000
Accelerated surface transport	BRT	40 - 150	60 -300	4.000 - 8.000
	LRT	100 - 750	40 - 60	6.000 - 20.000
	Guided Bus Systems	180 - 360	60 -120	10.000 - 18.000
Rapid transit	Subway	140 - 2400	20 - 40	10.000 - 70.000
	Commuter Trains	140 - 2000	10 - 30	8.000- 60.000
Specialized transport systems	Detachable cable car	4 - 38	240 - 500	2.000 - 6.000

Source: (Alshalalfah & Shalaby, 2010) (Vuchic, 2007)

3.2. Soft factors

The so-called "soft factors" are decision criteria that have to be taken into account when choosing a holistic approach in decision making in the field of modal choice. However, these factors are not strict constraints as compared to the "hard

factors" which can be seen as yes/no factors. Soft factors show effects of an eventual decision that have to be weighed and compared to other soft factors.
The following groups of soft factors have been identified as relevant decision criteria:

- Operational factors,
- Economic factors,
- Effects on the urban structure,
- External effects,
- Effects on ridership.

Operational factors in general, focus on the operator's point of view. However, these factors ultimately result in effects on ridership. (Steierwald, Kühne, & Vogt, 2005) name *reliability*, *flexibility* and *safety* as main performance indicators for operational matters. A transport system's performance on these factors cannot be quantified and therefore have been rated from „very low" to „very high".
Operational *reliability* primarily means a low breakdown susceptibility, as described by (Deutsch, 2003). However from an operator's point of view, low maintenance systems contribute to operational reliability (Steierwald, Kühne, & Vogt, 2005). Generally speaking, reliability grows with a transport system's growth in independence from other traffic flows. To name an example, cable cars can be seen as very reliable since they hardly ever breakdown and are not influenced by any other mode. However, high wind speeds can lead to a temporary breakdown.
The term *flexibility* unites various aspects that determine a transport system's ability to react to external influences on operations. That includes abilities like running around other vehicles, overtaking other vehicles, demand-driven disposition and flexible line layout. Table 2 shows an evaluation of the chosen transport systems regarding flexibility.
Similar to *reliability*, the *safety* of a transport system can directly be linked to its independence from other traffic flows since (Stoop & Thissen, 1997) describe accidents as combinations of both a system's complexity and its number of interfaces.
Economic factors can be divided into initial costs (building and planning), operational costs and external economic effects. Although general benchmarks for initial and operational costs of transport systems have been found in literature, they have to be carefully estimated for every given case.
External economic effects can be divided into direct effects and indirect effects as done by (Huang & Xia, 2011). Direct effects include jobs and orders directly caused by the implementation of a transport system. Since building projects of greater volumes have to be procured by an EU-wide tendering process, it is hardly possible to anticipate how many of the jobs actually benefit the local economy. However, direct effects can be set equal to the amount of money spent for implementation.
Indirect effects include the effect of the implementation of a public transport system on the surrounding areas, i.e. property values. Multiple studies have shown, that rail guided transport leads to a higher boost for property values with access to the transport system than bus transport as shown by (Pagliara & Papa, 2011). Heavy rail systems also lead to higher increases in property values than light rail systems, according to (Ibeas, Cordera, Dell'Olio, Coppola, & Dominguez, 2012).

Table 2
Aspects of flexibility

Classification	transport system	Running around	Overtaking	demand-driven disposition	flexible line-layout	overall flexibility
Mixed surface transport	Bus	very high	very high	very high	very high	**very high**
	Tram	average	low	high	average	**average**
Accelerated surface transport	BRT	gut	high	high	average	**high**
	LRT	low	low	high	average	**average**
	Guided Bus Systems					**average**
Rapid transit	Subway	niedrig	niedrig	high	very low	**low**
	Commuter Trains	average	average	high	average	**average**
Specialized transport systems	Detachable cable car	low	low	very high	very low	**average**

Source: (Kehrer, 2013)

The principle for urban planning of European cities is described as a combination of four targets: *high density*, *mix of uses*, *public spaces* and *ecologically promoted spaces* by (Steierwald, Kühne, & Vogt, 2005). **Effects on the urban structure** by transport systems affect those targets. Since it is very space-efficient, public transport is beneficial for *public spaces* and *ecologically promoted spaces*. Due to increased accessibility and therefore shorter trips for inhabitants, the implementation of public transport systems usually both lead to an increase in *density* and the *mix of uses* as described by (Ibeas, Cordera, Dell'Olio, Coppola, & Dominguez, 2012) and (Steierwald, Kühne, & Vogt, 2005).

External effects describe all effects on nature or third parties that cannot be directly translated into a monetary value (Zhibin, Wei, Xuedong, Chen, & Yaotian, 2010). These effects include greenhouse gas emissions, other gas emissions, particulate matter emissions, noise emissions, vibrations caused and energy efficiency of the transport system. It is essential to take these effects into account and weigh them accordingly in the decision making process. However, these effects are not further described at this point.

Effects on ridership include time savings, acceptance and barrier free accessibility. Time savings are usually the key argument for promoting new public transport systems and are therefore the highest valued benefit (Steierwald, Kühne, & Vogt, 2005). This benefit needs to be put in proper perspective however, since it is a well-known phenomenon that greater velocities lead to greater trip lengths instead of time savings on a macroscopic level and in the long run (Rollinger, Emberger, & Brezina, 2009). Acceptance by ridership has often been observed to depend on the transport system. For example, rail guided transport systems are expected attract more customers than bus systems on the same line (Brezina, 2004). Barrier free accessibility to public transport systems is legally required nowadays. Due to technical innovations, all investigated transport systems may be designed to meet these standards.

Apart from the decision criteria mentioned above, there might be additional influences on the decision making process. Political will for example might lead – due to political considerations or strategies – to a different direction than the other criteria. Certain models for financing infrastructure might also arbitrarily prefer one transport system over another.

4. Ideal decision making

First the ideal decision making process is defined, followed by an evaluation of tools that are best for taking multiple decision criteria into account.

4.1. Process flow

A decision is commonly known as the *choice/selection of one among several options*. (Steierwald, Kühne, & Vogt, 2005) have defined a general ideal decision making process, as illustrated in Fig. 1.

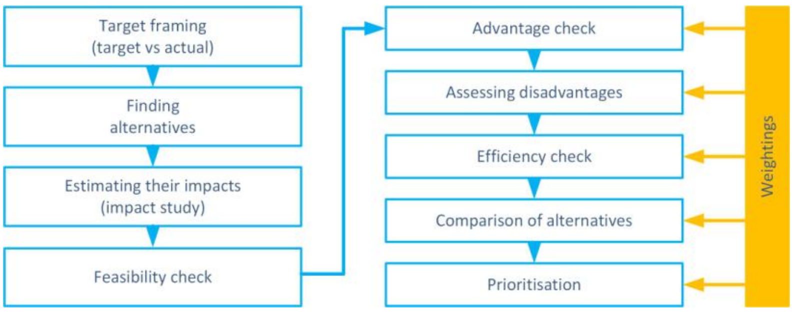

Fig. 1.
The ideal decision making process.
Source: (Steierwald, Kühne, & Vogt, 2005), own illustration

At the very beginning of a decision making process the target must be framed. It can be seen as the definition of a target, based on existing problems or challenges. In the field of public transportation this could be a desired shift from private to public transport, due to overcrowded streets. A target-seeking approach defines the constraints for the future decision making process. However, (De Bruijn & Veeneman, 2009) observed that decision making in the field of modal choice for public transport is mostly target-oriented. For example, decision makers already know, they want to implement a certain transport system and then define their targets. This can be seen as the first, big hindrance for a decision making process solely based on selected criteria.

Finding alternatives can be seen as the creative phase of the process. At this stage, both conventional and innovative approaches should be added to the list. In the field of modal choice this means all public transport systems mentioned above (and maybe even more) should be taken into account.

Estimating their impacts displays the impact of every single alternative. This step has to be carried out very carefully and with common standards, since they are weighed and directly involved in the comparison of alternatives later on.

The feasibility check filters out alternatives that cannot meet the targets defined in the very beginning. For the present field of decision making this may apply for „hard factors“ such as maximum capacity or geometrical constraints.

The advantage check eliminates all alternatives that are not advantageous for reaching the targets. Assessing the disadvantages leads to an elimination of all alternatives with serious disadvantages for the target.

In the efficiency check, disadvantages and advantages of different alternatives are compared in pairs. In the next step, comparison of the remaining alternatives are finally compared in pairs. At the very end of this decision making process, the alternatives are ranked – solely based on their performances in the steps before – and a „winner“ is named.

In the last five steps of the ideal decision making process, weightings are taken into account. Those weightings are subjective. However, criteria taken into account as well as their weightings have to be defined prior to assessing the alternatives‘performances in those fields.
At this stage, „soft factor“-decision criteria as mentioned above have to be assessed for each alternative. It is very important to use common standards and reach the same level of information for all alternatives, since these parameters are weighed and are the key part in the consecutive comparison of alternatives.
Having assessed all information, the comparison of alternatives should rank the alternatives according to their overall performance and finally name a winner.

4.1. Comparing alternatives

The last five steps – as seen in Fig. 1. – are not necessarily separated but can be accomplished by one evaluation method. According to (Hoffmann, 2013), standardised evaluation methods have to meet certain standards such as transparency, reliability of input data, consideration of all significant effects among others. If these standards are secured, a standardised evaluation method is preferable to other approaches.
The following standardised evaluation methods are examined concerning their suitability for modal choice:

- Impact analysis,
- Benefit analysis,
- Cost-impact analysis,
- Cost-benefit analysis,
- Lifecycle cost analysis (LCC),
- Multi criteria analysis.

Although the **impact analysis** is one of the very first steps in the ideal decision making process, it can also be used as the only evaluation method. (Hoffmann, 2013) describes it as an assessment of all effects of a project on its environment. These effects are displayed in a list but are not weighed or compared in a standardised way. This leaves plenty of room for arbitrary interpretation of decision makers. Since effects do not necessarily have to be quantified, external effects and other „soft“ decision criteria can easily be taken into account.
<u>Interpretation:</u> All in all, an impact analysis only leaves room for arbitrary decisions, since criteria and their weightings are not defined earlier in the decision making process.
A **benefit analysis** also just focuses on the effects of a project on its environment and does not take costs into account. In contrast to the impact analysis, a benefit analysis has a complex underlying model to compare alternatives to one another. Decision criteria and weightings are predefined. On that basis, a so called „grade of target achievement“ is calculated for every criteria and later on compared in a matrix. One alternative is finally awarded with the highest grade of target achievement.
<u>Interpretation:</u> The benefit analysis is a standardised method that can very well take into account various decision criteria. Criteria and weightings are selected beforehand in order to avoid arbitrary decisions. However, costs are not yet taken into account, although – especially for infrastructure projects – they are a key criterion.
The **cost-impact analysis** is based on the benefit analysis but also takes the costs of a project into account. The „grade of target achievement“ is finally divided by the project’s costs. It is essential to distribute and discount the costs over the whole operating life. The benefit per year divided by the costs is defined as the cost-benefit-quotient. The alternative with the highest quotient is the preferred one.
<u>Interpretation:</u> The cost benefit analysis can take all decision criteria – including costs – into account. Although external effects do not have to be monetarized in the first place, the comparison with the costs has a similar effect. Therefore, weighting of external effects has to be done carefully.
The **cost-benefit analysis** aims to reach a “complete monetarization of all relevant impacts of a measure (project), both taking costs and positive or negative costs caused by its impact into account.” (Hoffmann, 2013) The result of the cost benefit analysis can be displayed by two parameters. The benefit/cost quotient as an indicator for a projects efficiency on the one hand and the benefit-cost difference as a sign for a measure‘s total yield. Costs are usually discounted and distributed over a project’s lifespan.
<u>Interpretation:</u> the cost benefit analysis has two results. The efficiency criterion seems to be a fair parameter for comparing alternatives. The benefit-cost difference obviously tends to prefer big infrastructure projects over smaller ones. Besides, all external effects have to be monetarized before being taken into account.
The unique feature of the **lifecycle cost analysis** is its ability to ultimately display a project’s annuity as parameter for comparison. Since the indicator values of all selected decision criteria are discounted over a project’s expected lifespan, even projects with different lifespans can be compared to one another. Additionally, it is possible to publish intermediate accounts for investors, ridership or third parties. For example the amortization time can easily be assessed.
<u>Interpretation:</u> The lifecycle cost analysis results in an explicit recommendation for one alternative, independent from different alternatives‘ lifespans. It seems to provide the most holistic picture. In order to give a reliable forecast over an entire lifecycle, arising expenses have to be estimated well - regarding both time and volume. Additionally, external effects have to be monetarized over the whole lifecycle – not taking into account future social and environmental developments.

According to (Tudela, Akiki, & Cisternas, 2005), the **multi criteria analysis** is the most appropriate evaluation method in the field of decision making for infrastructure projects of any kind since they usually have multiple interdependent targets. In contrast to the methods mentioned above, the analytical hierarchy process (AHP) as a prime example for a multi criteria analysis converts a complex decision making process into a hierarchical structure. First targets are ranked (main target and subordinates). In the next step, decision criteria are rated in pairs, which ultimately leads to a consistent ranking of criteria (based on points given). Similarly, the alternatives are compared in pairs regarding the predefined and ranked decision criteria. They are also awarded with points according to their performance in each field. By using a mathematical model (not further elaborated in this paper), all criteria are carefully weighed. Finally, the different alternatives are ranked according to their performance and the criteria's hierarchy.
Interpretation: A multi criteria analysis like the AHP is a complex computerized mathematical model. Nevertheless, in this analysis, all decision criteria can be adequately taken into account without the need of monetarizing them before. Albeit complex, the AHP best takes into account external effects and other soft factors.
Based on the interpretations, Table 3 gives an overview over the strengths and weaknesses of the different analysis methods. Therefore, all methods have been rated concerning three criteria. Calculation effort characterizes the complexity of the underlying mathematical algorithm while required data accuracy states how precise input data has to be. For example, lifecycle cost analysis results in a precise and long term forecast. That is why its input data accuracy has to be extremely high. The last criterion is a method's ability to take non-monetary criteria into account. Whenever non-monetary criteria have to be translated into a monetary value to be taken into account, which leaves lots of room for inaccuracy. Multi criteria analysis, although it leads to high calculation efforts, is therefore found to be most suitable for decision-making processes in the field of modal choice for public transport systems. It does not require full data accuracy and can very well take decision criteria of any kind into account.

Table 3
Comparison of evaluation methods

evaluation method	calculation effort	required data accuracy	consideration of non-monetary criteria
Impact analysis	**very low**	**low**	**good**
Benefit analysis	**low**	**average**	**good**
Cost-impact analysis	**low**	**average**	**good**
Cost-benefit analysis	**average**	**high**	**average**
Lifecycle cost analysis	**high**	**high**	**average**
Multi criteria analysis	**high**	**low**	**very good**

4. Case studies: actual decision making

In this part, actual ongoing decision making processes are investigated with a focus on potential differences between the actual and the ideal process. Therefore, two such processes have been selected in the Austrian cities of Linz and Graz.

4.1. Second tram axis, Linz

In Linz, a city of nearly 200.000 inhabitants, two projects are currently under consideration: On the one hand, the "Mühlkreisbahn", a heavy rail line starting in the North of Linz, linking the north western hinterland to the city center, which is entirely isolated from the Austrian federal railway network and should somehow be integrated in an existing network. Political players favour a so called "tramtrain" which means a convertion of the heavy rail tracks to the narrow gauge tram tracks and an integration into the existing tram network of Linz.
The second project is an additional, 4,7 km long tram axis crossing the city center of Linz, linking the Northern branches of the network with the Southern ones. So far, only one overloaded axis connects the two parts of the network. The route of the second link has already been chosen. However, two options of alignment were considered: either leading the tracks on the surface in mixed traffic or accelerated mixed traffic, or building a tunnel structure.
Two areas of decision making could be identified:

- Modal choice for future operations on the existing "Mühlkreisbahn",
- Alignment of the second tram axis either on the surface or in a tunnel.

Due to operational reasons, a modal choice for the second public transport axis had not been taken into consideration.
As a hindrance for target seeking decision making as shown in the ideal decision making process, both areas of decision making have been politically debated in public. That is why political decision makers have declared their preferences early in the process. The only evaluation method for the modal choice of the "Mühlkreisbahn" so far is a feasibility study, a comparison of different alternatives was not done. The feasibility study is not available to the public.
The second tram axis through the city center had unanimously been decided in the city council of Linz without taking different transport systems into account. However, that decision appears plausible since the bottleneck of the tram network leads to unreliable operations.

In order to determine whether this axis should run on the surface or underground, a cost-benefit analysis has been carried out. The results were never made available to the public. Different sources claim that the costs for the underground alternative would be ten times the costs for the surface alternative. There has not been a comparison between the cost-benefit analyses of the two alternatives. However, transport authorities in Linz claim, the surface alternative would not be feasible due to "insuperable conflicts with car traffic."
The interests of tradespeople along the new tram axis are a special decision criterion taken into account in this process. In the beginning, they were in favour of the surface alternative. After an "information event" by the transport authorities of Linz, they changed their mind and now prefer the underground alternative.

4.2. Additional city crossing, Graz

In Graz (265.000 inhabitants) all 6 tram lines currently use the one city crossing through the "Herrengasse", a pedestrian area with lots of shops and restaurants. Similarly to Linz, the northern and southern branches of the network are only connected by this bottleneck. Brought up by political decision makers, a urban cable car along the river "Mur" has also been brought up to relieve the overcrowded tram lines through the "Herrengasse". Another goal is to increase the tram network's capacity due to an annual increase in ridership of about 2 to 3 %.
The following two areas of decision making have been identified:

- Modal choice for another city crossing,
- Increasing capacity of the existing tram network.

The urban cable car and a potential second tram axis connecting the northern and southern branches of the network, both alternatives have been regarded separately, the cable car has never been seen as an alternative to the tram link but as a separate project.
A feasibility study for the urban cable car was carried out and a cost estimation was published, estimating costs at 92 million Euros. Although this price had been published, the study never was. The feasibility study is only now being used for political lobbying.
Experts have compared different alternatives for the second tram link based on their feasibility. Since technical constraints such as curve radiuses and soft factors like expected vibration emissions in narrow roads already eliminated multiple alternatives, the route through "Elisabethstraße" emerged as the only one feasible and reasonable. This analysis – albeit not published – can be seen as an impact analysis as a basis for decision making.
In the second area of decision making, the acquisition of longer trams on the one hand and denser intervals on the other hand have been named as alternative approaches. Costs have been assessed for both alternatives and have been directly compared – favouring the acquisition of longer trams because of their lower costs. However, the use for ridership was not taken into account although denser intervals increase the comfort for ridership while longer trains only increase capacity. In town council in Graz, the decision for purchasing long trains was made.

5. Conclusion: Actual vs. target decision making

A comparison between the ideal decision making process in chapter 4, using a proper evaluation method to take into account multiple decision criteria as identified in chapter 3 and the actual decision making processes from the case studies in Linz and Graz, shows the following differences:

- Instead of a target-seeking approach driven by existing problems as being the very first step in the ideal decision making process both cities' areas of decision concerning modal choice are clearly target-oriented. Political decision-makers have favoured a certain solution from the very beginning. In Linz, the decision for a "tramtrain" has widely been promoted, while in Graz the tram link appears to be simply necessary while the urban cable car is politically driven – without taking other options under consideration,
- The second step of the process, finding alternatives, has been carried out for only two of the four areas of decision making – the alignment of the second tram axis in Linz as well as the increase in capacity in Graz,
- An impact analysis was only made in the case of raising the capacity of the tram network in Graz. Feasibility was checked for all areas of decision making,
- The following steps, where advantages, disadvantages and efficiency are tested, all alternatives are compared and finally the best option is named, in the ideal process has hardly been done in any of the defined areas of decision making in Graz and Linz. Although in Linz a cost-benefit analysis was carried out, it was only done for one option, leaving no room for comparison. In Graz, concerning the increase in capacity, costs were compared without displaying benefits of the alternatives,
- Decision criteria as outlined in chapter 3 have hardly been taken into account in the present actual decision making processes.

This comparison shows, that there is a huge gap between actual and target decision making in the field of public transportation. Although investments are large and usually funded by public authorities, the present decision making processes in Graz and Linz are not transparent processes.

Decision criteria that should be taken into account when comparing alternatives are hardly taken into account at all while methods for evaluation are sparsely used. Only fragments of the ideal decision making process can be identified in the actual processes.

This paper gives a recommendation for an ideal decision making process for the field of public transportation, i.e. modal choice. Apart from transport systems that should be taken into account, decision criteria that pose a significant impact on the environment were identified and were correlated with the named transport systems. However, the comparison with actual decision making processes show that political will and a target-oriented approach hinder an efficient, fair decision making process. Extending and evaluating the list of decision criteria that should be taken into account, as well as transport systems regarded, could be subjects for further research. Besides, more actual case studies could be compared to an ideal decision making process.

The findings of this paper draw a disillusioning picture and shows that arbitrary decisions seem to be the general rule.

THE SELECTION OF AN APPROPRIATE DISTRUBUTION CHANNEL

David Hrdý[1], Petr Průša[2]

[1,2] University of Pardubice, Jan Perner Transport Faculty, Department of Transport management, marketing and logistics, Pardubice, Czech Republic

Abstract: Selection of distribution channel type is an important decision of every manufacturing company. Appropriate choice of distribution channel can save a considerable cost while maintaining a high level of customer service. Determination of an appropriate strategy for the management of enterprise distribution channel.

Keywords: distribution logistics, distribution channel, ANP.

1. Introduction

In this article, the selection of the type of distribution channel is proposed using ANP method to determine the strength of influence of input factors on the target set of potential options.
Submitted model is very clear, understandable and according to the proposed methodology easy to implement, while also providing clear and understandable results during selection of the type of distribution channel.
The proposed model is primarily targeting for distribution of high value stone which need to decide which distribution strategy should be chosen or if to switch to another distribution strategy more suitable for the company needs. From the perspective of Multiple Criteria Decision-Analysis (MCDM) there is a wide range of methods used for dealing with choice of not only the type of distribution channel. MCDM history goes back about 40 years ago, with Alias, et al. (2008) reviewed over 70 of these techniques. Aruldoss et al. (2013), for example, compiled the inventory of multi-criterial methods with examples of their application. A plenty of studies uses MDCM to select and evaluate a supplier. Ho, et. al. (2010) and Agarwal, et. al. (2011) prepared a summary of MCDM techniques and their use in choosing a supplier evaluation (Table 1).

Singh & Malik, (2014) divided MCDM in their work into two categories: Multi-Attribute Decision Making (MADM) and Multi-Objective Decision Making (MODM). MADM focuses on the selection of the best alternative from the set of pre-defined alternatives where the set is limited by a number of input factors (Rao, 2007). One of the recent studies (Bernroider and Mitlöhner, 2015) seeks to raise awareness about the methodology of Multiple-attribute of Decision Making (MADM) in connection with Enterprise Resource plannig (ERP) projects. MODM on the other hand focuses on the design alternatives on the basis of the input factors (Zhang and Ruan, 2007). The possibilities are usually endless and aim is to choose the possibility that best fits the constraints and priorities set by the decision maker.

[1] Corresponding author: hrdy.david@gmail.com

The basis for the decision making in MCDM is Saaty‘s approach, which builds on a large number of studies. Sha and Che, (2006) used the AHP method to design a distribution chain network, where the focus was on the selection of a suitable partner, planning, distribution and manufacturing. Kahraman et al. (2003) dealt with a supplier selection using MCDM approach with help of the so-called Fuzzy AHP method.
The MCDM approach has appeared in a number of studies focused on distribution logistics. Mallen (1996) used this approach to select the distribution channel, where was this selection subdivided into several stages. Ho and Emrouznejad (2009) used a combination of AHP methods and logical operators for structural design of a distribution grid. Nilay Serbest and Vayvay (2008) proposed a model for selecting the most appropriate distribution channel using fuzzy AHP method.

2. Problem definition

Only very few manufacturers sell their goods directly to the final consumer. Between the producer and the final consumer there is a number of intermediaries, which make up the distribution chain. Distribution chain then can be understood as "part of the logistics chain that begins when the product leaves the company and ends at the final customer". Zylstra (2012) defined the objective of distribution chain as an overcoming of the time, space and property inconsistencies in the course of the movement of goods and services to customers. The structure of the distribution chain is determined by functions / activities that each organization in the chain carries out. From the discussed company’s perspective, which is the position of the manufacturer, its aim is to optimize distribution logistics for the customer. The aim is to design and build a suitable model for selecting the distribution chain, which will help the company reduce losses in the distribution part of the logistics chain. Discussed company currently uses the local branches in the Czech and Slovak Republic. The given model should provide an answer as to whether this is desirable or recommend switching to another type of distribution channel.
Lambert (2000) stated that most of the distribution chains is formed as a network of vertically aligned companies, without any fixed structure. The specific structure largely depends on the nature of the distributed product and nature of the target market of the company. Even for companies producing similar products the "best" structure of the distribution chain cannot be unambiguously determined (Gašparík, 2006). This should be created in relation to the overall business and marketing objectives of the company. The distribution chains thus differ in their length and width. Length is the number of distribution levels between the manufacturer and the customer. The width is given by the number of participants involved in the distribution at given level.
The distribution system must be therefore regularly inspected and modified by the manufacturer. Modification of distribution channels is essential if they are not functioning as planned, or if the shopping behaviour of customers changed, the market expanded, new competition appeared, new ways of distribution are created or product moves to the next stage of its life cycle. No distribution channel remains competitive throughout the product’s whole life cycle (Rosová, 2007). The first potential customers may be willing to pay the price for a big customer added-value, but other potential customers will move to a cheaper distribution routes.

3. Logical framework of the proposed model

The proposed model is based on the goal definition of the proposed study because of both maximization and minimization factors, and also include the dependencies between these factors (Kunz, 2010). To create the model all alternatives must be related to all limiting factors. As already mentioned, the creation of a model for the choice of distribution channel must take into account both the company’s perspective (minimization of cost factors) and the customer ‘s perspective (maximization of customer service factors).

3.1. Alternatives

A high importance is apparent when selecting a suitable distribution model for the given company. Distribution costs vary with the use of different types of distribution channels and it is at the discretion of company management to state its goal. For the proposed model four basic types of distribution channels were identified:

- ***Direct distribution*** - Products are stored in a central warehouse, or directly at the manufacturer, without the use of distribution centres in the distribution chain. Orders are processed directly and manufacturer delivers the order directly to the customer,
- ***Cross-dock centre*** - goods are assembled, merged, or tailored to customer requirements only after the production in cross-dock centre with added value. The customer receives the all his orders in one package.
- ***Local branches or warehouses / distribution centres*** - local branches cover the market in order to achieve a strategic position for the customer.
- ***Offtake by the customer*** - storage is provided in warehouses, or directly at the manufacturer (also in local offices), with the difference that the picking up of the goods is directed by the customer.

3.2. Selected factors of customer service

From the customer's perspective it is important to maximize customer service. Costantino and Di Graviá (2014) determined the factors of customer service, affecting the production rate of individual types of distribution channels. Adjusted factors useful for the proposed model are:

- ***Product Availability*** **-** period determining how available the demanded product is in distribution chain, it is a unit of time, it is goal is to maximize system availability,
- ***Customer satisfaction*** **-** a factor tracking customer‘s satisfaction with a type of the distribution chain. It is obtained by querying about customer's experience, it is goal is to achieve maximum customer satisfaction.
- ***Consolidation of orders*** **-** not all types of distribution chains are suitable for merging orders, the goal is to merge multiple potential orders so that the customer receives only one complete order,
- ***Order tracking*** **-** an important factor guaranteeing the possibility of accurate tracking of orders throughout the whole order process,
- ***Reliability of supply*** **-** the percent accuracy of ordered goods delivery,
- ***Speed of delivery*** **-** or also the distribution chain performance, measuring the speed of delivery of orders,
- ***Reverse logistics*** – the difficulty of reverse logistics for different types of distribution channels.

3.3. Selected cost criteria

Perspective of the company is limited by cost factors (Costantino and Di Graviá, 2014). Revised factors are:

- Information **-** in the distribution chain everything has to be properly monitored, planned and kept in records, This obviously results in rising of costs for each different distribution channels,
- Storage **-** every distribution channel retains a certain quantity of goods, which raises the cost of storage, handling, transportation within the warehouse etc. Expenses again depend on a type of distribution channel,
- Operational – covers all expenses related to the management and administration of the given type of distribution channel. More complex distribution channel arrangement results in higher operating costs,
- Boot **-** the initial costs of implementing new type of distribution channel, or the cost of switching to this channel from another type of distribution channel,
- Transport **-** traffic volume in the transport chain. Cost factor with big influences on the final results of cost criteria.

4. Proposed model

To achieve the best possible results in the choice of the type of grid a two-phase model was designed. The model uses a modified version of Delphi method and a method of ANP, which provides partial results subsequently used in the TOPSIS method. The process of the proposed model is shown in Figure 1:

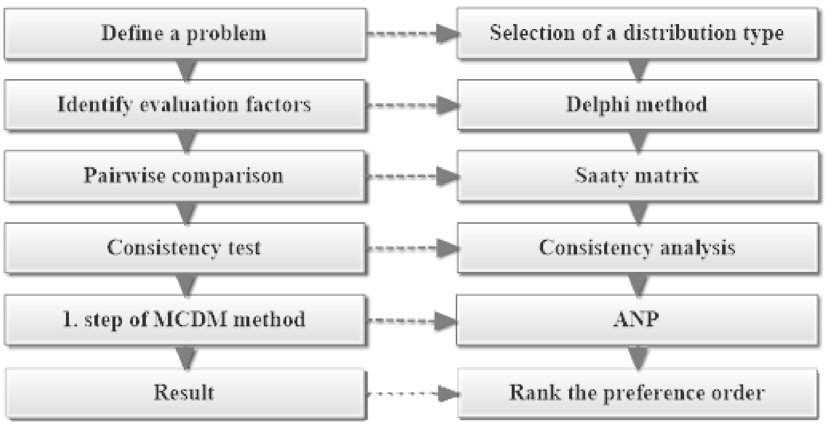

Fig. 1.
Proposed model

I. Delphi method

The first and most important step of the proposed model is a pairwise comparison of input factors and their influence on the resulting type of distribution routes. For this purpose, there is an assembled group of evaluators, consisting of logistics managers, researchers, but also professionals, in order to achieve the most correct evaluation of these factors possible.

For this purpose, the proposed method is Delphi (Linstone and Turoff, 1975) which is suitable for the determination of a professional estimate by a selected group of people. It's a technique that uses subjective opinions of members of the expert group in order to obtain an overall consensus views. Delphi method can be simply seen as a kind of brainstorming session with clear rules.

II. Saaty method

To obtain the weighting of individual factors a use of Saaty method is recommended (1980). The input to this method is the pairwise comparison of individual factors obtained in Step I. Each expert group is also assigned a weight, which represents the degree of influence on the resulting model.

This method takes into account different preferences between criteria and a wide range scoring scale, which is intended for evaluation (Formula 1). Therefore, it is possible to detect even slight differences in preferences between the selected criteria, using the process of determining weight:

$$(s_{ij}) = \begin{cases} 1 - i \text{ and } j \text{ are equals;} \\ 3 - i \text{ is slightly favour over } j; \\ 5 - i \text{ is strongly favour over } j; \\ 7 - i \text{ is very strongly favour over } j; \\ 9 - i \text{ is absolutely favour over } j; \end{cases} \tag{1}$$

Values of 2, 4, 6, 8 are designed for evaluation of so-called interphase. This method compares each pair of criteria i and j. Their evaluations is entered in the Saaty matrix (Formula 2), according to the following rules:

$$S = \begin{pmatrix} 1 & s_{12} & \cdots & s_{1k} \\ {}^{1}/_{s_{12}} & 1 & \cdots & s_{2k} \\ \vdots & \vdots & \ddots & \vdots \\ {}^{1}/_{s_{1k}} & {}^{1}/_{s_{2k}} & \cdots & 1 \end{pmatrix} \tag{2}$$

This methods is comprised of five steps (Saaty, 1980), which include weight calculation ν_i by using standardized geometric mean of Saaty matrix's rows.

III. Consistency analysis

An important factor to whom it is necessary to pay attention during pairwise comparison is consistency (Saaty, 1980). In case that we do not only transfer the exact measurements to elemental scale but use judgment, there is almost always inconsistency. (If we say that a is 3 times greater than b, but only 1/5 times as good as c, c would have to be 15-times better than b to avoid inconsistency.) Given the characteristics of reciprocal matrices and eigenvalues the minor inconsistency does not have any effect during determining the vector priorities.

The degree of consistency below the 0.10 (10%) value is considered acceptable (Chan et al., 2006). For higher values the pairwise comparison matrix should be adjusted, otherwise the results of the entire model quickly lose their predictive value. Experimentally derived RI values reported by Saaty (1980) for a matrix of order 1-15 are shown in Table 2:

Table 2

Experimentally derived RI values

Level	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
RI	0	0	0.58	0.9	1.12	1.24	1.32	1.41	1.45	1.49	1.51	1.48	1.56	1.57	1.59

IV. AHP / ANP method (Analytic Hierarchy Proces / Analytic Network Process)

Method of AHP (Saat, 1980, 1994), which is widely discussed in literature (Isiklar and Buyukozkan, 2007; Onut and Soner, 2007; Wu et al., 2009) is a method for priority setting which derives the relative priority based on pairwise comparisons of elements at the same hierarchical level using the absolute numbers at range from 1 to 9. Analytic Hierarchy Process (AHP) is a method that is appropriate for the hierarchical structure of the systems.

Absolute numbers of the scale are approximations of weights ratio w_j/w_k which make it possible to deduce the weights of w_j and w_k. AHP method uses a general model for the weight synthesis in a hierarchical structure where w_{ij} are local weights of $_i$ element on a given level with relation to the j element from previous level of hierarchical structure, w_j are weights of elements of previous levels of hierarchical structure and ui is a global element weight in terms of all elements of the previous hierarchical structure levels. Mathematically AHP method simply enrols via 3 steps, where we proceed from pairwise comparison matrix (Formula 2):

Method of ANP (Analytic Network Process) is a network generalization of AHP method (Analytic Hierarchy Process). Analytic network process (ANP) is a method that allows the system to include all possible interdependencies and feedbacks (Saaty, 2001). Strategic partnership of the chain units can be modelled using network structures. The structure of the ANP model is suitable for expressing dependencies within the network of supply / distribution relationships, where units of supply / distribution chains can be grouped into so-called clusters and linked by streams affecting their dependency. These model clusters can represent suppliers, manufacturers, distributors, customers and

these links between clusters represent possible influences between elements of different clusters and loops at individual clusters represent possible links between elements of the cluster.
For dealing with the network structures using ANP. There is a program available named Super Decisions by CDF company (Creative Decisions Foundation), which will be used in the proposed model.

5. The application of the proposed model

To determine the most accurate values of pairwise comparison there were three groups of evaluators created. The first group was composed practitioners in the form of logistics manager, purchasing manager and sales director. The second group consisted of a group of scientists, dealing with logistics, which drew on currently available studies and their own experience. The third group was the professional community, using different types of distribution channels in the form of transporters, customers and end customers.

I. Determination of input factors and suitable alternatives using a modified Delphi method

A model was designed based on the Delphi method, consisting of input conditions containing costs relevant to the choice of type of the distribution chain and the level of individual services, occurring in the distribution chain. From the perspective of each alternative of distribution channels four suggested types from Chapter II were assessed (Table 3):

Table 3
Input factors and a set of options for the proposed model

Selection of a distribution channel type	**FC - Costs**	FC1 - Information	**A - Alternatives**	A1 - Offtake by the customer
		FC2 - Storage		
		FC3 - Operational		A2 - Direct distribution
		FC4 - Boot		
		FC5 - Transport		
	FSL – Customer service	FSL1 - Product Availability		
		FSL2 - Customer satisfaction		A3 - Local branches or warehouses / distribution centers
		FSL3 - Consolidation of orders		
		FSL4 - Order tracking		
		FSL5 - Reliability of supply		A4 - Cross-dock center
		FSL6 - Speed of delivery		
		FSL7 - Reverse logistics		

Source: (Authors)

II. Assembling the resulting pairwise comparison matrix by using Saaty method

From the three resulting matrices obtained from each groups of evaluators, the resulting matrix was calculated using the Saaty method. Individual groups were assigned a weight according to the degree of their influence on the final model (Table 5). The resulting matrix is displayed is shown in the Table 6 and 7.

III. Determination of the linkages and the resulting weights by ANP

To determine the mutual linkages and calculate the resulting weights a Super Decisions program by CDF was used, which is useful in solving problems with multiple interrelated input factors. Solution by using AHP method would be slow and inefficient. The assembled model in the program is shown in Figure 2.

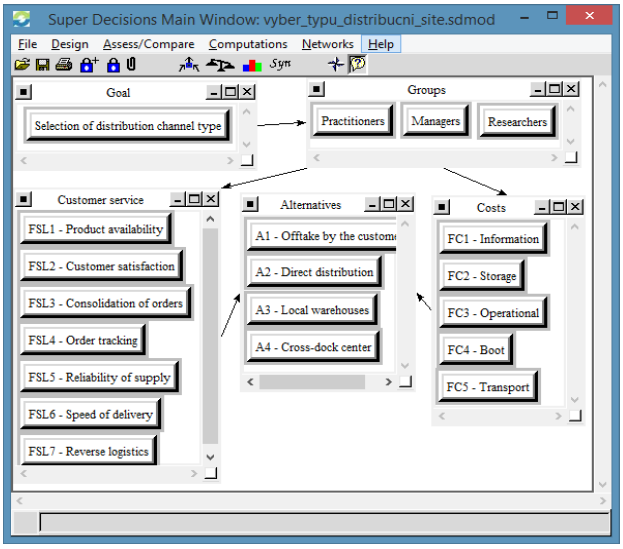

Fig. 2.
Proposed ANP model
Source :(Authors)

Paired comparisons obtained by using method of Delphi in step II. was entered into the program to individual evaluation groups and by exporting a unweighted matrix was obtained for each factor. This matrix is shown in Table 4 and 5.

Table 4
Unweighted ANP matrix of cost criteria

ANP matrix pro FC	*FC1*	*FC2*	*FC3*	*FC4*	*FC5*
A1	0.4587	0.0346	0.3225	0.0473	0.4364
A2	0.1508	0.5475	0.4860	0.6210	0.0857
A3	0.3558	0.1078	0.1094	0.0622	0.2601
A4	0.0348	0.3101	0.0821	0.2694	0.2178

Source :(Authors)

Table 5
Unweighted ANP matrix of customer service

ANP matrix pro FCL	*FSL1*	*FSL2*	*FSL3*	*FSL4*	*FSL5*	*FSL6*	*FSL7*
A1	0.0419	0.4177	0.2654	0.0500	0.1768	0.5426	0.6629
A2	0.5329	0.0776	0.0344	0.1800	0.0845	0.0401	0.0449
A3	0.0608	0.1746	0.1821	0.0858	0.2754	0.3352	0.2270
A4	0.3643	0.3301	0.5180	0.6842	0.4634	0.0821	0.0652

Source :(Authors)

In conclusion, we calculate the proposed model using an ANP method. The results are shown in Table 6.

Table 6
Result of the ANP method

Name	*Ideal*	*Normal*	*Raw*
A1 - Offtake by the customer	0.864610	0.277077	0.092359
A2 - Direct distribution	0.689286	0.220892	0.073631
A3 - Local warehouses	0.566574	0.181567	0.060522
A4 - Cross-dock center	1.000000	0.320465	0.106822

Source :(Authors)

The results are clear. The best option for the proposed issue is set up a distribution channel with one cross-dock centre or warehouse placed on the targeting market. The results have been counted with an APN method and 3 different values has been shown. Column Ideals (ideal variants) shows a variant with the higher weight as an ideal variant and the others are its shares. These results are used for comparing values between each other. Normal (normalized variants) shows weights normalized in the exact way then their sum is equal 1. These values we can see in the AHP method. Raw (gross variants) is a vector acquired directly from limited super matrix. These values are useful for future counting. The table 6 is graphically illustrated in Figure 3.

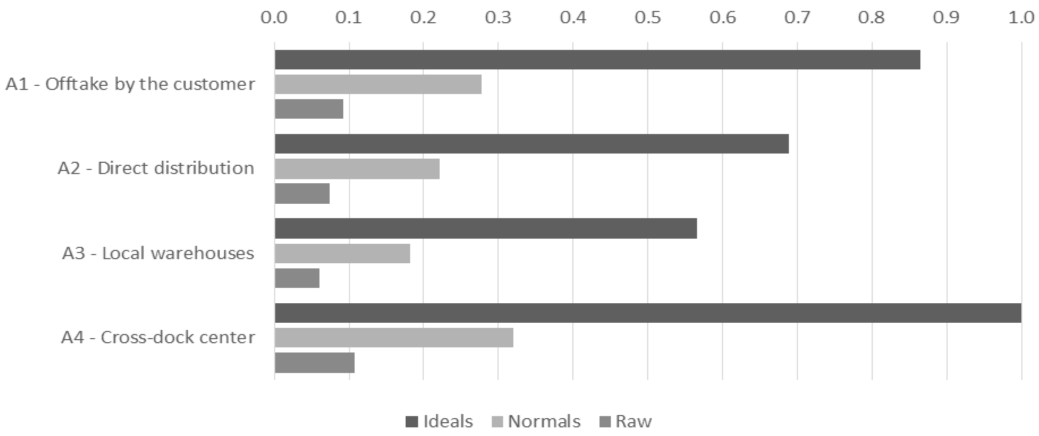

Fig. 3.
Graph of the results of the ANP method

Source :(Authors)

The model results clearly show that the current model in the form of local branches is the least appropriate one. Introducing distribution channel in the form of cross-dock centre for the company is preferable from the viewpoint of the level of customer service and of the significant reduction of costs, which is shown primarily by eliminating losses in the distribution channel. The company cannot afford the complete abolition of local branches due to a local dealership, so the reduction will be implemented in local warehouses, which will result in sufficient cost reductions.

6. Conclusions and final discussion

Appropriate choice of the type of distribution channel can save the enterprise considerable amount of financial resources. This article focused on designing and building a model for selection of a suitable type of distribution channel, mainly for to the expenses reduction of existing distribution channel and simultaneously for assessment of its suitability for the company.

The proposed model provides a clear insight on the discussed issues of selecting the type of distribution channel for the company's management while considering various input factors, with the possibility to modify these factors within the proposed model. The presented model is able to work with both qualitative and quantitative criteria.

Despite the quality and clarity of the proposed model, the greatest threat to the accuracy and relevance of the model is the input formation of pair evaluation. This evaluation may have a profound impact on the outcome of the model and even at small inconsistency level of input evaluation the outcome may be affected. In the presented model, this is prevented by setting up three major evaluation teams of more members which ensures removal of fluctuations or inconsistency of evaluation. For each pair evaluation there is also a consistency analysis which immediately warns you. about any evaluation discrepancy.

Acknowledgements

The authors would like to thank everyone who participated in this research for their valuable suggestions, comments and ratings. Big thanks also goes to all employees of the discussed company for their patience and willingness during the input evaluation processing for the model creation. The work was created in connection with the scientific research project of the University of Pardubice no. 51030/20/SG550001.

RISK ANALYSIS OF INVESTMENT IN WATERWAY INFRASTRUCTURE

Miroslav Bartoš[1], Hana Záhorská[2], Vít Hromádka[3], Eva Vítková[4], Miloš Waldhans[5]
[1,2,3,4,5] *Brno University of Technology, Faculty of Civil Engineering, Czech Republic*

Abstract: The project represents a unique process consisting of a number of dependent activities that bear great amount of risk. To ensure the success rate of the project, it is necessary to deal with risks already in the pre-investment phase, which can be done using the risk analysis, i.e. an inseparable part of the decision-making process regarding the feasibility of an investment. This article deals with investment in waterway infrastructure, namely in the Elbe waterway, a part of trans-European transport network. The current state of the Elbe waterway is characterized by its significant unreliability depending on navigational conditions. In the Czech Republic, *Methods of Effectiveness Evaluation of Investment in Waterways* is currently used as it also includes risk assessment. The article focuses on the comparison of risk assessment methods, thus the above-mentioned *Methods* and the empirical RIPRAN™ method. Both methods are demonstrated on a case study of a project connected to the development of waterway infrastructure, namely the most significant construction in terms of navigability of the Elbe from Děčín towards Germany. The aim of this article is to propose an adjustment of the current method of risk assessment of investment projects based on the results obtained by the comparison.

Keywords: RIPRAN™, risk analysis, waterways, risk assessment of investment.

1. Introduction

Risks are inevitable part of every project and in order to reach the desired outcome, one needs to take risks into consideration. The article deals with risk analysis of investment projects connected to the development of waterway infrastructure. The aim of this article is to compare qualitative risk assessment by *Methods of Effectiveness Evaluation of Investment in Waterways* and RIPRAN™ method. The risk assessment is performed on a case study dealing with the Děčín weir construction, which is the most significant construction in terms of ensuring the navigability of the Elbe from Děčín towards Germany, i.e. towards a maritime port.

2. Analysis of current situation

Water transport is one of the most ecological means of long-distance transportation. Another advantage is also the cost and rather large shipping capacity. However, it is not possible to make use of these advantages due to the present condition of waterways. According to the Transport Union of the Czech Republic, conditions of EU states waterways are of different quality. Almost all the states realize the importance of inland shipping as inseparable part of transport system, but, given the currently decreasing share of inland shipping in the overall increase of transportation, the states at the same time recognize the necessity to take measures to change this trend on state level. Transport policies of individual states focus on inter-modal transportation with more significant use of shipping, which is the reason they take part in ensuring suitable infrastructure. Programs for support and directing of inland shipping differ greatly in individual states as they proceed from local conditions and previous development. As European Court of Auditors (2015) presents, within the pursue of better effectiveness of inland water transport financing, EU states should prefer such projects that relate to the corridors, rivers and river segments as they are of the greatest benefit to the overall improvement of inland water transport.

In the Czech Republic, freight transport is used within the means of import, export, and inland relations as well. The total share of all realized transportations is however very small as it represents a little less than 1 % of the total volume of freight transport. The most influential factor regarding the current situation is the unreliability of navigational conditions due to the unfinished infrastructure of waterways. Water transport in the Czech Republic is economically favourable, but highly unreliable. The unreliability lies in the fact that the shipper cannot guarantee the required transport volume in scheduled time. The stated fact is a result of bad quality of waterways in the Czech Republic; the most suitable watercourses for shipping are the Elbe and the Vltava. With regard to the unstable navigational conditions on Czech waterways, new projects are not implemented and current transport volume is shifted elsewhere. One of the important factors is also quite obsolete watercraft which worsens the competitive ability of freight water transport and also limits the potential advantages regarding the environment.

The priorities of waterway infrastructure development are the Děčín weir on the Elbe-Vltava waterway and Přelouč weir, which should ensure the extension of navigability of the Elbe waterway to Pardubice port (The Transport Union, 2016).

The implementation of projects related to the waterway infrastructure development is connected to a great amount of risk that needs to be managed properly. The term ‘risk’ in relation to a project represents a chance that something influencing the aims of the project will occur. The risk includes the possibility of loss or profit, potentially some variation of planned or required outcomes as a consequence of uncertainty connected to particular way of conduct (Smith, Merna, Jobling, 2006).

[2] Corresponding author: zahorska.h@fce.vutbr.cz

According to (Kerzner,2009) risk is defined as follows: *"Risk has two primary components for a given events – a probability of occurrence of that event and impact (or consequence) of the event occurring. Both the probability and consequence must be considered in risk management. Risk constitutes a lack of knowledge of future events. Typically, future events that are favourable are called opportunities, whereas unfavourable events are called risks. Risks and opportunities may be uncorrelated or only partially correlated on a given project."*
Nowadays, risk management can be performed in accordance with International Project Management Association based on risk engineering which represents a techno-economic discipline dealing with the issues of risk. In certain cases 'positive risk' is mentioned, though it is not a correct term according to IPMA. From the point of view of risk engineering, risk management includes processes such as risk identification, risk analysis, risk assessment, risk treatment, risk re-examination and monitoring and communication and consultation of risk with involved parties. More detailed description of mentioned processes is stated by (Doležal et al., 2012).
In practice, many types of risk can occur; according to Fotr et al., 2011, it is for instance: technical-technological risk, manufacturing, economic, market, financial, credit, legislative, political, environmental or information risk, or an intervention of superior power.

3. Used methods

The assessment of projects related to the Czech Republic waterway infrastructure proceeds from *Methods of Effectiveness Evaluation of Investment in Waterways*, hereinafter referred to as the *Methods*. This document functions as a tool to assess the effectiveness of investment in waterways. One of its aims is to determine prerequisites, content and method to process the assessment of effectiveness of individual investment actions. Another aim is to introduce the authors to Cost-Benefit analysis (CBA) with reference to entry data that change in time and thus need to be updated on a regular basis. The authors furthermore focus on risk assessment of a project related to waterway infrastructure.
Such focus of risk assessment has, according to Žďánský et al. (2013), two main objectives:

- to ensure and prove that the project is suitable for financing (economic and financial literacy) even if some entry data and prerequisites are with regard to potential risk influence overestimated or underestimated,
- to assess if the identified risks related to project preparation and implementation are acceptable and whether there is no pitfall leading to the project's failure.

According to the *Methods*, the first step is the identification of risks, which must to the utmost degree represent independent variables. Next step is the division of risks into two groups, thus to the quantifiable risks and the other risks. The quantifiable risks are integral part of the CBA and are assessed by quantitative analysis. The other risks are assessed by qualitative analysis, which is always performed within the CBA if the overall costs of a project exceed 100 Mil CZK. Sensitivity analyses are included within the qualitative analysis. The discussed variables can be a part of the CBA and examined on the basis of sensitivity test. The testing deals with variables and uncertain prerequisites of investment plan and also with impact of their change on the resulting indicator. In this case, the influence of identified variables on determinative indicators EIRR, FIRR, ENPV, FNPV and BCR is assessed. The acceptability of a project should be conditioned by reaching the expected value of the indicators as calculated by source probability distributions, followed by a performance of usability analysis and its limits.
In practice and not only in waterway projects, a situation when quantitative division of risk probability is not applicable might occur. In such cases, qualitative risk assessment is used instead. These methods proceed from a relation defined by probability of risk occurrence and seriousness of its impact. To determine the probability of risk occurrence, a scoring method is used with probability ranked from 1 (least probable) to 5 (highly probable). Similar scoring is used for risk impact, with value 1 representing almost imperceptible consequences and maximum value 5 the catastrophic ones. The risk rate is then calculated by multiplying the probability of risk occurrence by risk impact (Žďánský, Forman, Kumpoštová, 2013).
RIPRAN™ is an empirical method developed by doc. Ing. Branislav Lacko, CSc., in order to support project risk analysis. The method is based on procedural conception of risk analysis. It understands risk analysis as a sequence of processes while each process has its own defined inputs, outputs and activities. These activities transform inputs to outputs when certain objectives are reached. The point of this method is to support systematic performance of risk analysis so as to reach quality processing and effective results in terms of risk management in time available, Doležal et al. (2012). This method takes account of TQM (Total Quality Management), i.e. philosophy of quality, includes processes ensuring the quality of risk analysis-related activities as specified by ČSN ISO 10006 and follows the requirements for risk management by PMI® and IPMA®.
By RIPRAN™ method, the performance of risk analysis is divided into five basic phases:

1. Risk analysis preparation,
2. identification of threats,
3. qualification of risks,
4. response to risks,
5. total assessment of riskiness of a project.

The aim of the first phase, i.e. risk analysis preparation, is to prepare all that is needed to perform the analysis by RIPRAN^{TM}. A schedule of the progress of analysis performance is worked out by beforehand chosen team whose task is also to decide what requisites and sources will be used within the analysis.
The second phase identifies the threats, dangers and various scenarios. However, validity and complexity of prepared sources must be ensured in the first place. Subsequently, a team discussion defines a list of threats and scenarios. A threat represents concrete manifestation of danger and the cause of scenario. Their relationship can be defined as cause and consequence. The output of the second phase is a list of pairs threat – scenario, with a list of risk factors included.
Qualification of risks is the third phase by RIPRAN^{TM}. Its objective is to classify the probability of scenario occurrence and impact rate, as well as to assess the risk rate as such. The required quantities can be assessed numerically or verbally, using beforehand negotiated assessment scales. The assessment of the probability of risk occurrence and its impact rate is based on a team discussion. The resulting value is a product of probability value and impact value. The last phase of risk classification is the division of risks by their significance into the minor risks that can be managed during the implementation of the project and the risks that are of great significance.
The proposal how to lower the risk to acceptable level is created during the fourth phase. Solutions for individual scenarios are once again proposed during a discussion. It is possible to reassess the risk rate with regard to precautions and thus take into account the costs related to the implementation of proposed measures.
Overall assessment of the project riskiness is done in the final phase, as well as the assessment of overall risk rate based on the established criteria. More information can be found at (Lacko, 1999).
Subsequently, risk monitoring and evaluation follows. In the case of more complicated projects, it is advisable to work out a comprehensive report describing risk management in detail.

4. Case Study

The case study deals with waterway infrastructure development and risks related to the issue. The authors further focus on the above-mentioned Děčín weir on the Elbe watercourse, which is 247 km long, but not navigable in its entirety. The Děčín weir represents the most important construction on the Elbe waterway in terms of ensuring its navigability and economic use. Given the fact that the Elbe represents the only one, yet at the same time insufficient access to the maritime port on water, the Elbe transport corridor is of key importance for Czech international trade. Both railway and road transport are on the brink of exceeding its effective capacity. Water transport, if functional, effectively lowers competitive market prices of shipping. During dry seasons, thus with insufficient navigability, freight transport is ceased, as well as recreational and passenger transportation. The lower reaches of the Elbe, stretching for approximately 41 kilometres from German borders to Ústí nad Labem-Střekov, represent the critical point. Navigation is due to low flow stopped for approximately three to six months a year.
The Děčín weir would ensure draught of 140 cm for 345 days per year and draught of 220 cm for 180 days per year. Moreover, the construction of the weir is related to an adjustment of navigational water duct below the weir, adjustments in the reservoir of the weir, operational facility, implementation of right-bank aquatic and terrestrial migration zone, controlling gauging station and small hydroelectric power station located on the right bank of the Elbe, as the water transport section of Transport Union states.
Earlier, the authors dealt with quantitative analysis of risks performed on the basis of the *Methods of Effectiveness Evaluation of Investment in Waterways* published by Czech Ministry of Transport. The main risks influencing the project were identified as the investment costs and number of shifted tonne-kilometres from road and rail transport to water. The main finding was the necessary number of shifted tonne-kilometres in terms of ensuring economic effectiveness of the project. The calculation was based on the net present value of the project using the interpolation method, resulting in the number of 17 364 thousands of tkm for inland transportation, and 63 943 thousands of tkm for cross-border transportation.
To perform a complex assessment of the project, this article focuses on determination and assessment of risks of the selected case study with the aid of verbal assessment in accordance with the *Methods*, followed by the empirical method RIPRAN^{TM}.
Qualitative assessment of risks by the *Methods* is shown in Table 1. The first step was the compilation of registry of risks respectively assigned with the probability of occurrence and severity of impact. The resulting indicator represents the risk rate, calculated as a product of stated factors. The most significant risks are those related to construction, exceeding of the budget, political risks, risk of postponing the construction of related synergetic infrastructure and risk of strategic decision.

Table 1
Risk assessment of the Děčín weir project by methods of effectiveness evaluation of investment in waterways

ID	Risks		Probability of risk occurrence	Severity of risk impacts	Risk rate
1	Construction-technological and project risks	Project documentation risks	3	3	9
		Construction risks	3	4	**12**
		Exceeding of the budget risks	3	4	**12**
		Locality risks	3	3	9
		Technology failure risks	2	4	8
2	Market risks	Demand risks	2	4	8
		Other market risks	2	3	6
3	External risks	Political risks	3	4	**12**
		Superior power risks	1	3	3
		Legislative / tax risks	2	2	4
		Postponing construction of related synergetic infrastructure	3	4	**12**
4	Operational risks	Equipment-related risks	3	3	9
		Human factor risks	2	2	4
		Safety risks	2	3	6
5	Strategic risks	Contractual risks	3	3	9
		Strategic decision risks	3	4	**12**

Source: author's processing

Qualitative assessment by RIPRAN^{TM} method is shown in Table 2. The same registry of risks is applied as in the previous case. Individual threats are assigned with probability of occurrence. Each threat includes scenarios that can happen with certain probability. Overall probability of the risk, its impact and value are based on such assessed threats. To complete the risk assessment, each scenario is paired with respective measure to eliminate its occurrence. The table below shows that exceeding of construction costs and wrong strategic decisions related to the project represent the most significant risks.

Given the five-degree assessment scale commonly used for qualitative risk analysis by the *Methods*, similar framework of 5 x 5 x 5 was chosen for the RIPRAN^{TM} so as to perform a comparison. Verbal assessment is done in accordance with recommended categories of risk probability, impact and value, ranging from very low to extremely high.

Table 2
*Risk assessment of the Děčín weir project by RIPRAN^{TM}**

ID	Threat	Threat PROB	ID	Scenario	Scenario PROB	Overall PROB	Impact	Risk value	Measure
1	Construction-technological and project risks	MP	1.1	Project change, prolonged negotiations etc.	MP	MP	MODI	MRV	Firm schedule creation and its observance, quality proposal creation

Impact: MINI - minimal; MI - minor; MODI - moderate; SI - significant; SEVI - severe
Risk value: VLRV - very low; LRV - low; MRV - medium; HRV - high, EHRV - extremely high.

5. Results

The authors focus on qualitative risk assessment comparison of commonly used method based on *Methods of Effectiveness Evaluation of Investment in Waterways* and RIPRAN™ method. Based on the performed analysis, the authors created a registry of risks for the Děčín weir project which later provided entry data for both considered methods.

Risk assessment by the *Methods* is primarily based on relations between probability of risk occurrence and severity of its impact. The assessment process is thus influenced by two factors that eventually determine the risk rate.

As for RIPRAN™ method, the first step is to determine the threats and probabilities of their occurrence followed by determination of scenarios, once again assigned with probability of their occurrence. The overall probability was determined on the basis of these two probabilities. Subsequently, the impact rate was determined. Risk values were taken from the matrix for category assignment of risk value. Each scenario was assigned with proper measure leading to risk neutralization.

If compared to the *Methods*, the empirical risk assessment by RIPRAN™ is more detailed, complex and laborious. The advantages are more precise results and the fact that this method encourages to search for measures that would decrease risk value. RIPRAN™ offers so-called 'type measures' that help to find concrete measures more easily. Its users gradually update the database of risks and measures and thus are step-by-step creating more and more complex instrument for project risk analysis.

Different results are obtained due to different approach of the used methods. According to the *Methods*, five significant risk factors were identified. As for RIPRAN™, only two significant risk factors were determined, both in accordance with outputs obtained by risk assessment by the *Methods*.

It is advisable to take measures to minimize risks related to exceeding of construction costs, such as creating the budget with reserves included, all based on quality and complex source material. There is also the option to conclude a contract with selected contractor, where the price would include all the costs connected to the realization of the project and would remain firm and definitive, with exception for extra works that cannot be expected.

It is necessary to eliminate strategic risks, mostly by choosing a qualified team of professionals eligible to make the required decisions. In general, the important measure is to conclude all the necessary contracts for most of the works in all stages of project service life.

6. Conclusion

The authors deal with project risk assessment focused on the development of waterway infrastructure on the Elbe, which represents the one and only access to maritime port by waterway. Given the fact that currently the Elbe waterway potential is not used due to unstable water flow, the authors focused on the most significant construction in terms of ensuring the navigability, thus the Děčín weir. In the first phase, registry of risks was worked out in order to perform a qualitative risk assessment comparison of commonly used method based on *Methods of Effectiveness Evaluation of Investment in Waterways* and RIPRAN^{TM} method.

Subsequently, an assessment of risk significance was carried out on the basis of the *Methods* and then on the basis of RIPRAN^{TM}. The most significant risks are those related to construction, i.e. exceeding of the budget, political risks, risk of postponing the construction of related synergetic infrastructure and risk of strategic decision. Exceeding of the budget and wrong strategic decisions are also significant risks as identified by RIPRAN^{TM}.

After applying both methods on a case study, a comparison was held, resulting in the fact that both methods identified exceeding of the budget and wrong strategic decision as the riskiest factors of the project. These risk must be handled carefully, though it is not advisable to underrate the other risks as well.

Eventually, the authors prefer RIPRAN^{TM} method, despite the fact that its risk assessment process is overall more demanding. Currently used risk assessment by the *Methods* is divided into qualitative and quantitative part. Quantitative assessment is being dealt with in more detail if compared to qualitative assessment. Therefore, the authors suggest to supplement qualitative risk assessment with RIPRAN^{TM} method. The main reason is its systematic approach to risk analysis and high-quality processing and effectiveness of the results.

COMPARISON OF RAILWAY AND ROAD PASSENGER TRANSPORT IN ENERGY CONSUMPTION AND GHG PRODUCTION

Tomas Skrucany[1], Jan Ponicky[2], Martin Kendra[3], Jozef Gnap[4]
[1,2,3,4] *University of Zilina, Faculty of Operation and Economics of Transport and Communications, Zilina, Slovakia*

Abstract: This paper due to the simulation of energy consumption an GHG production of two different modes of regional passenger transport which use the same type of fuel – diesel. Simulation of an energy consumption in transport is often used due to satisfactory accuracy and cost efficiency. The simulation is not influenced by many surrounding factors which are acting during the measurements in real operation. Energy consumption and GHG production is calculated by using computer simulation. System "well to wheel" is used in evaluation.

Keywords: bus, energy consumption, GHG, production, simulation, train.

1. Introduction

Mobility is one of the most important human needs in this century. Average number of trips and the average traveled distance per man is constantly rising. Transport is becoming a very important element of human existence which has very negative impact on the environment by noise, vibration, accidents, areas needs, congestions and energy intensity (Kalina, T., Jurkovic, M., Grobarcikova, A. 2015, Dolinayova, A. 2011).
During the transportation process energy entering transforms in to the movement of vehicles which provide the required transfer of goods and people in the area. Therefore, the transport depends on the supply of energy (Camaj, J., Lalinská, J., Masek, J. 2015). Today transportation is largely dependent on oil, as the vast majority of vehicles are driven engines combusting petroleum products - hydrocarbon fuels.
Railway transport is representative mode of transport where most railway vehicles are now powered by electric traction motors, so the rate of dependence on oil is lower than previous modes. But the fact is that in most countries the electricity is produced through petroleum products or coal. All of these are non-renewable natural resources and their stocks have steadily declined.
Proper selection of traction in the railway transport can help implement the objectives of the White Book to minimize the energy consumption of transport and create a sustainable environmentally friendly mobility (Zitrický, V., Gašparík, J., Pečený, L. 2015, Kampf, R. et. al. 2015).

2. Model situation

In this case study we consider the transport along one chosen valley in Slovakia. There is a diesel railway track. Nowadays small trains run at this track regularly several times a day. There are two modes of passenger transport in the valley – train and bus. Tracks of both transport modes are situated along the river Rajcanka. This track connects Zilina (administrative capital city of northern territorial unit of Slovakia) and a small town Rajec situated in the southern part of valley with amenities for people lived in valley villages. Routing of track is North – South with distance of 21.3 km (Kendra, M., Babin, M., Barta, D. 2012.).
Difference of the altitudes between Zilina (340) and Rajec (450) causes the track slope which reaches the highest value 13‰, except a small hill before the railway station in Zilina where is the slope 17‰ but only on a short distance. Average slope between end stations is 5 ‰.
There are 12 stops (stations) on the track, Zilina is the first one on the beginning and the last one is Rajec at the end of the track. Between them there are 10 other stops. The highest track speed limit is 60 km/h but on some sections there are the speed limits only 50 or 40 km/h. Travelling time between the end stations is 37 minutes.
The average number of transported passengers for the year 2014 is 32 passengers on one train (Nedeliaková, E. et. al. 2014, Lizbetin, J. et. al. 2016).

2.1. Vehicle technical parameters

Simulation of the energy consumption was done for a real bus and railway vehicles used in this valley. The bus Karosa C 954 was made by Karosa Vysoké Mýto from the year 2001 till 2006 (Liscak, S., Rievaj, V., Sulgan, M. 2008). The railway vehicle with series number 813-913 made by ZOS Zvolen as a reconstruction of an old diesel one unit railway vehicle with series number 810. ŽOS Zvolen has been making this diesel railway vehicle since 2007.

Table 1
Basic technical parameters of the vehicles

vehicle	***Train unit 813-913***	***Bus Karosa C 954***
drive arrangement	*1´A´ + 1’1’*	*-*
power system	*diesel*	*diesel*
power transmission	*hydromechanical*	*mechanical*

3. Calculation of energy consumption and emission production

Software Railway dynamics has been used to calculate the energy consumption of the train. This software was developed by Pavel Siman (Czech railways) and Jiri Petras (University of Pardubice) from Czech republic.
The power consumption of the train has been calculated on the basis of predefined and selected values on the defined route. The software works with imported maps and elevation profile of railway routes. Based on these defaults and selected parameters (locomotive type, train weight, train length, axle load, number and location of stops) power consumption was calculated in kWh. This software can be used to calculate energy consumption and operational or driving time of some arbitrary train on some arbitrary railway track. It is needed to import data of train and track for calculation (Klinko, M., Grenčík, J. 2008).
It is necessary to use the principle well-to-wheels for relevant comparison of the results for different types of consumed energy (Zamecník J., Jagelcak, J, Vrabel J. 2014, Knez, M. et. al. 2014).

3.1. Standard EN 16258: 2012 and its using in calculations

This European Standard specifies general methodology for calculation and declaration of energy consumption and greenhouse gas emissions (GHG) in connection with any services (cargo, passengers or both). It specifies general principles, definitions, system boundaries, methods of calculation, allocation rules (allocation, assignment) and recommendations on information to support standardized, accurate, reliable and verifiable declarations regarding energy consumption and greenhouse gas emissions associated with any freight services. It also contains examples of these principles use.
The calculation for one given transport service must be performed using the following three main steps:
- Step 1: Identification of the various sections of the service;
- Step 2: Calculation of energy consumption and greenhouse gas emissions for each section;
- Step 3: Sum the results for each section (EN 16 258:2012).
The standard does not consider only the production of the secondary emissions and energy consumed during the combustion of the fuel (energy conversion from fuel to mechanical energy) but as well as primary, incurred in the extraction, production and distribution:

- e_w well-to-wheels energetic factor for defined fuel,
- g_w well-to-wheels emissions factor for defined fuel,
- e_t tank-to-wheels energetic factor for defined fuel,
- g_t tank-to-wheels emissions factor for defined fuel.

Well-to-wheels is "well on wheels" and also covered primary and secondary emissions and consumption. This factor is somewhere also called as LCA (life-cycle-analysis).
Tank-to-Wheels factor is thinking only of secondary emission and consumption.
This Standard specifies general methodology for calculation and declared value for the energetic factor and factor in greenhouse gas emissions must be selected in accordance with Annex A (EN 16 258:2012).
Emission gases are composed of several individual components (gas). Each of them have different chemical and physical properties, so they otherwise participate in environmental degradation. In order to compare emissions from different activities, fuels, vehicles where emissions have different impact, one representative unit used in the comparison must be designated. This is the CO_2 equivalent which is a measure of the impact of specific emissions and likens it to the impact of CO_2. The label is CO_2e (equivalent).

3.2. Energy consumption calculation

The calculation procedure for the diesel train using the software simulation is following. It is appropriate to use the factors and procedure form of the EN 16 258:2012 for diesel train. The amount of consumed fuel should be multiplied by energy factor for that fuel from Appendix A of the standard to calculate the total energy consumption.

$$E_{TF} = FC_V \,.\, e_W = [(E_{ME} \,.\, BSFC).\, 1/\rho_F \,].\, e_W \quad [MJ] \tag{1}$$

Where; E_{TF}: total energy consumed by diesel vehicles [MJ], FC_T :consumed fuel of vehicle [l , dm^3], E_{ME} :mechanical energy consumed by the movement of the train (train dynamics software result) [kWh], BSFC :break specific fuel

consumption of the vehicle engine [g/kWh], ρ_F :fuel (diesel) specific weight (density) [g/dm^3], e_W :energetic factor „wtw" for defined fuel [MJ/dm^3].
The calculation of consumed energy by the bus was easier. The fuel consumption data were provided to us from the bus carrier. He does fuel consumption measurements regularly, so the number of average fuel consumption is known. This value is exactly for one type buses operating in the valley with the corresponding capacity usage.

$$E_{TB} = FC_V \,.\, e_W = [(FC_A \,.\, L) / 100] \,.\, e_W \quad [MJ] \tag{2}$$

Where; E_{TB} :total energy consumed by bus [MJ], FC_V :fuel consumption of vehicle [l, dm^3], FC_A :average fuel consumption [l/100km], L :driven distance [km], e_W :energetic factor „wtw" for defined fuel [MJ/dm^3].

GHG production

For the GHG production calculation, the consumed amount of diesel fuel should be multiplied by an emission factor for that fuel from Appendix A of the EN standard.

$$G_{TF} = FC_V \,.\, g_W = [(E_{ME} \,.\, m_{Pe}).\ 1/\rho_F\ ].\ g_W\ [gCO_2e] \tag{3}$$

Where; G_{TF} :the total amount of emissions produced by diesel train [gCO_2e], g_W :emission factor for defined fuel [tCO_2e/MWh], for the buses the same principle

$$G_{TFB} = FC_V \,.\, g_W = [(FC_A \,.\, L) / 100] \,.\, g_W\ [gCO_2e] \tag{4}$$

Where; G_{TFB} :the total amount of emissions produced by bus [gCO_2e], g_W :emission factor for defined fuel [tCO_2e/MWh].
The basic units of MJ and gCO_2 were chosen for the calculation because they are declared units in the standard. However, for better comparison and expression, it is possible to expressed individual amounts in other units, for example GJ, KJ, tCO_2, $kgCO_2e$ or a combination of them, in the case of proportional expressing of quantities (see the evaluation) (Skrucany, T., Gnap, J. 2014, Skrucany, T. et al. 2015).

3.3. Evaluation

The calculation for this model study was done on the track in bidirectional ways, so one way down the hill and the other way up the hill. This elevation is seen in the energy consumption which is higher for uphill track, from Zilina to Rajec. Only the numbers as the results from transport in both directions are in the evaluation table and graphs.

Table 2
Final evaluation

State	Vehicle	Fuel consumption (L)	Total energy consumption (MJ)	Total emissions production (kgCO2e)	Passenger number	Energy per capita (MJ/person)	Emissions per capita (kgCO2e/person)
Full loaded	**train**	22.98	981.2	74.4	83	11.82	0.90
	bus	12.48	532.9	40.4	49	10.88	0.83
Real passenger number	**train**	17.72	756.6	57.4	32	23.65	1.79
	bus	11.76	502.2	38.1	26	19.31	1.47

Source: author´s calculation

Table of the final evaulation shows the advantage of the road transport vehicle – bus. There are very similar engines (performance and consumption) in both of the vehicles. However the railway track is not so difficult in slopes like the road, thus the railway vehicle does not reach the fuel consumtion lower than bus. It is caused by its tare weight – 39 t what is about 28 t more than cca 11 t of bus tare weight.

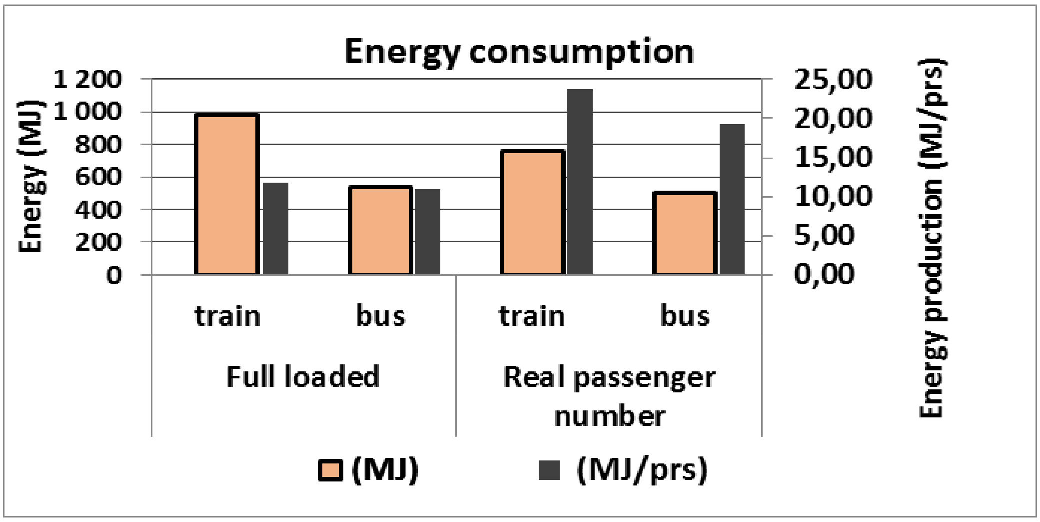

Fig. 4.
Evaluation of the energy consumption
Source: author´s calculation

The simulated fuel consumption of the diesel train was compared to the real consumption of this train operated on this track. This simulated result was validated because the simulation error was only -8%. So every consumption results were increased of the value 8% to be closer to the reality.
However, the diesel train reaches higher value of the real passenger number, thus it does not reach higher efficiency than the bus. As mentioned above, this fact is caused by the tare weight of the train. The total energy consumption of the bus represents only 54 - 66 % of the train consumption, according to the actual capacity usage. In the unit expression (MJ/prs) the difference is lower on account of higher capacity and passenger nr. values regardless of the effectiveness reached by the road vehicles.
Similar case as the energy consumption is the GHG production. The share between GHG production of vehicles is the same as the energy consumption because it was calculated according to the EN 16 258:2012 where the GHG production is a multiply of the fuel consumption and emission factor (Eq. 3, 4).

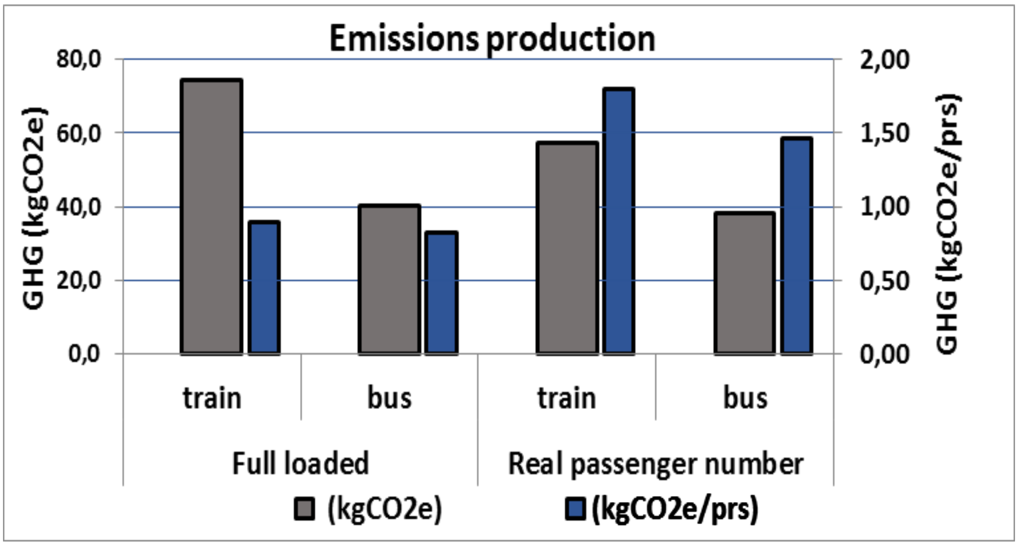

Fig. 5.
Evaluation of the GHG production
Source: author´s calculation

4. Conclusion

The results of this simulation do not determine which transport mode is better, greener or friendlier to the environment. It is not possible to do it, because the energy efficiency and GHG production is not dependent only on the fuel or energy consumption but also on the capacity usage. It is necessary to load the vehicles with the adequate number of passengers (suitable choice of the vehicle according to the transport flow). The transport efficiency is decreasing with the decreasing of actual capacity usage. So the coordination of the transport flow and vehicle operation is the step to greener transport.

OPTIMISATION OF RAIL TRAFFIC FLOW DURING MAINTENANCE ON INFRASTRUCTURE

Jelena Aksentijević[1], Andreas Schöbel[2]
[1,2] OpenTrack Railway Technology GmbH, Kaasgrabengasse 19/8, 1190 Vienna, Austria

Abstract: Within the by H2020 founded project DESTination Rail, a task is dedicated to the development of a tool for rail traffic flow optimization in terms of maintenance work. On a single track line priority is set for as much work as possible to be done in one time slot between two trains. Sometimes, the timetable is even modified to allow more efficient maintenance work. On a double track line all traffic has to run over the remaining track, where typically a slow speed zone is established to protect working staff. For this bottleneck section, it is very important to have an efficient usage of capacity. Therefore, it is necessary to optimize the speed profile of approaching trains to let them pass the bottleneck section exactly at the allowed speed limit to keep occupation time as short as possible.

Keywords: Kronecker algebra, rail traffic flow optimization, rescheduling.

1. Introduction

Rail infrastructure managers are responsible for safety measures and investments within the infrastructure network. Their choices are usually not only based on poor data availability, but also on the visual assessment of infrastructure conditions. Unfortunately, there is enough evidence that visual analysis shows indications for needed actions very late in the deterioration infrastructure process, or not at all. Consequently, the objective of the EU project DESTination RAIL [1] is development of a Decision Support Tool, which relies on reliable data, for rational decision making of infrastructure managers to offer safer, reliable and efficient rail infrastructure. The idea of developing a flexible decision support tool enables possibilities to use it across a range of asset classes, such as: bridges, earthworks, tunnels, switches, and tracks. Rail traffic flow optimization represents a priority in cases of restricted network availability. It is a part of a four-step process, which infrastructure managers face in their decision-making processes. Namely, location and identification of risky assets before they fail, then real-time safety assessment of existing infrastructure; furthermore, evaluation of safety and assignment of scarce resources and finally, choosing the optimal rehabilitation techniques. Using Kronecker algebra, which showed good results in dealing with bottlenecks [2] a case study for optimization of rail traffic flow during maintenance work at Boyne viaduct in Ireland (Fig.1) was conducted.

2. Rail traffic flow optimization tool

The focus of this paper lays in the fourth stage of the flow optimization, namely, the analysis of the possible infrastructure maintenance or renewal strategies. Application of microscopic simulation of railway operations based upon a physical and mathematical model of the railway system is the state of the art in railway traffic operations. Such tools output indicators for the operational performance (e.g. delays). These have a series shortcomings, most notably that optimisation is typically predefined by the user of the tool and introduced into the simulation. This common practice allows the user to find solutions for bottleneck management and planning of maintenance work. However, it often misses the opportunity to find the optimum solution. It is, therefore, not fully capable of solving dispatching questions or handling headway conflicts. To close this gap in future railway operation with increased traffic flow, algorithms have to be applied which consider all train runs at the same time. Within DESTination RAIL, microscopic simulation tool will both improve traffic flow and assess the impact of maintenance and renewal proposals.

3. Dataflow Model

The input data used for the traffic flow optimization tool is defined by two components: first, the current characteristics of the rail system will be supplied. Second, the infrastructure manager will indicate a desired assessment of a change in the network. Those two components will be merged using simulation tool OpenTrack [3] for the visualization of the data, and further processed into the concrete syntax of the input files needed by the optimization tool. This workflow is shown in the Figure 2:

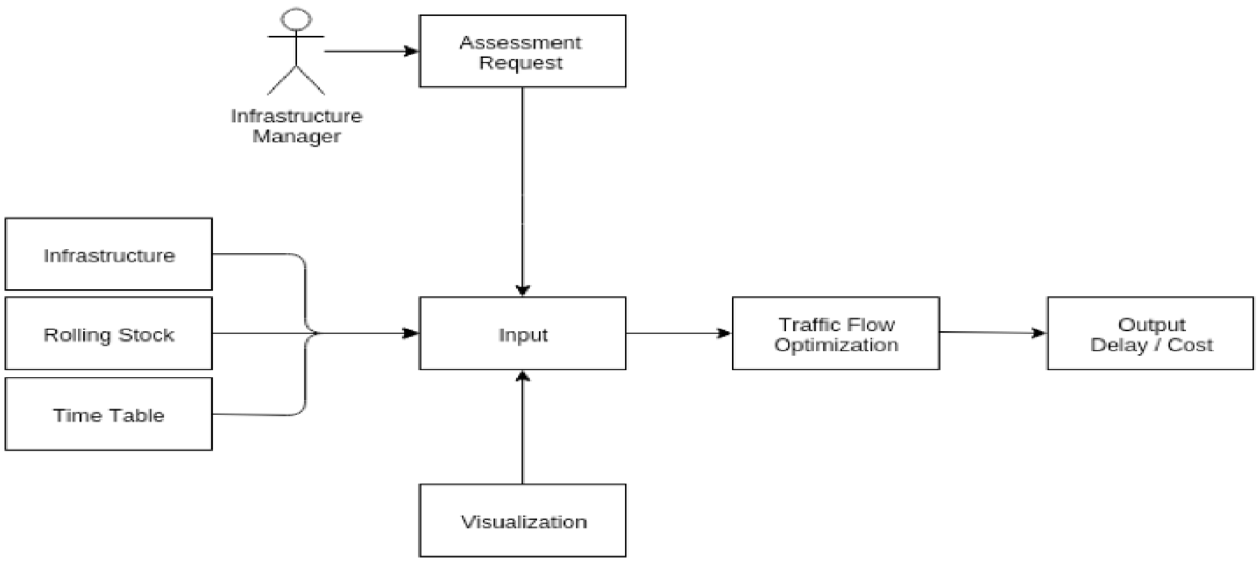

Fig. 2.
Dataflow model
Source: www.destinationrail.eu

As it can be seen in the Figure 2, in order for Traffic Flow Optimization process relying on Kronecker algebra approach to deliver Output data, a number of input data is needed. First, and most important, is the set of Infrastructure, Rolling Stock and Timetable characteristics, which represent the base of future calculations. Secondly, infrastructure manager's identification and assessment of consequences of whether it be restricted availability of infrastructure assets, of operational incidents.

4. Data required

The level of details and accuracy directly influences the quality of output. As it can be seen from the Figure 1, two types of sources are used for a complete input data. First represents the crucial elements for the operation of the railway network. Second, the desired change in the network must be indicated. These two components will be merged using lightweight visualization tool before being further processed into the concrete syntax.

4.1. Input Data: Infrastructure, Rolling Stock and Timetable

Infrastructure data comprises information about tracks and operation control points, as well as all related information. The rolling stock data concerns physical characteristics of trains that are part of the traffic system under consideration. The timetable data provides information about planned train routes and their associated time schedules.

4.2. Input Data: Infrastructure Manager Assessment Request

Infrastructure manager can analyze different possible changes in network. First, consequences of restricted availability of infrastructure assets can be assessed. The aim of this is to reduce the impact of restricted availability of infrastructure assets. The incident can be maintenance work on a given track section, which leads to a reduced speed limit for that section or on the neighbouring track, as a protection measure for the staff. Furthermore, consequences of operational incident can be assessed. An interruption event can be a result of the broken down train or unavailability of the track section due to external factors, for example, flooding of a bridge. For both above mentioned cases, the following data has to be provided by the infrastructure manager:

- affected track or track section (reference: infrastructure & timetable input)
- speed change [km/h]
- time period (begin [hh:mm:ss] – end [hh:mm:ss])
- thresholds for delays of affected trains [hh:mm:ss]
- costs of delay per minute for different train categories (regional, intercity, freight) and for the passenger transport information about differences in costs depending on the day of the week.

Finally, there is a possibility of assessment of benefits from infrastructure enhancement. Examples of infrastructure enhancement can be the construction of an additional cross over on a highly frequented line or construction of an additional bridge. The following data has to be specified by the infrastructure manager:

- location of the planned section and connections to existing tracks (reference: infrastructure input [track::id] and position on the track [meters])
- length of the planned section [meters]
- speed restriction on the selected section [km/h]
- gradient on the selected section (if changed) [‰]
- set of affected trains (reference: timetable)
- costs of delay per minute for different train categories (regional, intercity, freight) and for the passenger transport information about differences in costs depending on the day of the week.

5. Use case of Irish Rail

Within DESTination Rail project, Irish Rail network, more precisely, the Boyne Viaduct (shown in Fig.1.), is used as a case study for the development and analysis of a rail traffic optimization tool. OpenTrack [3], a software for simulation of railway operations, offered visualization of railML input data by converting them into graphic representation of infrastructure (Fig.3), where Boyne Viaduct represents the test (maintenance work) zone between Drogheda and Dundalk, obtained from the Network Statement of the Irish Rail [4].

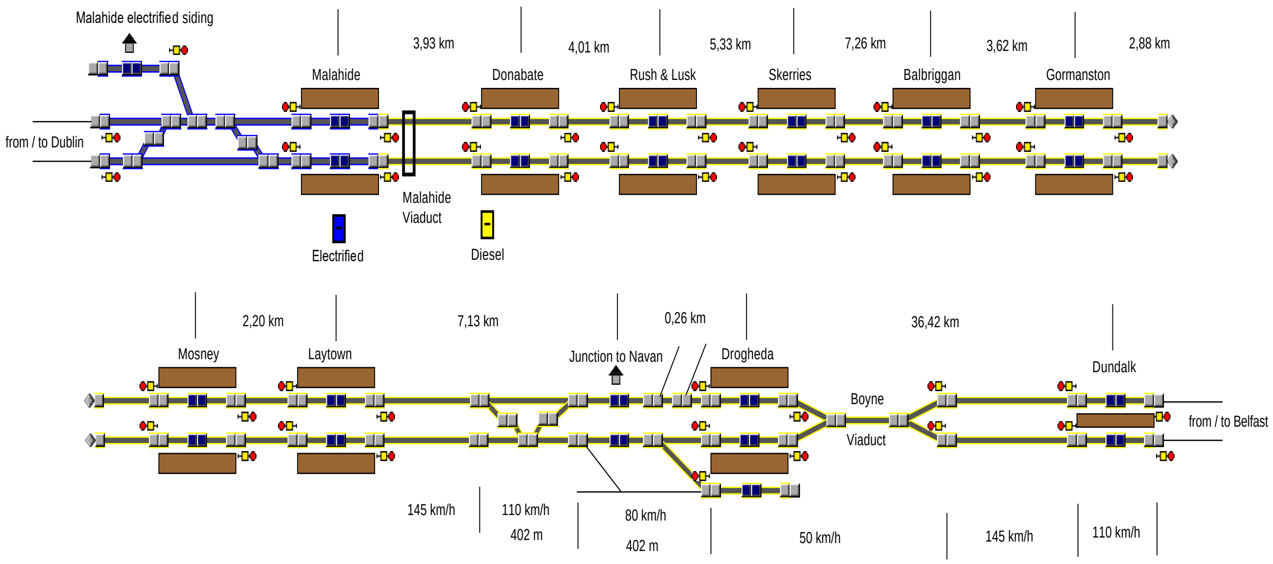

Fig. 3.
Infrastructure: Boyne Viaduct
Source: www.destinationrail.eu

Rolling Stock data includes IC and Cargo trains using class 201 and DART traveling only to Malahide. Finally, timetable data (only for passenger trains) is shown in Fig. 4.

Figure 5 shows a train graph, whereas in Figure 6 the optimized train run is displayed, both presenting an output of Kronecker algebra use. Clearly, the optimized train runs do not run at the maximum allowed speed, since Kronecker algebra approach offers solutions for avoidance of deadlocks. Further information and detailed outline of the function of the Kronecker algebra can be find in [5]. The solution offered by this approach shows the optimal way for passing bottleneck sections at exactly allowed speed and given time, in order to keep the occupation time at the given section as short as possible without unnecessary energy consumption due to, for example, braking for signal.

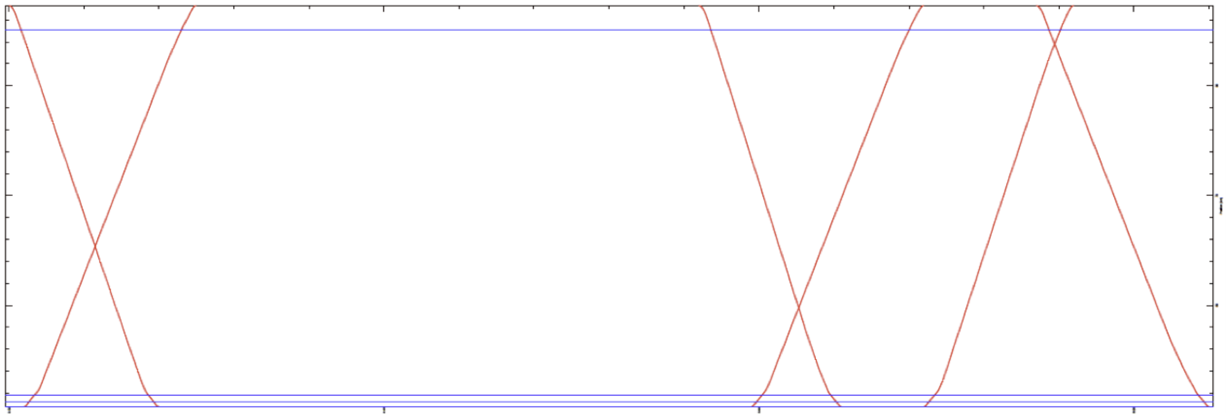

Fig. 5.

- New minimum found: 1252.9

Fig. 7.
Output from Kornecker Algebra: Delay and Energy Consumption
Source: www.destinationrail.eu

6. Conclusion

In conclusion, development of rail traffic flow optimization tool enables infrastructure managers to base their decisions on reliable data without output surprises. In other words, optimal solutions will ensure high level of efficient use of, very often scarce, resources and optimal process flow. This tool will enable one to set clear priorities based on reliable date and ensure minimal loss of operations, and more importantly, energy.

MOBILITY STRATEGIES AND ACTIONS TO REDUCE CARBON FOOTPRINT IN ATLANTIC AREA TERRITORIES

Dominique Breuil[1], Lobna Haouari[2], Véronique Seel[3]
[1,3] EIGSI, 17000, La Rochelle, France
[2] EIGSICA, Casablanca, 20000, Morocco

Abstract: Based on the outcomes of two Atlantic Area (AA) Interreg projects like Climatlantic and REPUTE, the presentation focuses on mobility actions adapted to the specificities of rural and peri urban territories in order to reduce related carbon footprint and to analyze the transferability of these recommendations on Mobility in other similar areas.
The general approach was to compare possible strategies/actions envisaged by local authorities and behavior/expectations of citizens regarding transport modes in order to point out convergences (and divergences). The analysis is based on the exploitation of surveys done:

- for local authorities, by interviews of 52 transport policy makers of several cities of the AA, concerning the best mobility strategies and actions for reducing carbon footprint
- for citizens, by questioning 3000 travelers living in the area on their habits ; this lead to sort 8 socio-types regarding mobility behavior, each having their own specificities..

The merging of these two approaches gave the opportunity to identify which strategies and actions could meet the travelers' expectations.

Keywords: carbon footprint reduction, demand driven mobility, policy making.

1. Introduction

Climate change has become a major concern for the future of Europe. This applies both to efforts to mitigate climate change by tackling the growth in greenhouse gas emissions and the need for measures to adapt to the impacts of climate change.
Together these challenges will impact on the development of Europe's economies and societies over the coming years. The different regions of the Atlantic Area will not be concerned in the same way with these challenges due to the wide diversity of productive structures across the Atlantic Area, more sectorial specialisations in the southern countries and more diversification in the northern part of the Atlantic Area.
The Atlantic Area is likely to be more vulnerable to climate change than other European regions. Apart from the consequences of climate change, the transfer of population towards coastal zones, unemployment rates and economic issues will have a direct relationship with transport organisation and mobility demand. The range of the impacts on transport is quite large, directly or indirectly, from the eventual reductions of land and increase of flood risks to population moves and agricultural production changes. The pillars of the CLIMATLANTIC project {CLIM 2013) aimed at fostering the development of strategies at regional and local level to reduce the carbon footprint in the European Atlantic Area ; the "Mobility" pillar activities were focused on the complex and very diverse mobility situations of the various territories of AA.
Mobility for passengers and goods was considered as a multilevel problem which requires coordinated and coherent solutions from the bottom level (ex cities) to the top level which is has no real existence. However, several institutions like Conference of Atlantic Arc cities or Conference of Peripheric Maritime Regions propose orientations or directives.
Usually, decisions concerning mobility are taken at intermediate levels, by regional authorities and urban communities (group of several cities). For these, several tools and methodologies exist in order to help local authorities when improving mobility with regards to Climate criteria, for instance Sustainable Urban Mobility Plans (SUMP 2015). But these tools are focused on local actions then the resulting local optimisations suffer sometimes some lack of coordination and some incoherencies between neighbouring or similar cities/regions.
In order to avoid such situations, the Mobility Pillar developed a "meso" approach based on the combination on different points of view regarding actions to reduce carbon footprint:

- The identification of the specificities of the different type of territories along AA
- The possible mobility strategies and types of actions
- The behaviours of travellers in the AA

The objective was to compare the actions envisaged by decision makers and the expectation of travellers. This approach (eg criteria, analysis,…) was developed in coherence with the 3 other CLIMATLANTIC pillars dealing with energy, land management and behaviour change

[2] Corresponding author: dominique.breuil@eigsi.fr

2. Specificities of AA territories

From the territorial structure point of view, the AA area integrates several regions with different urban typologies that in the coming years will not have the same objectives or position with regards to the major topics that influence both urban settlement and transport demand of passengers and goods, namely Demography, Urbanization and Economy.
Thus it would not appear reasonable to have identical recommendations or strategies for all the regions. However, it will not be possible to determine which strategy is optimal for each region or even sub-region. In this case, the approach has been to identify the most significant contexts in which each AA territory can recognize its own situation.
The recent ESPON projects (DEMIFER, FOCI and EDORA cf ESPON 2013) clearly show the differences between AA regions regarding several criteria. The report on metropolitan areas in Europe (MAE 2011) proposes a complementary approach on the functions performed by cities and agglomerations at the regional or local level in order to organise and control the various social systems that are represented in their territory. Six types of function may be identified:

- Living facilities: housing, shops, crafts, etc.
- Social facilities: transport, health, etc.
- Administration: politics, law& courts, police, etc.
- Innovation & prospective: research, education, innovation, etc.
- Culture: arts, sports, tourism, etc.
- Economy: industries, services, etc.

If these functions are combined with the demographic and economic parameters (especially employment), four main types of regions can be defined representing the various structural situations that can be found in the AA regions regarding both territorial organisation and mobility in terms of accessibility to the main centres for daily work or shopping

- predominantly urban, dominated by a metropolitan area
- group of equivalent medium sized cities grouped in a polycentric network,
- medium sized city with smaller satellites
- low demographic density (predominantly rural)

3. Mobility strategies for AA

The objective of this global level approach is to focus on recommendations which should be significant for AA territories and decision makers. These have been consolidated by interviews with politicians in charge of mobility in several cities.

3.1. Strategic domains

The following mobility domains have been identified as the most susceptible to be the theatre of local authorities' decisions applicable in each of the 4 types of territories based CIVITAS approaches (CIVITAS 2016):

- Clean fuels and vehicles grouping all actions in favour of the development of more environmental friendly transport resources
- Mobility management encompassing decisions which tend to organise mobility of citizens and goods, from personalised travel plans to integrated pricing. These decisions are also linked to development strategies of the Territory and of its main components (ex cities)
- Alternative mobility usages or modes which can be described as less car intensive life style or "soft measures". This domain encompasses activities dedicated to the behaviour changes from stakeholders
- Demand management: this covers all actions which aim to optimise the demand response
- Collective passengers transport on several aspects like quality of services, travel information, network development, intermodality, ticketing. Although this is clearly people oriented, similar actions could be developed for goods in the future, especially with the development of Internet of Things or freight mixity
- Logistics : this deals with the actions aiming to improve the distribution of goods over an area, urban, peri urban or regional. They can be related tofleet management, route planning, storage facilities…..
- Mobility information systems which covers all actions related to information technologies, from mobile exchange to operation exploitation software
- Infrastructures : covers all actions related to the design and implementation of any kind of infrastructure not taken into account in previous topics. This domain is strongly linked to Land Planning actions.

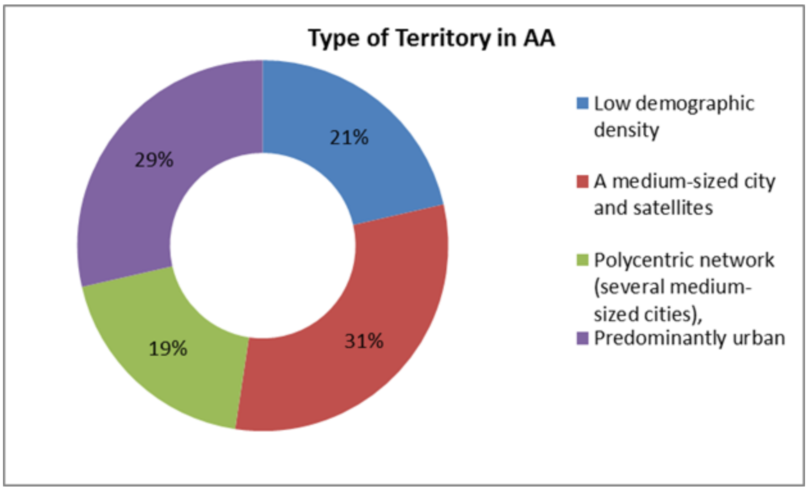

Fig. 1.
Split of interviews

21 mobility relevant strategies have been identified to reduce carbon footprint on AA; the list is in fig 2 below. Obviously, each action strategy which could be envisaged is likely to concern many mobility domains. Several types of actions were associated to each strategy ; the list of actions could be increased by respondents. For instance the strategy "*To develop Collective Transport network homogenously with land planning*" was split in:

- *Traversability of AA from/to hubs, ports, gates*
- *Capillarity inside territories*
- *Interoperability*
- *Intermodality between regions, specially with rail*
- *Others….*

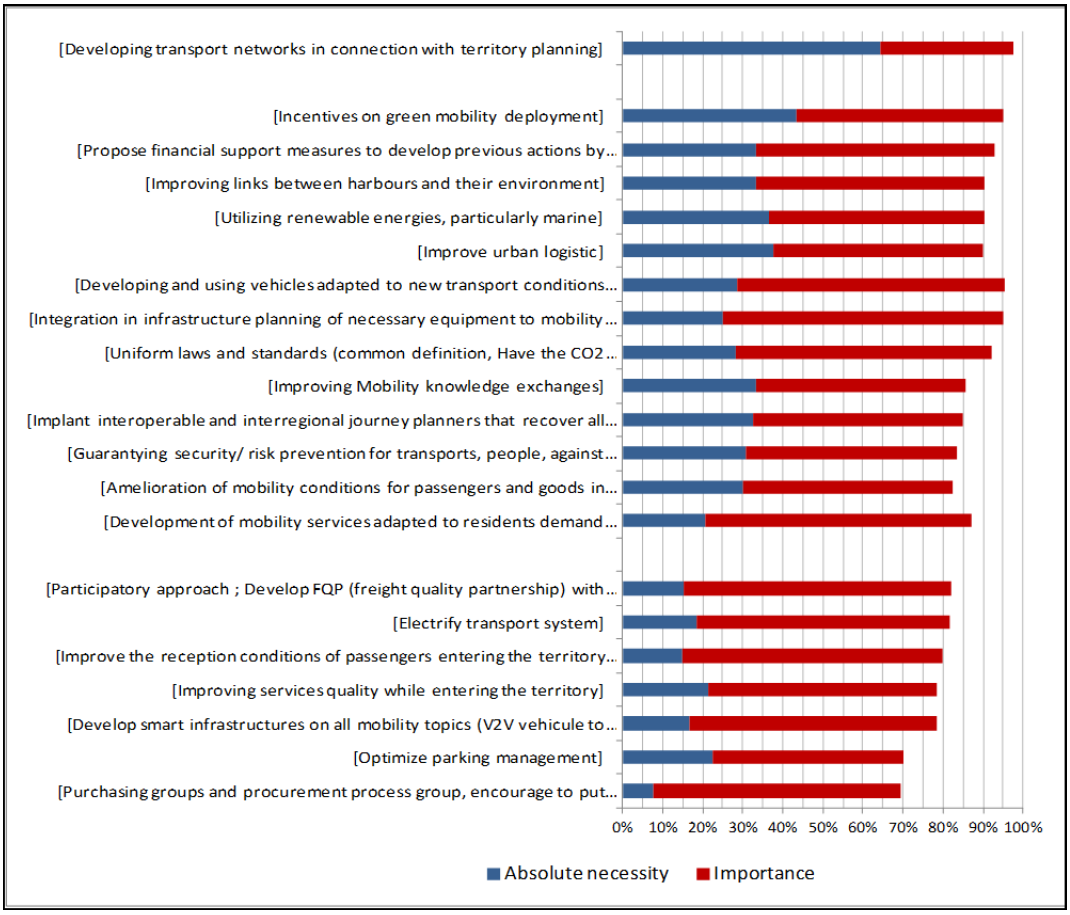

Fig. 2.
Classification of mobility Factors

3.2. Mobility factors in AA

In order to determine priorities from the decision makers, 52 stakeholders were interviewed and the envisaged time scale was 2025.
The rating had 4 positions (*No importance, low contribution, Importance or Absolute necessity*)for each of the actions.
Among the 21 actions and strategies, almost all of them are highly rated in terms of contribution for carbon footprint reduction, showing the difficulty for decision makers to choose between all this strategies and actions.
However all opinions were not identical and some "controversies" appeared between interviews due to the ratio between the rating of an action as an « absolute necessity » and as a « low contribution/no importance » contribution. Among the global result and the weight of the "absolute necessity" into the answers of importance, we could also observe a split between actions with an antagonist position between responsible of transport thinking that this action is an absolute necessity and others rating the contribution as "low" or "no importance".
Regarding mid term (by 2025), the "Developing transport networks in connection with territory planning" action clearly stands out, rated by about 65% of responsible of transport to be "an absolute necessity". 33% rated this action as "important"
6 strategies and related actions are approved by quite all respondents rated between 95% and 90%[3] as "an absolute necessity" or "important"; with no controversies. They are dealing with Infrastructures and land planning domain, Finance instruments, Clean fuels and vehicles domain, logistics and mobility management.
4 strategies and actions highly rated in terms of contribution by all responsible of transport might be subject of "controversies"
They essentially deals with Demand management and Managerial position such as

- "Development of mobility services adapted to residents demand (elderlies, suburbs, low density territories…) for example TAD"
- "Amelioration of mobility conditions for passengers and goods in interregional rails trips (comfort, frequency, access…)"

7 strategies and actions are both subject of "controversies" AND with relative low contribution although the "lowest" one is rated at 70% as important. To enhance the relevance of the actions with AA specificities, they were grouped in 3 categories,

- Strategies and actions strongly linked to AA, Those actions are mainly related to marine (Altlantic) proximity and European entry.
- Strategies and actions which are influenced by AA situation but could be found in other European areas, like tourism
- Strategies and actions which can improve mobility in AA territories similarly as in other areas

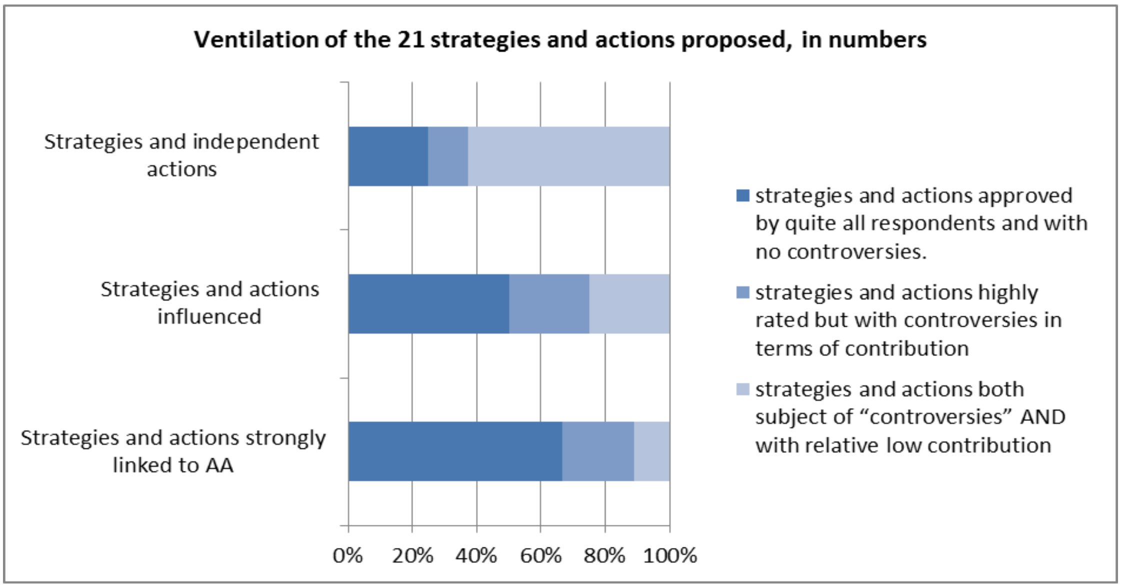

Fig. 3.
Analysis of stakeholders' answers according objectives

In order to explore more clearly those "controversies", a multiple correspondence factoral analysis has been conducted. Similarities were identified between the ratings and answers of

- Mobility managers in low demographic density (rural) territories and 75% of territories with a medium sized city with smaller satellites on one hand.

[3] Base : all answers

- Mobility managers in predominantly urban territories and 75% of polycentric network on the other hand.

Territories predominantly urban or with polycentric network are far more concerned about urban logistics, parking management and demand management than other territories.
Moreover, another characteristic of this second group is that 100% of "absolute necessity" ratings of "Improving links between harbours and their environment" are in this group.

4. Travelers behavior analysis

The objective of this analysis was to point out the feeling/ behavior of travelers living or going to low density areas or medium sized cities. The survey was conducted during the first semester of 2015 and concerned 3000 people over the AA (REPUTE 2015).

4.1. Sociotypes of travelers

Socio-types are built on three dimensions:

- The "size of modal habits" differentiates people who use only one mode of transport to those who use several (multimodality) . This mode is entered by frequency of use of different transport modes.
- The "values" dimension differentiates respondents describing the transport offer depending on individual interest (makes independent, comfortable, etc.) of those qualifying Transport modes according to the general interest (ecological, pollution, noise, etc.).
- The "size of the different attitudes" of the respondents according to their preferences of use, ie the opinion (positive, neutral or negative) they have regarding different transport modes.

Based on these dimensions, the typology was constructed with factor analysis of principal components which were used as variables for a Cluster analysis. The robustness of the groups thus created was then tested using topological log-linear models to ensure the identical structure of the building in different contexts (different types of cities and contexts of residence).
The groups are characterized by high homogeneity of actions underlying modal practices, particularly as regards:

- The differentiation between favorable adjectives to public transportation (rapid, practical, ecological, etc.) to those who are against (their expensive, slow, binding, etc.)
- the differentiation between adjectives relating to the cost of travel by public transport opposing "expensive" to "cheap"
- A strong differentiation between the ecological dimension of transport and polluting nature of private cars,
- A strong differentiation by use of transport modes.

To ensure reproducibility and comparability of the method, the complexity of the analysis in Key components used to construct the principles of this type, this one was simplified analytical method from the variables used in its construction. The typology obtained by this means has been optimized to be as close as possible socio-kind from the multivariate analysis. In the end, eight socio-types are selected.
The eight socio-type identified in this study are:

1. Convinced exclusive motorists only use the car in everyday life; their routes are structured around accessibility offered by this means of transport.
2. Opened exclusive motorists. The only difference with previous group is the positive attitude regarding public transport ; they are therefore open abstractly their use.
3. exclusive alternatists never use automobile; their routes and activities are structured around the accessibility offered by public transport, walking and cycling.
4. Ecologists civic prefer the use of Green vehicles to be consistent with their beliefs.
5. Time comparators use the fastest mode of transport; they know public transport as well as automotive advantages and constraints and choose case by case.
6. Motorists forced (to the use of public transport). They prefer to use the car, but forced by parking, traffic…. conditions to use other means of transportation for everyday destinations.
7. Predisposed Alternative prefer to use public transport, walking or cycling to the automobile for the characteristics of the mobility offered by these modes.
8. Vicinity anchored : they do not like to travel by means of transport motorized; they are (or would be) strongly anchored in the vicinity.

Socio-types allow also to distinguish people categories according to:

- Their modal patterns between single-mode using a single mode of transport and
- Multimodal who use several (even briefly)
- Their values regarding mobility as they apprehend modes of transport so group or individual;
- Attitudes to whether they represent the different modes of transport so positive, negative or neutral.

4.2. Main findings

The analysis of the answers of the 3000 interviewed people lead to the following global tables which summarise the main outcomes.
The results of this survey showed that if households are highly motorized, they also have the opportunity to use Public transport, and for the majority of them by bus networks whose frequency is daily. The demand analysis confirmed that households used occasionally (ie less than once per month) public transport, even if they mostly traveled in private cars. Predispositions for the use of alternative transport to the car are strong. Age and country residence vary the distribution of socio-eight kinds, unlike the type of inhabited area. So, younger people are more prone alternative to the automobile.

Table 1
Repartition of sociotype according type of territories

	Peri Urban	Inter mediate	Rural nearby city	Rural far from city
Convinced exclusive motorists	1%	1%	1%	1%
Opened exclusive motorists	12%	18%	21%	12%
exclusive alternatists	3%	3%	2%	2%
Constrained motorists	4%	3%	3%	3%
Opened alternatists	43%	39%	43%	48%
Time comparators	25%	28%	22%	22%
Civic ecologists	1%	2%	1%	1%
Vicinity anchored	7%	4%	6%	8%
No Answer	4%	2%	1%	3%

Table 2
Repartition of sociotype according countries

	France	Ireland	Portugal	Spain	UK
Convinced exclusive motorists	1%	1%	1%	1%	1%
Opened exclusive motorists	34%	12%	12%	11%	11%
exclusive alternatists	1%	3%	2%	2%	5%
Constrained motorists	3%	4%	3%	3%	3%
Opened alternatists	29%	51%	48%	35%	46%
Time comparators	23%	18%	27%	42%	18%
Civic ecologists	4%	0%	1%	1%	1%
Vicinity anchored	3%	9%	4%	3%	10%
No Answer	2%	2%	2%	2%	5%

The eight socio-kind vary by country residence with:

- A high proportion of "proprietary drivers open" in France in connection with a strong attachment to the automobile;
- A "predisposed to alternative" among the Irish in connection with a mean age more lower than in other countries;
- "comparator time" among the Spaniards looking to move with fashion more suited to their needs in terms of cost, comfort and journey times;
- "exclusive alternative" and "anchored in the vicinity" (10%) in the UK, which is explained by a lower motorization and mobility costs more.

This study helps to have a comparable measure between Atlantic Arc regions for the collection of transport modes and modal practices. The collected database in this study could be the subject of further analysis in particular regarding links with commuting

5. Conclusions

Although logistics impacts on mobility were not considered in the citizens survey, the comparison between the 2 approaches point out several outcomes among which the most obvious were :

- The majority of travelers are flexible and opened to various transport modes ; they tend to choose according pragmatic criteria (time, cost,…) rather than by conviction. Then the deployment of efficient public and/or collective transport may offer a valuable alternative to private transport resource. This is in line with the first strategies/actions for policy makers.

- This should also push local authorities to give more importance to actions leading to enhance mobility conditions and services adapted to areas contexts which were not among the prioritized strategies in figure 2
- Green vehicles and renewable energies are not so requested by travelers

These first results are the basis for a more detailed study on these specific areas in the AA which should be launched beginning of 2017 aiming at increasing the knowledge on the match between behavior/ expectation and possible actions for reducing carbon footprint.

ELECTROMOBILITY IN RURAL AND PERI URBAN AREAS

Dominique Breuil[1], Mohamed Khafallah[2], Abdelilah Hassoune[3]
[1] *EIGSI, 17000, La Rochelle, France*
[2] *Laboratory Electricals Systems & Energy – LESE, Hassan II University ENSEM, Casablanca, Morocco*
[3] *EIGSICA, Casablanca, 20000, Morocco*

Abstract: The communication focuses on rural and peri urban deployment of electromobility, where, in many cases, public transport is unavailable. The aim of the communication is to point out how electromobility can satisfy some aspects of the specific demands and reinitiate new ways of living in these areas. There are some general transport features which affect these areas such as:

- People living in rural areas may travel up to 50% further than their city counterparts;
- Lack of integration of different modes of transport;
- Lack of real-time information.

The first part is dedicated to the identification of the specificities regarding mobility demand (passengers and goods) in those areas; it is based on several surveys among which a large survey conducted during an Interreg Project over Atlantic Areas citizens living in such areas (from Scotland to Portugal) Several factors influences the behaviour of people living in these areas like demography, distances to attractive places or fuel availability must be taken into account. This survey showed also clearly the relationships between the citizens and their transport modes. The second part deals with the various technical solutions which can be envisaged to deploy electro mobility, the necessary adaptations to the local context. The last part concerns the methodologies to implement electromobility in these specific areas, the barriers and drivers..

Keywords: electromobility, rural and peri urban areas, sustainable transport modes, policy making.

1. Introduction

In most of rural , peripheral and landlocked regions, minimum services are available with reasonable cost but accessibility to services (distance and time) is often longer and public transport are not as well developed than in urban areas and the possibility to choose amongst different alternatives is concentrated in highly populated urban areas. Then residents are more owned car dependent and supply of goods is more restricted.
The "EU White Paper on Transport " objectives (EUWPT 2016) for reducing CO_2 and other pollutions represent a difficult challenge for the concerned local authorities which do not have a range of policies and resources as large as in those located in denser areas.
Several studies and reports have pointed out the challenges facing rural areas regarding sustainable mobility; environment (climate, air quality, health), energy efficiency or even territory attractiveness are concerned but the most important concern social ones which influences economic dynamic (job and services access, travel time, …)
Electric mobility is expected to play a major role for achieving these goals for three reasons: (a) The electric power train is significantly more energy efficient than the conventional one, (b) electricity can make use of energy from renewable sources available for transport, and (c) of connected to the power grid, batteries of electric vehicles could stabilize the grid and balance supply and demand and thus facilitate the integration of renewable sources.
Moreover, Electromobility is a vector for changing mobility behaviour and new services will facilitate these evolutions especially in these territories.
Therefore electro mobility should be more developed in rural areas but solutions must be adapted to the local context. Demonstrations have been launched (cf for instance European Alternative Fuels Observatory reports) providing a better knowledge on the adaptations to be realised, on the drivers and barriers specific to these situations.

2. Mobility in rural areas

Rural communities can include a number of complex and contradictory specificities However, it is possible to identity some common criteria which have significant direct or indirect influence on the organisation and deployment of mobility solutions, mainly their nature, demography and localisation as well as the transport demand (residents' expectations).

2.1. Nature

Most rural communities can be grouped into five categories (ICMA 2010) though many may fall into more than one:

- Gateway communities are adjacent to high-amenity recreational areas such as National Parks, National Forests, and coastlines. They provide food, lodging, and associated services mainly linked to tourism
- Resource-dependent communities are often home to single industries, such as farming or mining, so their fortunes depend on an external market
- Edge communities are located at the fringe of metropolitan areas and typically connected to them by state and interstate highways. They provide their residents with access to economic opportunities, jobs, and services…

[2] Corresponding author: dominique.breuil@eigsi.fr

But precisely because they are such attractive places to settle, edge communities often face pressure to continue to provide more housing and services to new residents.

- Traditional Main Street communities enjoy compact street design that is often accessible to a transportation hub. Still, these communities often struggle to compete for tenants and customers with office parks, regional malls, and big box stores.
- Second home and retirement communities may overlap with some of the above groups, particularly edge communities and traditional Main Street communities. They often struggle to keep pace with new growth while maintaining the quality of life that drew in residents in the first place.

2.2. Demography and social issues

The key social process in contemporary rural change is migration which depends on three factors (EDORA 2013) :

- the “rural exodus” which (selectively) drains human capital out of remote rural areas, in favour of urban and accessible rural locations;
  the flow of economic migrants from the poorer regions of the New Member States (NMS12) towards both rural and urban regions of the EU;
- “counter-urbanisation” movements from cities and towns into accessible rural areas.

The social and economic impacts of the first of these upon the origin regions are predominantly negative. The other two kinds of flow result in a complex balance of positive and negative effects upon rural regions.
These three types of migration bring new population in the areas and lead to a changes in demand and behaviour regarding mobility independently of the (more or less according to areas) demographic ageing. These changes are linked to the requirement for a certain level of quality of life and access to services (education, health, social services, NTIC ….)
These structural changes in the rural economy is associated with changes in the robustness and capacity of local communities and lead to new ways of rural governance, including the organisation of mobility and the appetence for new technologies such as electromobility. For instance, the report on metropolitan areas in Europe (MAE 2011) proposes 6 types of residents' attractiveness which must be fulfilled by local authorities (and of course accessible):

- Living facilities : housing, shops, crafts,…
- Social facilities : transport, health,…
- Administration : politics, law & courts, police…..
- Innovation & prospective : research, education, innovation,…
- Culture : arts, sports, tourism
- Economy : industries, services,…

2.3. Accessibility

Accessibility is a two dimensions driven variable: Accessibility consists of two components, available activities of interest and transport infrastructure leading to them. Accessibility is important because it provides access to opportunities at distant locations or makes it possible to receive goods and services or visitors from distant locations. For policy making, the maximisation of accessibility is therefore an objective only as far as it helps to improve the quality of life by facilitating access to opportunities, goods and services and so participation in social and cultural life (TRACC 2015).
Several surveys (like SURVEY 2008, SURVEY 2011, SURVEY 2015), point out the main characteristics of sparsely populated areas (as shown in fig 1 and 2 below):

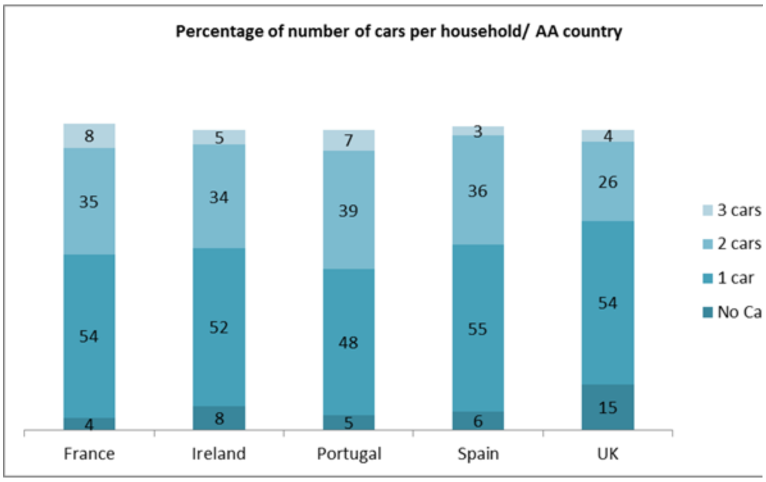

Fig. 1.
Percentage of number of cars per household / AA country

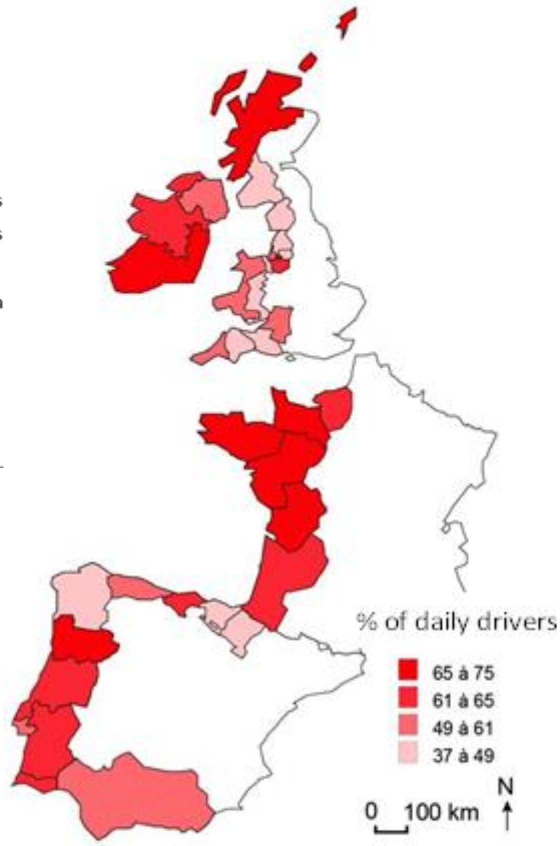

Fig. 2.
Percentage of daily drivers

- Daily trips longer in distance, not really in time ; the average length for home to work trips is 21 to 25 kms and average time 20 to 30 mns, but there are significant differences according to the countries, average 24kms in Ireland and UK versus 13 kms in France, Portugal and Spain
- 75% of trips are realised by cars, due to very poor public transport networks more oriented towards school travels for children than other categories of travellers
- A high number of short travels, globally half of the travels are less than 5kms and realised quite quickly
- Very small practices of intermodality (use of several transport modes in the same trip)

However, no significant differences have been observed by the TRACC project (TRACC 2015) for performance in regional and local accessibility between regions located at the European Periphery and regions located at the European Core. Regional case studies have revealed relatively homogeneous patterns within regions ; this was also observed on the Atlantic Area regions (SURVEY 2015, cf below)

2.4. Targets and demand

The knowledge of residents' behaviour regarding mobility is somehow biased by the availability of transport modes. Although globally, mobility drivers are the same as those of people living in densely populated areas, some expectations and practices regarding transport modes and resources are different due to the way of life in the various types of rural communities. These differences concern mainly:

- The number of cars per household depends on the remoteness, for instance 45% of households in rural areas have more than 1 car instead of 30% in urban areas (SURVEY 2015 / not counting cities over 100 000 inhabitants)
- Seniors mobility decreases with ageing, from more than 3 travels/day before age of 75 to 1.5 travels/day between 75 and 85. The motivations of seniors for travelling are : Health 59%, Family 51%, Travels 41%, Leisure (sport, association, shopping…) 41%, Reading 32%(survey Panel Progrès October 2015)
- Adults, working or not residents tend to work in their area, for instance 90% of people leaving in rural areas (like Traditional Main Street) work in the same area (SURVEY 2015). 77% of them drive their cars daily to go to work.
- Young people represent a very specific demand category since they usually do not own a car and few of them use a 2 wheels vehicle for a school or leisure purpose. Students (eg older ones) strongly use public transport (for instance 37% of daily trips in SURVEY 2015) . Young people mobility in rural area is a critical problem

which retain some family to live in those territories since all activities other than school are rarely accessible through public transport ; then parents have to drive their children to the concerned places.

- Tourists represent also a growing demand (INTEGRA 2013, ATOUT 2014); in general the more remote an area is, the more interesting it is for tourists ! Their demand regarding mobility presents several aspects from very short distances inside a city, larger ones around the country side or to travel from one area to another.
- Goods delivery and transportation have also their own specificities. The transport problems are inversed since usually travel time to go through a village or a small city is quite short although the distances between delivery points are longer than in urban areas. New behaviours are emerging with the growth of e commerce whether goods are home delivered or collected by receivers in specific points ; these modify the organisation of runs by logistics operators and/or is a source of new trips for inhabitants.
- Farmers and all the local food transformation activities represent also a specific demand. Agricultural machines (especially tractors) are mainly fuelled with oil and represent the 53% of the energy consumption for agriculture with2.090 ktep per year ; other consumers are breeding buildings and greenhouses 430 ktep (11 %) et 400 ktep (10 %). (TERRE 2014).
- Handicapped people who have the same demand that previous ones but require specific adaptations in the infrastructure and vehicles as well as accompanying persons

3. Possible Electromobility solutions

Development of electromobility in rural and peri urban areas may be considered according to four axes, like in all areas, but with some specificities

- The technologies : infrastructure and vehicles
- The services directly or indirectly linked to the deployment of electromobility and related organisation
- Finance since deployment of electromobility requires several investment sources
- Regulations

3.1. Technology axes

Infrastructures

In many EU countries, policies for deploying charging stations network have been designed and implemented. However, they concern mainly cities and main transport corridors. During the recent years, charging stations have also been installed in some quite small cities (less than 10 000 inhabitants, cf the European Alternative Fuel Observatory statistics in EAFO 2016). Unfortunately, many of these implementations have been done from a politic point of view and are not as successful as expected for pragmatic reasons (independently of the scarcity of vehicles) :

- The large majority were "slow" charging stations (4kw)
- They were installed according a marketing / political approach, often in wrong places regarding flows and efficiency; for instance charging at rail stations : if someone plugs its car during its journey, the station is unavailable during all this time…..

An important difficulty in rural situation is the grid connection. If a fast charging station (>40kw) is to be installed in the country side, the connection to the grid might be not powerful enough to support such power requirement. Hopefully the new fast charging stations, equipped with a buffering battery may decrease the instantaneous demand.
Moreover, the majority of population in those areas live in their own houses, contrarily to urban one which facilitates home charging and consequently decreases the need of on-street or parking stations and modify (in the right way) the ratio stations/ household.

Vehicles

Considering the demand, the variety of vehicles to satisfy mobility requirements inside those areas can be grouped in 4 categories :

- Vehicles able to go to the nearest town, for daily work trip or less frequent moves (like shopping, leisure…) ; the average return distance is less than 100kms, which is less than the autonomous range of current EVs (Electric vehicles). Owners can be also reassured if (rapid charging 20Kw) stations are available at their work or in the town
- Vehicles to go around the area, light vehicles or 2 wheels which can easily satisfy moves inside small cities, between villages…
- Professional vehicles for craftsmen, famers, local logistic operators ; today several electric vans or small trucks are available on the market with reasonable performances. In a few years, larger ones will be ready at reasonable costs, some of them been currently manufactured (for instance 19t truck developed by Emoss…) with a satisfactory battery autonomy range. Electric tractors are not yet enough performant but several prototypes exist and it is expected to have some cost reasonable ones on the market before 2020. One important aspect of these machines is their ability for autonomous or remote controlled driving ; this is much easier to realise than autonomous vehicles in city and may grandly facilitate farming (cf for instance the

Autonomous Tractor Corp. of Fargo) as many other electric machines (cf drones to monitor and analyse plants growth.

- Collective transport for which there is already a large panel of e-buses ranging from 12 seats to double-deckers in London on the market. Various en route charging solutions to increase the distance are demonstrated in several cities to reach distant suburbs which could be easily transferred in country side (cf ZeEUS)

3.2. Services

Several mobility services may be adapted to fulfil transport demand with EVs. This adaptation is linked to the context and to the necessity to reach an equilibrated financial balance (eg specific Business models). Some of them have already been implemented and brought out valuable outcomes such as the following.

- Experimentation of EV car sharing have been deployed and lessons learned from these various implementations, for instance the car pooling experience in Poitou Charentes called REGIONLIB (ended in 2016). One major difficulty is the localisation of the car stations : if the customer must take his car to reach the station, then he will continue his trip and it is impossible to ensure the availability of cars in all villages. Then there are several solutions, one is the reservation of a car which was never really successful, another one is the reservation of a car and a chauffeur which completely changes the business model and provides a secure travel for all elderly people living in the country side or youngers going to extra scholar activities…. and creates employment.
- The utilisation of public fleet by authorised drivers ; since EVs or E buses are expensive, the local authorities which buy them may rent these vehicles when not used by the public staff to other institutions like retirement mansions for excursions, local associations, local very small enterprises.
- E bikes or scooters for tourists which may travel from one area to another if local authorities cooperates, sometimes through tourism offices ; this is also feasible with e boats on canals or rivers.
- Rural Consolidation Centres (with E Vans) which may avoid logistic operators to spend time and money on isolated delivery trips. As for the Urban CCs, they must provide several services (not only cross docking and delivery) to be profitable like temporary or dedicated storage (ex for craftsmen), last end supply chain activities…

3.3. Finance

Local authorities of these areas do not have the same resources and finances than larger communities. Therefore they need to find other funding sources for their investments, the deployment of infrastructure or promotion of cleaner transport modes. Apart from subventions given by various institutional bodies or bank loan three possibilities are often used:

- Grouped procurement by several local authorities, which makes for instance charging infrastructure more affordable and coherent over a larger territory
- Collaborative funding with individuals or local bodies which has been already used for vehicle sharing stations and vehicles and is quite appropriate for small areas
- Other private partnership with enterprises liked for instance the management of Consolidation centers

Moreover they cannot use some incentives offered to urban citizens like free car park for EVs, dedicated lanes or specific delivery areas. But specific ones may be developed like the access to "good" market places for sellers' market, priority for some administrative services,….

3.4. Regulation

As in larger cities, deployment of electro mobility must be accompanied by the strict application of regulations intending to favour electromobility. Small cities or communes may create access controlled zones in inner town, prioritise EV parking or access in historic, touristic places (ex country roads, wood trails,…)

4. Implementation, drivers and barriers

Many European local and regional authorities have put in place e-mobility measures but not so many have developed e-mobility policies and included them in the overall mobility strategies. On another hand, specificities of electro mobility are not clearly taken into account in the proposed methodologies to deploy clean, sustainable mobility plans in rural or peri urban contexts, cf for instance Polycentric SUMPs (PSUMP 2015) or Metric tools (JRC 2015), the "plan de mobilité rurale" (CEREMA 2016). EU projects like ZeEUS (ZeEUS 2016) or FREVUE (FREVUE 2016) are mainly focused on larger cities demonstrations and resulting guidelines are more appropriate to urban implementations than rural ones.

Some European projects have experienced how to develop e-mobility strategies in low demography areas, such as for instance the ELMOS (ELMOS 2016) and REPUTE (REPUTE 2015)projects providing valuable context related lessons and information which are first outline to the definition of E-mobility strategies in rural areas.
The global implementation approach remains valid and is similar for all electro mobility projects, especially the necessity to set up a holistic approach encompassing all stakeholders' expectations (passengers, logistics operators, professional..) and integrated in overall land planning strategy. However some aspects must be considered with specific concern, mainly the following.

- The scarcity of reliable data concerning traffic flows, local practices etc. ; such situation often requires a detailed diagnosis at the beginning which takes time in order to obtain a representative cartography of the flows, a comprehensive vision of behaviours, practices and expectations.
- Linked to above, the definition of specific indicators to measure the progress
- The step by step deployment of electro mobility measures along with other clean mobility actions ; this deployment must be planned according to the envisaged technical evolutions as well other constraints like finance, citizens changes and awareness…
- The necessity to develop new governance schemes, often coordinated between several territories and involving public/private partnerships like for instance vehicle sharing managed by tourism offices or social institution for old and/or disabled people

Barriers and drivers in rural context are also similar to those in urban one with few differences ; main barriers are still :

- Costs since vehicles are still more expensive than oil fuelled ones, even with national or regional subventions
- Perceived autonomy which will become less a barrier with the evolutions of the batteries (currently 250kms) and the deployment of networks for long distance travels
- The lack of specialised vehicles, especially for professional utilisation or adapted to country trips which should be filled in a near future (before 2025)

Concerning drivers, main ones are

- Examples given by local authorities, local politicians , public bodies owning EVs in their fleet
- Information addressing specifically all targets, promoting electro mobility as well as proposing new vision of multimodality and intermodality.
- The deployment of new services managed by centralised institutions over one or several territories for specific targets especially concerning collaborative mobility or sharing vehicles

5. Conclusions

Mobility is a key stone to keep alive rural and peri urban territories which can be further developed if services are accessible as in larger cities. New information technologies (NTIC) may facilitate working in these areas but people living there will still need to travel easily from these places even if the travel behaviours regarding modality will change with the next generations.
Electromobility is just at the beginning, progress in the range autonomy are expected in the next future for all modes and development of charging facilities will also be facilitated by these evolutions. Combined with NTIC it will support the sustainable revitalisation of many territories providing a good quality of life of residents and offering nice hosting and travel conditions to tourists and visitors. The recent developments done for autonomous vehicles in real life situation like in La Rochelle (CITYMOBIL 2016) or the experiences of Rambouillet city show the way for the mobility in low demography territories.
However new business models have to be set up based on collaborative approach between residents, local authorities and enterprises in order to optimise the multi modality which satisfy the demands of the various categories of inhabitants; In the same way, new mobility behaviours have to be generated among the population leading to a larger use of multimodality facilities.

ESTIMATING THE HOURLY VARIABILITY OF BICYCLE TRIP PATERNS AND CHARACTERISTISC FROM AUTOMATIC BICYCLE COUNTERS: CASE STUDY IN PRAGUE, CZECH REPUBLIC

Vojtěch Jirsa[1], Yusak O. Susilo[2]

[1] *University of Pardubice, Jan Perner Transport Faculty, Department of Transport Technology and Control, Czech Republic*

[2] *KTH Royal Institute of Technology, Division of System Analysis and Economy, University in Stockholm, Sweden*

Abstract: Nowadays it is common for many cities around the world to use automatic bicycle counters laid at main road segments to monitor the cyclists' traffic flow at any given time in the given location. In most cases, this data is then used to identify the peak period of the bicycle traffic. This paper introduces a method to classify the characteristics of bicycle traffic flows and inferring different proportion trip purposes based on the variations of hourly counts. Whilst of many previous studies investigated the key determinants of bicycle travel demand detected by these counters, none of these studies tried to distinguish different portions of different traffic characteristics in each counting section. In most cases the trip purposes of cycling were grouped into either prevailing utilitarian or prevailing recreational. In reality, however, these recorded bicycle traffic contains both trip purposes. The method which is introduced in this paper was developed and tested on the longitudinal datasets obtained from the bicycle counting system in the city of Prague over five years' period, i.e. 2010 to 2015. The system consists of 26 counting facilities in various city quarters covering wide variety of road segments. In achieving the study objective, first, a theoretical assumption was done to differentiate three different basic traffic characteristics and their respective hourly variations, i.e.: utilitarian, recreational affected by workhours, and recreational not affected by workhours. These hypothetical hourly variations were tested and confirmed based on the observed Prague sample. Obtained results were discussed with respect to geographical location, built environment and knowledge of local situation. The hourly variations of the recorded bicycle flow were influenced by the build environment factors such as specific land use in the proximity of counting section. The results also indicate some specific routes (and its direction) preferences.

Keywords: cycling, traffic characteristics, hourly variations, optimization.

1. Introduction

Many studies have been carried out measuring impacts of various factors on the use of bicycle and some of them more specifically measuring the impact on bicycle traffic flows (e.g. Thomas et. al., 2012; Miranda-Moreno and Nosal, 2011; Cools, 2009). Different characteristics of bicycle traffic such as utilitarian or leisure showed different sensitivity to explanatory variables such as season, built environment, weather, etc. Among others Liu et. al. (2014, 2015) proved in his mode choice oriented studies that the impact of weather is more significant for leisure cycling than utilitarian. This was also confirmed by studies devoted solely to recreational cycling (e.g. Hamilton, 2005; Jeuring and Becken, 2013).

None of the analyses, focused on bicycle traffic flows, included the characteristics of bicycle traffic flow as continuous explanatory variable. This is due to the fact that information about the trip purpose for every single count is not available. Some of the authors of previous studies made the presumptions about the prevailing traffic characteristics in particular sections according to the knowledge of the local situation. Thomas et. al. (2012) distinguished three types of cycling paths: utilitarian, recreational and mixed according to their location in built environment (connecting municipalities, open to the country side, mixed). Brandenburg at al. (2006) divided counts in two categories according to the time of counting: commuting (working-days between 0700 and 0900 CET) and recreational (working-days after 0900 CET and weekends). The later division is questionable since it presumes that no cyclists commute from work in the afternoon. Other studies performed the analysis for each counting section separately (Miranda-Moreno and Nosal, 2011) and obtained different model parameters for each section.

In modelling dependency of cycling flows on various factors the more comprehensive consideration of bicycle traffic characteristics is necessary. Knowledge of bicycle traffic characteristics is important not only for assessment of the significance of various influencing factors (and hence evaluation of trends and prediction). In practice traffic planners may be more interested in utilitarian cycling which has the potential to relieve other transport modes, while health professionals and tourism workers may be as well interested in leisure trips. This paper suggests the possible classification of bicycle traffic characteristics and outlines the method for calculation of different traffic characteristics ratio for particular section. The calculation is based on hourly variations of traffic flows during working-days and the method used is linear optimization.

In following chapters, first the data sample will be introduced. The time-bound variations analyses will be followed by the theoretical assumptions about the different characteristics of bicycle traffic. Then the used method for bicycle characteristics assessment and calculated results will be described and discussed.

2. Data explanatory analyses

2.1. Study area description

The data used in this study was collected at Prague, the capital of the Czech Republic. The area of the city is 496 square kilometres with roughly 1.3 million inhabitants. It has a good public transport system which covers 43 % of all trips, share of pedestrian trips is 23 % and car trips count for 33 % (TSK, 2014). According to the annual report of city authority responsible for the development and maintenance of road infrastructure (TSK) (TSK, 1988-2014), Prague has rather small mode share of cycling – 1 % of all trips. This figure is monitored from 2007 and remains unchanged until 2014. Over the last years, cyclists are continuously counted in several locations. Whilst in some locations there were not substantial changes captured in bike counts, in some other locations, there were found multiple increases in term of bike counts. This increase was not a surprise as the cycling infrastructure in Prague has been steadily improved over the last few years.

2.2. Data collection and sample characterization

The data used in this study were collected with the system of automatic bicycle counters. The technology of counters is based on processing of electric current induced in the wire loop installed under the pavement. Counters can distinguish bicycles from cars, busses, strollers and other road and sidewalk users and can be used at various types of cycling infrastructure both on and off-road.

In 2015 there was 26 counters installed at different locations. First seven counters were placed in 2010. In 2011 there were altogether 20 facilities with installed counters. The data available from most of the counters were collected during the years 2011 and 2015. In each section the missing and inadequate values were recorded in periods of temporary facility closures and minor counter malfunctions. The data set was thoroughly analysed to remove missing and inadequate values (through the analyses of aggregated daily counts). The data were logged in one hour intervals separately in both directions. The map in figure 5 shows the intention to distribute the counters at the locations with high demand of cyclists such as road arterials, locations along rivers and other natural and artificial barriers and places where the barriers can be overcome. Counters are placed on both on-road bicycle infrastructure (usually bike lanes) and non-motorized paths (usually mixed cycling and pedestrian paths). Either locations with expected leisure and utilitarian cycling are included. The data are collected by TSK and available from the website (Camea, 2015).

Figure 1 comprises the overall information about the sample size and its quality. The height of the columns represents the overall time of operation for each counter from January 2010 to December 2015. Seven counters were in operation over 70 months. The total time of missing values and identified malfunctions is marked in blue and green respectively. The time of one-direction counting is marked in orange and valid both-direction counts in grey. The counters are designed to count in both directions. Therefor the unidirectional counting is considered an error and for further analyses all one-direction, missing and malfunction values were excluded from the sample. Yellow curve in the graph shows the total valid counts in each location. The highest record was captured in the location "Modřany" with over 2 million counts.

Three counting facilities were excluded from the sample (the error records accounted for over three quarters of overall entries): Hlubočepská, Košíře, Podolské nábřeží – vozovka. No valid counts are available for facility Košíře at all. Data available for facilities Hlubočepská and Podolské nábřeží - vozovka are few (less than one-year time period) and do not cover all seasons, which would compromise the accuracy of results.

2.3. Hourly Variations of Bicycle Traffic Flows

As can be seen from Figure 2 and 3, there were a clear pattern of hourly variations among observed working-days and non-working-days, respectively. In this study analysis, the dataset was divided into two groups: a) working-days (excluded weekends, bank holidays and national school holidays); b) non-working-days (weekends and bank holidays). Average hourly variations for the whole operating duration were calculated for each counter. Then average shares of daily counts were calculated for the better interpretation and comparison (see Figure 2 for non-working days and Figure 3 for working-days).

Two typical hourly variations may be identified for non-working-days. Both types are characterized by rising intensities in the morning hours. For the first type the growth slows down around 10am to 11am but continues growing until the intensities start to decrease approximately between 5pm and 6pm. The second type is characterized by slight drop during the lunch hours (11am to 1pm) and by ongoing growth until approximately 3pm to 4pm, when the intensities start to decline. For the second type the growth and decline is steeper than for the first type. Nevertheless, the difference between both types is insignificant. The drop during the lunch hours, which is characteristic for the second type, is always less than 2 % of share of daily intensities. These minor differences may be caused by different ratio of utilitarian/recreational trips, but also by another hidden trip characteristic (proximity of significant employer with weekend shifts, etc.).

For working-days the differences between typical hourly variations patterns are more significant. Three basic types may be identified. The first type is characterized by significant morning peak between 7am and 9am, followed by significant drop (e.g. drop over 7 % of share of daily intensities) with the minimal intensity around noon and evening peak between

5pm and 7pm. The morning peak is roughly equivalent to the evening peak. It is presumed that the first type represents sections with prevailing **utilitarian** cycling (cyclist going to work in the morning and back home in the evening). This first type of variations (utilitarian) was recorded in 16 of 23 counting facilities.

Second type of variation in working-days is characterized by gradual increase in morning and forenoon hours with accelerated growth in the afternoon and peak between 4pm and 6pm. It can be assumed that this type of variation refers to **recreational cycling which is affected by working-hours**. Distinctly higher intensities in the afternoon hours may be due to cyclist going for a ride after they have returned from work (e.g. afternoon peak is 10 % of share of daily intensities higher than morning hours).

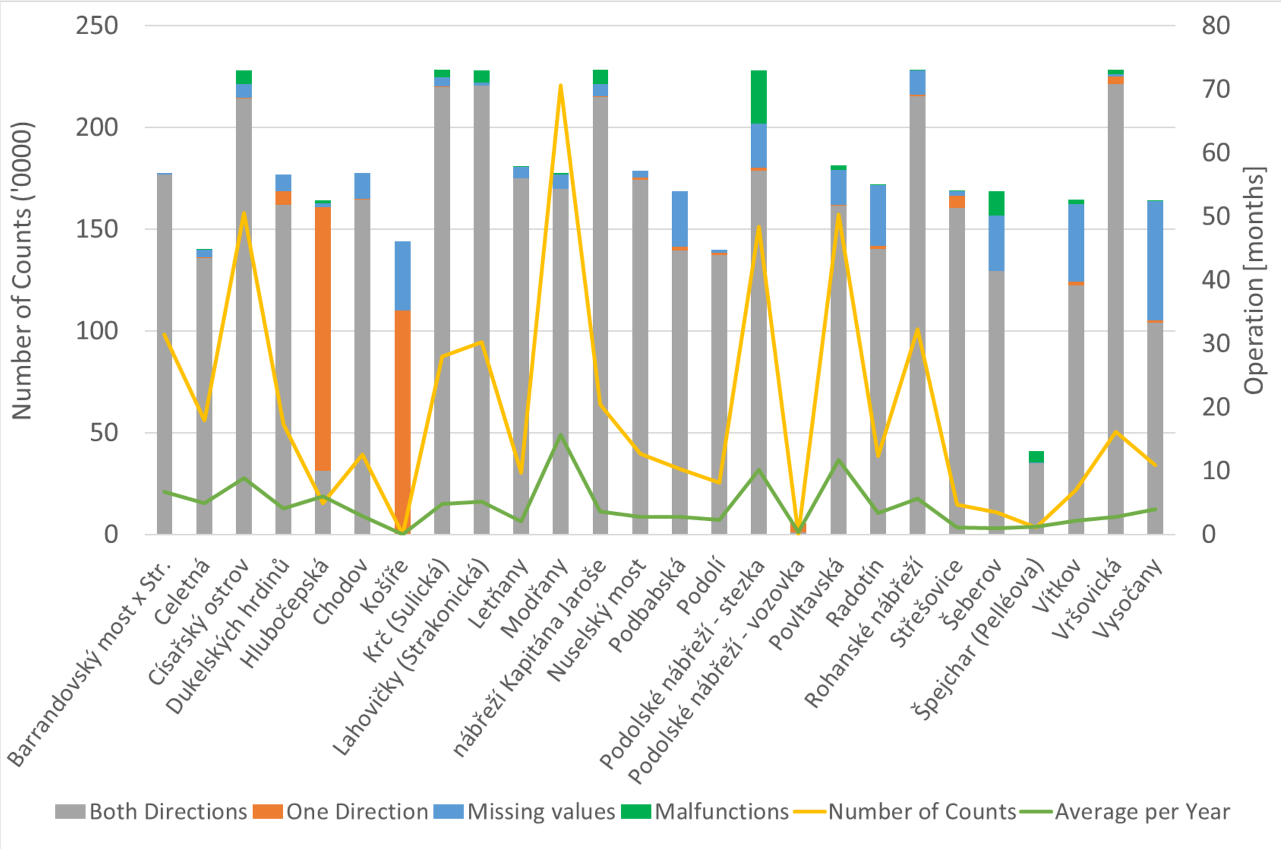

Fig. 1.
Sample size and quality

Last type of variation in workday was recorded by only one facility. This type of variation is remarkably similar to the variations in non-working-days. It can be presumed that this type of variation is characteristic **recreational cycling not affected by working-hours**. After the morning growth the intensities remain constant until 7pm when they drop.

In most of the sections the recreational (either affected or not affected by work hours) and utilitarian trips are mixed in different rations. In the figure 4 three examples of herein described typical variations are depicted. These variations were selected as they the best characterize three described type of basic variations. While estimating the ration of different traffic characteristic in each profile (see chapter 3) variation in the figure 4 will be taken as a reference.

3. Estimating the Traffic Characteristics

3.1. Assumption for the hourly variations

The estimation is based on the hourly bicycle traffic variations during working-days, since the differences in working-days variations are more distinctive than differences in non-working-days variations. Hypothetically there are three basic categories of hourly bicycle traffic variations:

a) utilitarian (U)
b) recreational affected by work hours (RA)
c) recreational not affected by work hours (RU)

Presumably in most locations all three categories contribute to the overall traffic flow. In the following section the method of calculation of the share of different traffic characteristics on overall flow in individual location is described.

3.2. Calculations

For each location it is assumed, that traffic counts for certain time period (I_T) may be calculated as sum of contributions of all cycling traffic characteristics in respective time period. In equation 1 these contributions are represented by I_{TU}, I_{TRA} and I_{TRU} (utilitarian, recreational affected and not affected by work hours respectively). The same relationship

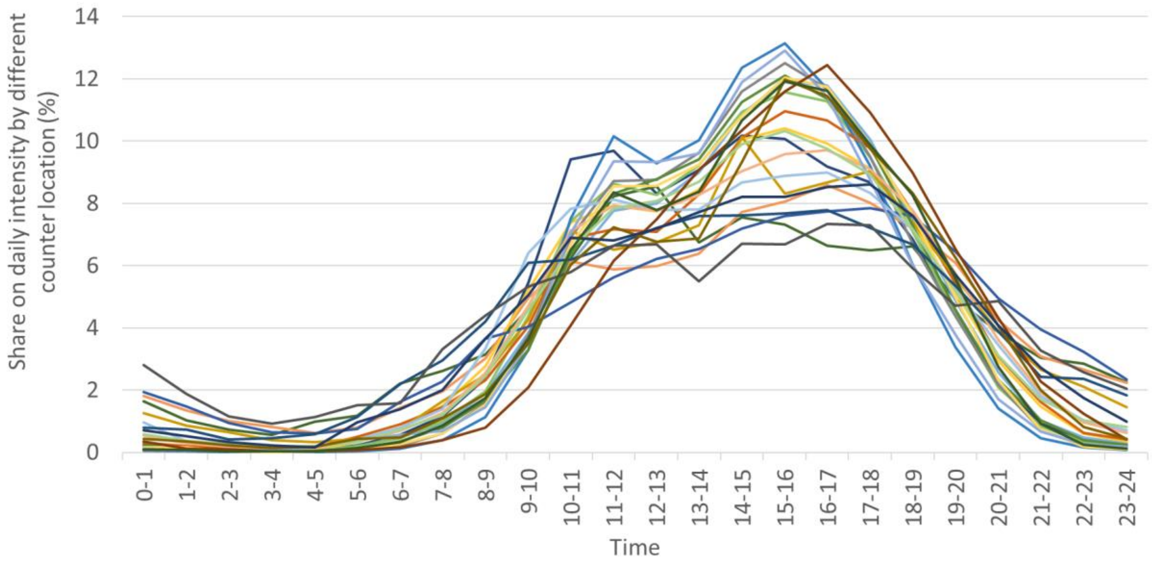

Fig. 2.
Average shares of daily counts – Non-working-days

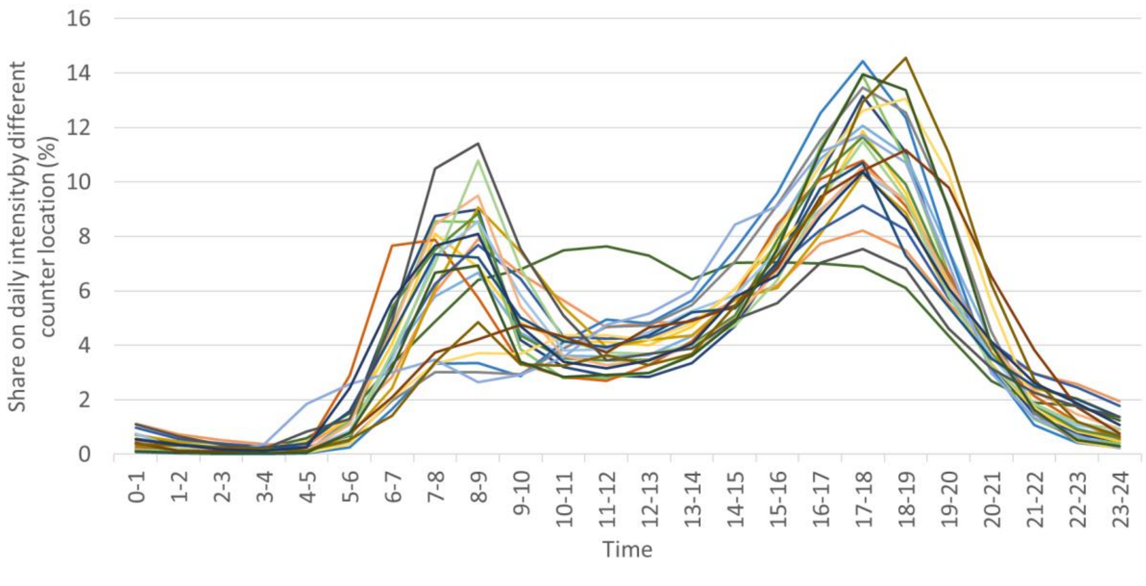

Fig. 3.
Average shares of daily counts – working-days

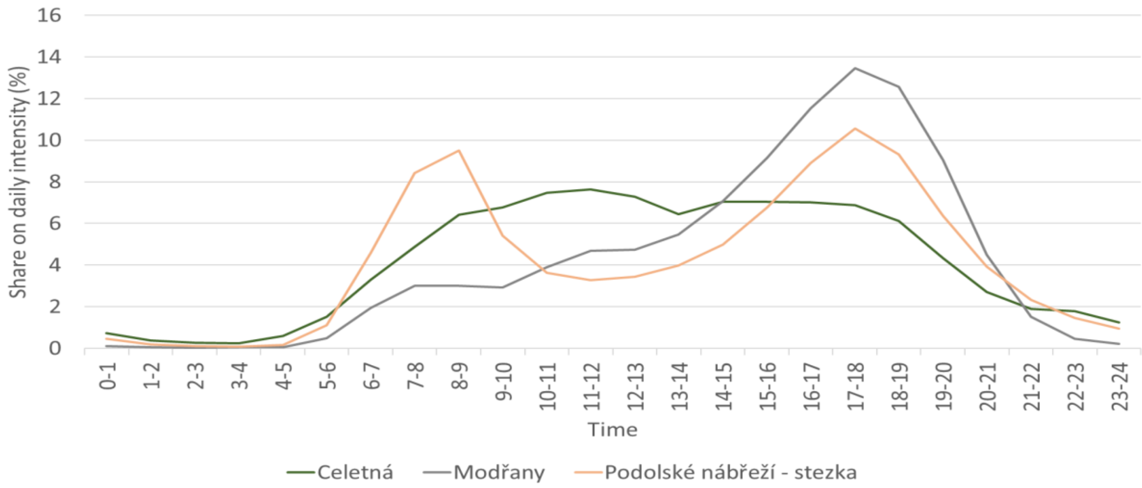

Fig. 4.
Average shares of daily counts – working-days, reference sections

can be written for shares on daily counts for certain time period (see equation 2).

$$I_T = I_{TU} + I_{TRA} + I_{TRU}. \tag{1}$$

$$\frac{I_T}{I_{24}} = \frac{I_{TU}}{I_{24U}} + \frac{I_{TRA}}{I_{24RA}} + \frac{I_{TRU}}{I_{24RU}}. \tag{2}$$

Similarly, the shares on daily counts can be calculated for hypothetical one-trip purpose locations. These can be referred as reference shares R_{TU}, R_{TRA}, R_{TRU} (see equation 3). In this case study, reference locations were approximated by selecting locations with the highest level of conformity with anticipated daily variations and according to the knowledge of local situation. To calculate reference shares, variations from figure 4 were taken into account.

$$R_{TU}=\frac{I_{TU}^{r}}{I_{24U}^{r}},\ R_{TRA}=\ ,\ R_{TRU}=\frac{I_{TRU}^{r}}{I_{24RU}^{r}}. \tag{3}$$

In equation 4, variables P_U, P_{RA}, P_{RU} represent the share of individual trip purposes on overall counts. The contribution of each traffic characteristic to the share on daily counts for certain period is the product of respective reference share and P_U, P_{RA}, P_{RU}. Expression 2 can be adjusted as:

$$\frac{I_T}{I_{24}} = P_U \cdot R_{TU} + P_{RA} \cdot R_{TRA} + P_{RU} \cdot R_{TRU}. \tag{4}$$

Next, the values P_U, P_{RA}, P_{RU} are optimized, so that the total difference between the two sides of equation 4 for various time periods is minimized. Optimization is done with the linear programming (gradient method) and the problem is defined as follows:

Minimize:

$$\left|\frac{I_T}{I_{24}} - P_U \cdot R_{TU} + P_{RA} \cdot R_{TRA} + P_{RU} \cdot R_{TRU}\right|. \tag{5}$$

Conditions:

$$P_U + P_{RA} + P_{RU} = 1, \tag{6}$$

$$P_U \geq 0, P_{RA} \geq 0, P_{RU} \geq 0. \tag{7}$$

It is necessary to choose more time periods for optimization, so that the differences in hourly variations between different traffic characteristics are taken into account. Three time periods 5:00-10:00, 10:00-13:00, 13:00-23:00 have been chosen. In the first time period R_{TU} is expected to be considerably higher than reference shares for recreational cycling. For the noon period the highest share on daily counts is expected for recreational cycling not affected by workhours (R_{TRU}) and R_{TRA} is expected to be the most important in the afternoon.

3.3. Results description

Map in figure 5 shows calculated bicycle traffic characteristics for each counting location in Prague. The utilitarian cycling (violet) is rather more important in the central part of the city (places characterized by higher urban density and concentration of trips origin and destinations). Utilitarian cycling also dominates at the river banks which form natural barrier and ensure small trip elevation gradient.

Considerable share of recreational cycling not affected by workhours (green) was estimated for facilities in the proximity of downtown core (Dukelských hrdinů - 48,5 %, nábřeží Kaptána Jaroše – 28,5 % and Rohanské nábřeží – 10,6 %). This may be caused by more frequent occurrence of tourists who decide to enjoy the city by bike while spending their vacation in Prague. There are four more sections with high share (15 % – 29 %) of recreational cycling not affected by workhours which are not directly connected with the touristic areas.

Considerable share of recreational cycling affected by workhours (orange) was estimated for facilities in parks and also for facilities further away from the city centre. At the outskirt of the city the riverbanks seem to be popular locations for recreation of city inhabitants and less important for commuting (Modřany, Lahovičky, Radotín). However, this assumption needs to be supported by further research.

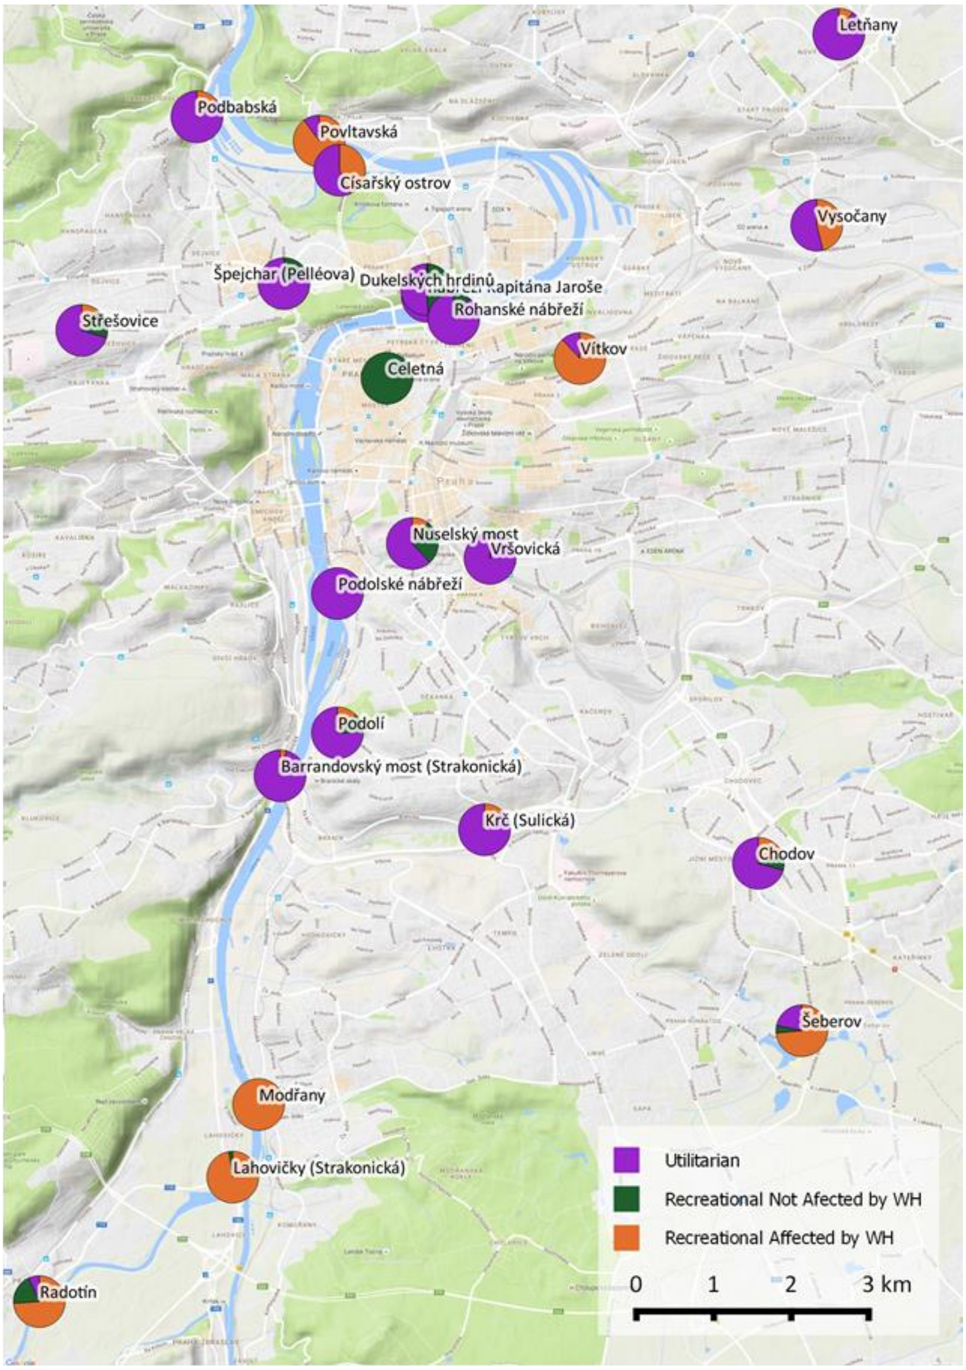

Fig. 5.
Calculated bicycle traffic characteristics for each counting location in Prague

4. Conclusion

In Prague 16 out of 23 counting sections were estimated to be predominantly utilitarian. This may be due to location selection and it gives no information about prevailing characteristics of bicycle trips made in Prague. The estimated representation of different traffic characteristics corresponds to expectations based on the analysis of the land scape of the city and built environment. Nevertheless, there are several sections with unexpected traffic characteristics (e.g. Nuselský most, Radotín). For better understanding to these exceptions, it is necessary to obtain more information about particular sections (e.g. interview locals and users, analyse trips and destinations of respective trips).
Results can be further used in infrastructure planning in Prague. Presumably different user groups (utilitarian/recreational) demand different type of infrastructure. The method used can be further implemented for yearly averages, so that changes in bicycle traffic characteristics in each section can be evaluated as well as overall changes in attitudes towards cycling. To assess these trends, more complex models need to be utilized reflecting other variables such as weather, season, special occasions (road closures, public transport strikes, etc.) etc.
Used method is based on evaluation of working-days hourly variations averages for the whole operating duration. In reality these variations change over the year as well as the traffic characteristics. It is also to be mentioned, that the used method provides no information on non-working-days traffic characteristics, which may not be in-line with working-days traffic characteristics (e.g. recreational cyclist may be willing to travel further during weekends).
The most uncertain part of the method is to estimate reference shares. Reference shares are calculated from the hourly variations in hypothetical one-trip purpose reference locations (see equation 3 and figure 4). In this case study, reference locations were approximated by selecting locations with the highest level of conformity with anticipated daily variations (described in previous chapter 3.1) and according to the knowledge of local situation. In reality reference variations may differ for each location and especially for different towns/cities/regions. Also the method used for calculation – optimization may provide only local optimums. For these reasons it is difficult to assess the confidence of obtained results.
The method introduced in this paper may be utilized in towns and cities which possess data from bicycle traffic counts (either continuous or manual). It is especially valuable for cities which have no information on travel behaviour and mode share (e.g. developing countries, small cities). It helps to estimate the importance of utilitarian cycling, which may be undervalued in regions with high share of recreational cycling (some people may perceive cycling as purely sporting activity). Obtained results provide important input into the strategic planning as well as infrastructure measure design. The method can be further included into more complex models which asses impact of other variables on bicycle traffic flows.

Abstract: National climate commitments to date will not be sufficient to keep global warming to below 2°C. Transportation has the highest growth of CO2 emissions of any industrial sector. The UN Conference in Paris (2015) recognized the importance to build more sustainable, green and smart transport systems. Increased environmental pressure impacts on a number of interrelated socio-economic and technological trends. Although mobility is essential to the functioning of European society it does, at the same time, presents major problems in terms of congestion, safety and environmental impact. Transport is a complex system that depends on multiple factors, including infrastructure availability, level of services, advances in technology, socio-economic needs (European Commission, 2009). The performance of the transport system is influenced by several different key drivers and has itself an effect on mobility, passenger transport and corresponding framework developments in the future. In order to understand all the significant relationships in context, one has to consider the key drivers that have an effect on changing mobility behavior and the transport system. Therefore this paper presents the results of an analysis of the future trends based on demand/behavior factors. For the forecast of trends, the Delphi Method was used to identify key mega-trends, the most predominant of all proved to be the 'Development of large metropolitan areas' which according to the participating experts is expected to be the most challenging trend with a great impact on mobility. Delphi method is also used to determine the relation between the selected key drivers grouped in clusters representing the social, economic and environment trends. In this paper, sustainable mobility is defined as: "A sustainable transport system is one that is accessible, safe, environmentally-friendly, and affordable" (Ministers of Transport, 2004).

Keywords: sustainable mobility, transport trends, Delphi method, trend clusters.

1. Introduction

According to the EEA (2016), transport accounted to a quarter (25%) of total GHG emissions and slightly more than a quarter (27.9%) of total CO2 growth rate of GHG emissions in the EU28. Although mobility is essential to the functioning of European society it does, at the same time, presents major problems in terms of congestion, safety and environmental impact. Traffic congestion, for example now affects about 10% of our major road network and costs estimates to €50 billion per year, or 0.5% of EU GDP (Papí J, et al, 2007). In the EU, compared with 1990 levels, no other sector has the growth rate of greenhouse gas emissions (GHG) as have been as high in transport.

Decision makers and stakeholders in the field of transport and mobility are facing challenges due to changing framework conditions. A demographic change is taking place in Europe and the demand for mobility is increasing. At the same time the energy consumption, emissions and costs should be reduced and access to mobility should be provided for all. Sustainable planning and practice is seen as a solution for future challenges even and at the same time the principles of sustainability are controversial and have to be negotiated by relevant stakeholders. Decisions should be based on current changes and trends while at the same time include the future requirements. The need to plan and decide according to the trends for the future is especially challenging in the field of transportation as the cost-intensive infrastructure requires long-term planning and investment.

This paper aims to provide an overview of the most important trends and overall relationship between key drivers that are expected to influence the transport system in the short term (2030) based on experts' opinion received by applying the Delphi method. This is envisaged to support policy making in terms of deciding directions for future Research and Development investments in order to ensure a greener, integrated and more sustainable transport system in Europe. Sustainable mobility is understood as a long term vision that needs to be achieved in the context of achieving a more inclusive and competitive society and economy in a continuous changing context.

2. Transport factors and trends (literature review and status quo)

The interaction between supply and demand of transport determines system performances and mobility patterns. The way the transport system performs generates impacts which can be compliant or not with sustainability criteria. External key factors and policy actions interact within the passenger transport system. External key factors relate to those variables, which are not specific to the passenger transport system, but have impacts on it and contribute to shape its development. They include socio-demographic and cultural factors, economy, environmental and technologies. Policy actions are the fundamental instruments used to coordinate and steer the development of social and economic systems and naturally the development of transport systems. Therefore, policy actions have impacts on the development of both external key factors and passenger transport system key characteristics.

2.1. Social trends

Globalisation is recognized as a major driver of **urban sprawl**, fostered by the development of ICTs, along with increased accessibility (EC, 2011). The rapid increase in globalisation has been accelerated by cheap transport and the

[1] Corresponding author: e.anoyrkati@coventry.ac.uk

massive growth in communication systems. It is anticipated, however, that the **political and economic crisis** (which started in 2008-2009), and the delays in trade negotiations, could hinder further globalisation in the short term. Recent years have witnessed economic growth, rising average incomes and improvement in the quality of living. Regional **disparities** such as economic specialisation or different rates of growth of employment influence mobility demand (Rosenbloom, 2002). The **centralisation** of economic activity in cities and **agglomeration**s goes along with decline of rural regions (Cervero et al, 2006). Cities as well as specialised regions with complementary functions have to be served by high-quality transportation links. As one main important factor, **income** enables actors to choose conditions and areas for living as well as the transportation mode connecting them to work. The result can be more or less traffic; for example sub-urban residents drive more and walk less (Cao et al., 2009). Depending on oil price movements and mobility price development, social exclusion via poor accessibility due to rising real oil prices might increase; even more so if income disparities are increasing as well (Currie and Stanley, 2008). The EC document on a *Sustainable Future for Transport* (EC, 2009) has identified **urbanisation,** a key trend of the last three decades, and its impacts on transport as one of the main challenges in making the transport system more sustainable. In general people will live longer, be better educated and **emigrate more** (EEA, 2011). An increase in the share of the population over 65 is expected in future, especially in the European Union; **demographic ageing** is one of the most important trends challenging transportation policies and planning (Lisiankova, 2005).

2.2. Economy trends

Income raise and sustainable mobility rely on a stable, if not growing, world economic outlook, without which some of the ambitious aims will be seriously hampered. While the announced recovery in 2014 has strengthened in 2015 and 2016 and it is expected to continue in 2017, forecasts are less optimistic than in previous assessments. As of Spring 2016 (IMF, 2016) the expectations of global growth for 2016 have already been revised 0.2 % down since the beginning of the year, setting at 3.2 % like the year before. As a matter of fact, the recovery, driven primarily by emerging market and developing economies, proved not to be as strong as previous data suggested, given increased uncertainty of various kind (political first of all, with the Brexit and the US Presidential Elections in November 2016). Also, worsening internal conditions of countries like Brazil and Russia have not helped in this sense. Growth in the EU, one of the main areas of interest for sustainable mobility thanks also to the funding committed by Horizon 2020 to the development of circular economy, remains flat at 1.5% overall, and forecasts for 2017 gives the Euro area at a 1.6% of increase (IMF, 2016). Global trade seemed as well less sustained as previously expected, in absolute terms (2.8% in 2016, same of last year) and in ratio of GDP growth, which is more worrying, highlighting structural weaknesses. While it should pick up momentum in 2017 (WTO, 2016) it will remain still far away from the 5% growth averaged in the 1990s. Also, the modest growth in quantity contrasted with the sharp decline in US dollar value, mainly due to fluctuation in commodities and energy prices and to the renminbi depreciation.

This is confirmed by recent national data of Chinese import-export surprisingly negative in July 2016 (The Economist, 4 August 2016), which hint to a slower manufacturing output in the country partners and in a dip in internal consumption in China’s domestic market. The so-called rebalancing of the Chinese economy, and that sees the transition of China from an export-led country to a more mature system internally driven, is proving less smooth than initially deemed, and it can destabilize world recovery in the following years.

2.3. Environmental trends

In a scenario building exercise on the future of transport, it is essential to take into consideration the variables introduced by environmental factors such as climate change and the overall energy outlook, both in terms of fossil fuel prices and renewable energy development. The effect of climate changes are visible everywhere. "The human influence on the climate system is clear and is evident from the increasing greenhouse gas concentrations in the atmosphere, positive radiative forcing, observed warming, and understanding of the climate system." (IPCC, 2015). However, steps have been taken after the undoubtedly successful United Nations’ 2015 Climate Change Conference (COP21), where all countries have finally committed to reducing their greenhouse gas emissions according to a scheme called Intended Nationally Determined Contributions (INDCs) and to transiting from a fossil-fuelled economy to one of clean energy. Years of effort have already contributed to reduce that share from 50% in 1970s to 30% in 2015 (WB, 2015).

Table 1
World energy usage (2013) – Millions of tons of oil equivalent

Energy Source	Power Generation (electricity and heat)	Final Consumption			Total Primary Energy Demand
		Industry	Transportation	Buildings	
Coal	2,404	768	3	128	3,929
Oil	284	302	2,357	317	4,219
Gas	1,172	557	96	627	2,901
Nuclear	646	–	–	–	646
Hydro	326	–	–	–	326
Bioenergy/Biofuels	155	194	65	861	1,376
Other Renewables	127	1	–	32	161
Electricity and Heat	–	842	26	1,040	...
Total	5,115	2,664	2,547	3,004	13,559

Sources: International Energy Agency, *World Energy Outlook* and *World Energy Balance*; and IMF staff calculations.

All this happens in a circumstantial outlook of declining commodities and energy prices since at least one year. As a matter of fact, the Primary Commodities Price Index has declined 19 % since August 2015 (WEO, 2016), especially metals, due to a slowdown in China's demand.
Reduction in oil prices is even more substantial, having stumbled down by over 70 % since June 2014, and by 32 % in the same period considered above (OPEC, 2016). Moreover, the forecast hints at a further reduction, with the world global demand in 2017 expected to fall by 1.2 mbd (IMF, 2016). Low oil prices, while generally constituting good news for economy and transport, can however represent a double-edged sword when it comes to curb emissions and invest in a more sustainable mobility framework, reducing some of the incentives to develop alternative, and cheaper, solutions.

2.4. Technological trends

The increased use of **Information and Communication Technologies** (ICTs) in transport is one of the emerging trends in urban mobility. According to Lee-Gosselin et al., (2009) '*a key characteristic of this trend is a ``post-modern" complexity, in which mobility is a reflection of expanding spatial and temporal choice, and of "on demand" consumption*'.
The trend towards more cooperative transport systems and new types of mobility requires new types of ICT technologies and new ways to exploit existing ICT technologies. Integrated multimodal travel information (IMTI) systems offer time savings (travel and search time) and effort (physical, cognitive, and affective) savings. During the pre-trip stage the passenger collects IMTI in order to plan multimodal travel; desired IMTI types in this stage are used to plan the part of the journey that is made by public transport. Wayside IMTI is most useful when it helps the traveller to catch the right vehicle en route. (Grotenhuis et al., 2007).
Communication between vehicle to vehicle or vehicle to infrastructure is also important in facilitating commuting and supporting co-modality. Kantowitz and Le-Blanc (2006) identified the following types of communication: 1. vehicle-to-vehicle (V2V), 2. vehicle-to-infrastructure (V2I), 3. infrastructure-to-vehicle (I2V). A large range of ICT technologies could be used as underlying technologies for these different types of communication between vehicles and infrastructure. Some examples mentioned by Kantowitz and LeBlanc (2006) are: WiFi, radio frequency identification (RFID) tags and infrared (IR), DSCR (dedicated short range communication) and cellular data connections (3G or 4G).
Expected developments in ICT technologies may also result in changes in mobility services offered and types of mobility. An important trend that is expected by many experts is autonomous driving based on vehicle-to-vehicle and infrastructure-to-vehicle communication; autonomous vehicles will become available in the future. (Giannopoulos, 2004).
A further trend that is anticipated to take on major importance in the future is the increased use of car sharing services supported by ICT applications. This trend is encouraged by the social trend of a shift from private ownership to shared use of vehicles. As stated at the transportation sustainability research centre's (University of California, 2012) report, carsharing schemes have grown drastically over the last years: point-to-point car sharing counted 346,610 members in 2006 while this number was increased to 1,788,027 members in 2012.
A major improvement in fuel economy is projected by 2020 due to improved **propulsion and vehicle technologies,** including weight reduction. The World Energy Council report (2011) projected the technology mix for cars was for the period from 2015 to 2050, including years 2020 and 2030 for two scenarios: a "freeway" scenario in which pure market forces prevail to create a climate for open global competition; a "tollway" scenario where governments decide to intervene in markets to promote technology solutions and infrastructure development that puts common interests at the forefront. Shell (2009) has analysed the fuel consumption of different types of propulsion systems with projections until 2030 (petrol and diesel, with and without hybrid-propulsion) in two scenarios: the trend-scenario in which primarily conventional and simple technology is used; the alternative-scenario in which technical developments (like downsizing of engines, new transmissions, better aerodynamics, lightweight constructions etc.) are taken into consideration. In the

trend-scenario, average fuel consumption of the vehicle stock is projected to decrease from 7.8l/100km in 2006 to 6.1l/100km (22% less than the consumption in 2006) in 2030. The alternative-scenario shows a more significant reduction up to 5.2l/100km (41% less than the consumption in 2006).

2.5. Policy trends

The EEA (2008) study, outlines as vital to increase coordination between all policies affecting the environment, such as **transport policy and planning** while the future promotion of reforms to favour the share of **sustainable mobility** should be outlined (Colonna 2009). The **internalisation of external costs** (externalities) is integrated in the list of policy measures designated as “smart pricing and taxation”. The White Paper “Roadmap to a Single European Transport Area” (EC, 2011) illustrates the EU objectives for the internalisation of externalities.
EU has issued the Directive 2002/49/EC relating to the assessment and management of **environmental noise** stress on the strategic noise mapping. Member States must draw up action plans designed to manage, within their territories, noise issues and effects. Member States must also **involve the public** in the action plan development (CEC, 2008). The vast majority of energy taxes are being levied on (mostly road) transport fuels (EC, 2009a). Policy measures envisaged in the White Paper are to (EC, 2011): “establish a link between vehicle **fuel taxation** and environmental performance; to full **internalise the cost of GHG** emissions for all modes of transport in a co-ordinated and stepwise manner; assess the possibility of introducing **VAT** on all international passenger transport services inside the EU; promote a revision of company car taxation to eliminate distortions or, as a second best, to **provide incentives for clean vehicles.** Europe’s future is said to depend on cities resilient to climate change and, this need will include assuring a r**esilient transport** for the future of European urbanized areas (EEA, 2012). On the other hand, transport adaptation to climate change will require specific policy instruments **and investment in a low-carbon economy** (CoR 2011).
The diverse structures of passenger car taxation in Europe were analyzed by Kunert and Kuhfeld (2007). **Taxes and fees** related to the registration, ownership and use of cars are assessed differently across Europe, and their rates vary significantly.
Infrastructure projects include the European global navigation satellite systems (Galileo and EGNOS), which will complement the 'traditional' networks and improve their exploitation” (EC, 2009). The Trans-European transport networks policy has much increased the **coordination** in the planning of **infrastructure projects** by the Member States. The extension of the **TENs** to cover the new Member States, building on the investment already made prior to enlargement, has provided the blueprint for **Structural and Cohesion Funds** to gradually fill their infrastructure deficits. Significant changes in **urban mobility** require comprehensive actions that bring together **land-use planning**, **road use and parking, transport pricing, infrastructure development, public transport policy** and much more (EC, 2011b).
The development of **decentralised economic activities** will require an efficient, flexible and intermodal transport system. The current situation in terms of accessibility in the EU suggests that there is a marked division between central and peripheral areas as regards their transport connectivity and costs as a result of geography and patterns of economic activity (Christidis and Ibañez, 2010).

3. Methodology

A wide range of methodologies were applied in this paper: desk study, surveys, interviews and Delphi analysis.
The research started with a literature review on the most important trends in order to enable us draft a list of the most predominant mega trends that were included in the questionnaire. The survey questionnaire was designed based on the results of the literature review where the trends included there consisted of the ones that were cited the most. The Delphi expert questionnaire was applied in order to estimate the key megatrends on passenger mobility volumes and patterns. Based on the Delphi results, relationships between the mega trends were defined.

3.1. Delphi method

The **Delphi technique** is a widely used and accepted method for gathering data from respondents within their domain of expertise. The technique is designed as a group communication process which aims to achieve a convergence of opinion on a specific issue. The method consists of a series of repeated interrogations, usually by means of surveys. After the initial interrogation of each individual, each subsequent interrogation is accompanied by information regarding the preceding round of replies, presented anonymously. Thus, experts are encouraged to revise their earlier answers in light of the replies of other participants. In this way, the group may converge to a broadly supported opinion. The final position of the group is determined by averaging the individual opinions after the last round.

In this study the Delphi approach will consist of a two-round online survey :

1. *Online survey – Round 1*; based on the results of the assessment on key drivers and megatrends with respect to mobility patterns an online survey was developed to gather the opinions of experts on the importance of the various megatrends and their impacts on mobility patterns. Before inviting all stakeholders to fill in the survey, the online

survey undertaken by a selected group of stakeholders. In this way we can make sure that the survey will be understood by the participants.

2. *Online survey – Round 2*; based on the results from the first round of the online survey a second round of the online survey was developed. This second round of the survey resulted on a more concrete list and shorter of the most predominant Megatrends. Preliminary definition of the relationship between them was done based on the obtained Delphi results.

The questionnaire was answered by more than fifty renowned experts on a Pan-European level.

4. Results

The objective of the first expert online questionnaire was to collect expert opinions on:
1) the importance of critical factors in terms of their impact on passenger mobility;
2) factors that were not found in the literature review

The questionnaire consisted of 10 groups of factors, which relate to the following influential areas:
1. Demographics;
2. Behaviour ;
3. Spatial organisation;
4. Economy;
5. Social structures;
6. Globalisation;
7. Environment;
8. Institutional structures and policies;
9. Transport policies;
10. Information and Communication Technologies;

Experts were asked to rate: the importance of each factor in terms of its impact on passenger mobility from the scale of "Not at all important" to "Extremely important".
Since only a selection of critical factors for each influential area was provided, experts were given the possibility to suggest up additional factors that they might consider critical and that were not already included in the list. The questionnaire was filled in by 59 high calibre experts representing the industry, academia, policy makers and also the European Commission.

The table below shows how scores have been assigned to the degree of importance in order to perform calculations.

Degree of Importance	Score
Not at all important	1
Slightly important	2
Moderately important	3
Very important	4
Extremely important	5

As demonstrated in the table 2, demographics have been rated on average as being very important to extremely important. The level of consent, estimated considering the value of the standard deviation, is good being in general around 1. The factor that stands an out is the ‘Ageing Society’ with average score 4.3 and low standard deviation (0.79) This factor has been also highlighted as one of the European Challenges by the EC, while measures to meet this challenge have been integrated in many policy documents as well as heavy investment on research has been put forward already.
Spatial organisation has also received high score for almost all factors. However, the factors that stand out the most are the development of large metropolitan areas and the urbanisation which have also received very good levels of consent
The table 2 below presents the twelve most important factors with the lowest deviation levels, as identified by the experts[2].

[2] In random order.

Table 2
Most important factors affecting passenger transport system

Trends	Factors	Score	Standard Deviation
Demographics	Ageing society	4.3	0.79
Spatial Organisation	Development of large metropolitan areas	4.41	0.9
	Urbanization	4.2	0.93
Economy	Financial recession	3.98	1
Social Structure	Unemployment rate	3.8	0.9
Globalisation	International Trade	3.75	1
Environment	Sustainable Development Renewable energy options	3.86 3.73	0.96 0.87
Transport policies	Charges (e.g. for congestion) Inadequate infrastructure investments Taxation of fuels Pricing	4.17 4 3.94 4	0.95 0.93 0.98 0.86

The experts were also asked to suggest factors that according to their opinion are important but they have not been included in the questionnaire. The great majority of the factors that were suggested by the partners were already included in the list above.
During the second round of the questionnaire, the experts were asked to rank the abovementioned factors that affect the major trends identified in the first round. According the majority of the experts the predominant factor that really affects sustainable mobility is the development of large metropolitan areas.
Chosen trends and factors, as indicated by the scores, are characterized with different influence on sustainable mobility However, the question is whether they act independently on the mobility? As some factors have similar characteristics they are grouped in three clusters i.e. social, economic and environmental trends (Figure 1). The primary goal of clustering is to measure the impact of social, economic and environmental trends to passenger perception mobility. In order to consider interdependence, based on Delphi results and subjective perceptions, relationships between trends and factors showing the degree of interdependence among them are drawn. Next, once the influence between the trends/factors was determined, interactions have been made until a consensus is reached. The process of solving the interdependence of key drivers of mobility is resulted with the relationship framework of trends/factors.

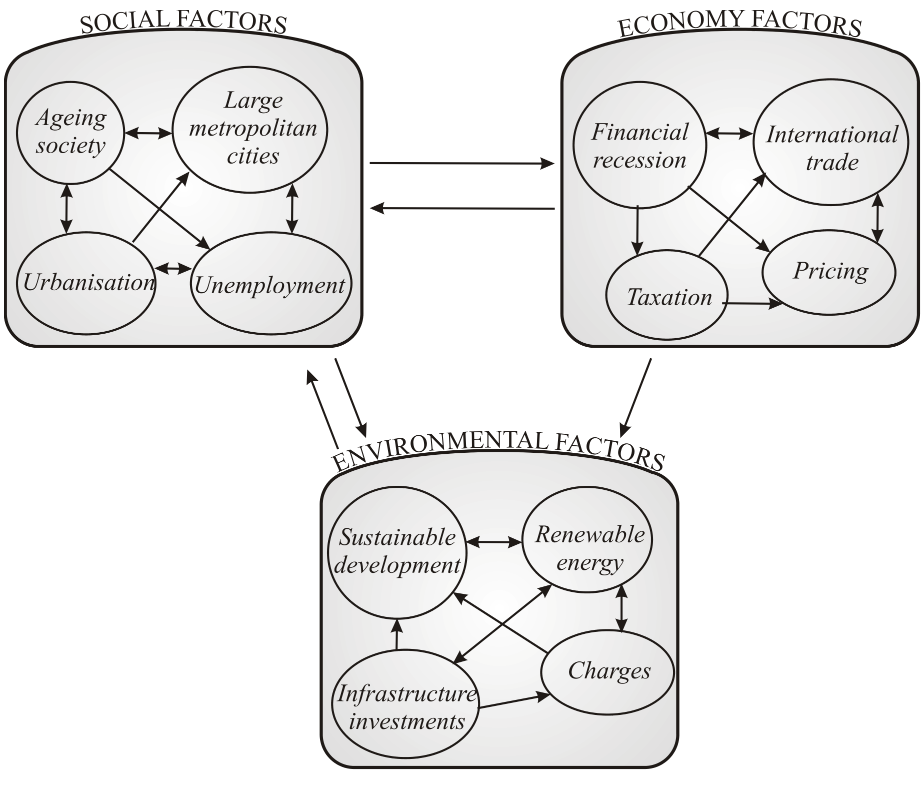

Fig. 1.
Relationship framework
Source: own elaboration

3. Conclusion

The goal of this paper is to identify key mega-trends or factors that are expected to impact the transport system in the short term (2030) and have a great impact on the mobility. These impacts can be compliant or not with sustainability criteria striving for an accessible, safe, environmentally-friendly, and affordable European transport. Identification of critical factors in terms of their impact on passenger mobility was based on experts' opinion received through application of Delphi method. Factors like development of large metropolitan areas, ageing society, charges (e.g. for congestion) proved, by the experts, to be the most challenging for the further development of the passenger transport system in Europe. In addition, based on the Delphi results, the relations between the selected key drivers, grouped in clusters that represent the social, economic and environment trends, were determined.

The future step in this research process will be determination of the degree of impact and influence between the trends/factors using ANP method or combination of more multicriteria decision methods. ANP is a more general approach to decisions that is a generalization of dependence and feedback relationship between elements to network system. By applying the ANP, it will be possible to determine the relative importance of a set of trends and factors in a problem of selection of sustainable mobility development scenario of the future passenger transport system. Therefore, interaction between factors and trends will be used for evaluation of different mobility scenarios. The aim of the scenario analysis and selection will be to highlight and make visible large-scale forces that push the future of passenger transport system in different directions.

PUBLIC TRANSPORT ACCESSIBILITY AND SOCIAL EXCLUSION: MAKING THE CONNECTIONS

Matteo Ignaccolo[1], Giuseppe Inturri[2], Nadia Giuffrida[3], Vincenza Torrisi[4]
[1,2,3,4] University of Catania – Department of Civil Engineering and Architecture, Italy

Abstract: Social exclusion is a condition affected by different factors: quality of life, low income, inadequate housing conditions, high crime rates, elderly age and ethnic/cultural minority are all crucial aspects that must be considered. The possibility to have a good access, in a spatial sense of the term, to work places, education and healthcare services is a key factor to achieve that the whole population could take part to the society. In many South Italy cities, access to opportunities is mainly guaranteed by private transport, since public transport supply and services are low quality. Public transport should have the main role to overcome the mobility difficulties faced by disadvantaged groups. Accessibility to destinations by public transport can be considered a proper indicator and a simple measure to assess the impact of changes in the transport system on potential users and to evaluate solutions to remove spatial barriers. Accessibility indicators can aid decision makers in the determination of those population categories that are socially excluded and they can also be used to improve transport urban service supply. In this paper transit accessibility measures are evaluated for an urban area using a GIS approach, taking into consideration socio – economic factors from CENSUS data. Moreover, Lorenz curve is used to measure how accessibility by public transport is redistributed among different categories as a result of different alternative transport projects; through the use of this methodology, the Gini coefficients provide a single measure of overall accessibility equity. Methodology is tested in a case study related to the city of Catania.

Keywords: sustainable transport, transport equity appraisal, urban transport, spatial and transport planning.

1. Introduction

In the last few years, cities have been developing fast in more complex and fragmented systems: the reorganization of residential areas, activities and metropolitan services, as well as and the increasing mobility, have distorted rhythms and social dynamics. Vehicular traffic flows and land occupation by parked cars create a barrier effect and a consequent decrease of the possibilities of socialization.

An early form of social exclusion is manifested when individuals possess a poor "mobility capital" (Borlini and Memo, 2011), i.e. their ability to move is reduced, so they are ousted from all those resources located outside of its space range. People too young, too old, unable to drive, or too poor to afford a car or a plane ticket become "second class" citizens, leaning on a public transportation is often unreliable.

Van Wee and Geurs (2011) define social exclusion as the tendency of some people or groups of people to be excluded from a certain minimum level of participation in regional activities in which they wish to participate. The complexity of the phenomenon is evident: it is very difficult to recognize and quantify a minimum level of participation; moreover, the barriers that prevent the ability to participate in civil society are many and not only related to the economic factor. With regard to the field of transport, there is a close relationship between accessibility and social exclusion. The latter is not so much due to lack of services and social opportunities, as to a lack of access to such opportunities.

Preston and Rajé (2007) suggest that social inclusion can be achieved through both the proximity to the activities and services you want (which does not require to support travel costs) and the ability to reach distant destinations within reasonable time, even if with high transportation costs, or both by an intermediate state between those presented.

Lucas (2012) says that inadequate access to transportation and social disadvantage interact more or less directly resulting in what can be defined as "transport poverty". This in turn causes the goods and essential services and opportunities for social interaction to become inaccessible and at the same time cut off citizens from decision-making processes. The social exclusion that results risks triggering a degrading vicious cycle that causes an increase in social inequalities and centralized transport.

One of the policies for the urban mobility of large cities should be to discourage the use of private car when it is not necessary in order to promote new travel behavior and incentives to carry out an extensive and efficient public transport network. While all this is feasible, it must also be assured that the activities and main services are easily accessible by every transport mode. Therefore, a close interaction between the location of urban opportunities and the planning of public transport and of the urban transport system as well is strictly required.

Many people experiment different obstacles to reach opportunities and services: from physical barriers (availability and accessibility of transport) to economic (cost of transport) or urban structure mobility constraints (services located in places which are difficult to access). Until these barriers will not be removed, a significant portion of the population will remain unable to move as they would and, therefore, their opportunities to participate in the life of the communities will remain poor.

Public transport may be able to reduce this mobility gap and therefore to favor social inclusion. In fact, when it’s not accessible by the weakest population groups and it’s unable to break down the barriers that do not allow the participation to social activities, public transport fails its primary goal: to give access to employment or educational opportunities, medical care services and entertainment venues. In summary, public transport should offer everyone the ability to move and therefore it’s a critical issue for social inclusion policies.

[3] Corresponding author: nadia.giuffrida@dica.unict.it

The city of Catania, a medium-sized city (300,000 inhabitants) located in the eastern part of Sicily in Italy, has been for years on the top position of the Italian city for the highest car ownership rate. It appears totally necessary to convert this car possession trend by improving the efficiency of the whole transport system that presents some critical issues as traffic congestion, limited public transport utilization, little diffusion of cycling and walking for systematic trips, inefficiency of the parking management, absence of city logistics measures.
In this paper the relation between transport accessibility and social exclusion will be investigated by means of an approach using Lorenz Curve and Gini coefficient that will evaluate the relative accessibility of census regions in Catania city; methodology will be applied to public transport network and will verify the effectiveness in social inclusion improvements of different transport scenarios.

2. Methodology

2.1. Measuring social exclusion

The equity policies in the field of transport must be supported by a large amount of socio-economic indicators, in order to meet the high level of disaggregation required by social exclusion data.
One of the methodological approaches in the literature is presented by Currie (2010), which makes use of GIS technology by combining the offer of public transport measures with social needs indexes and transport poverty.
The extent of the public transport for each zone is a function of frequency of service and access to stops distance estimated by GIS, while for deeper analysis of the demand for public transport, Currie proposes an aggregate indicator called Transport Need Index. The measure is composed of a summation of social disadvantage indices associated with different weighting, as showed in Table 1. Weights are estimated through a survey of users' travel behavior in the city of Adelaide (Australia), but may not be the same in the case of an Italian city, whose inhabitants have a different travel behavior. Anyway similar indicators can be used to test the correlation among social exclusion and accessibility to public transport.

Table 1
Social disadvantage indicators

Need indicator	Weight
Adults over 18 without cars (Census, 2010)	0.25
Persons aged over 65 (Census, 2010)	0.13
Persons with disabilities (Census, 2008)	0.13
Low income households (lower quintile) (Census, 2008)	0.13
Persons over 15 without a job (Census, 2010)	0.13
Students (Census, 2010)	0.13
Persons 10-18 (Census, 2010)	0.13

Source: (Currie, 2010)

Other indicators of social exclusion, showed in Table 2, are suggested by the Italian Statistic Institute ISTAT (2015):

Table 2
Deprivation index parameters

Parameter
Young people abandoning education and training pathways
Regional poverty index
Population living in rural areas
People at risk of poverty or social exclusion
People in severe material deprivation condition
Overcrowding
Businesses and non-profit institutions that carry out activities with social content
Rate of juvenile crime

Source: (ISTAT, 2015a)

2.2. Measuring accessibility

The concept of accessibility plays an increasingly important role in in transport planning as useful tool to measure the combined effect of locations' proximity and transport connectivity. At the same time, accessibility indicators can incorporate social issues when they measure the level of difficulty experimented by different categories of individuals to reach the economic opportunities or social interaction throughout the area.
However, drawing up a strict and unambiguous definition of accessibility is a complex task. One of the first scholars which considered its importance in the context of spatial planning was Hansen, who defined accessibility as "the potential of interaction opportunities" (Hansen, 1959).

A recent definition that highlights the mutual interaction between land use and transport systems has been provided by Geurs and van Wee (2004). According to the authors, the accessibility can be considered as the measure with respect to which the use of the territory and of transport systems allow groups of individuals to reach activities or locations by a combination of modes of transport.

From these and other definitions in the literature, four major accessibility components can be identified: land use, the transport system, the time factor and the individual dimension (Geurs and van Wee, 2004).

A classification of accessibility measures depending on land use can be done considering the place in question as the origin or destination of the travel. We can therefore distinguish the active accessibility (or origin accessibility), and the passive accessibility (or destination accessibility) (Cascetta, 2009):

- Active accessibility refers to the need to carry out the activities located throughout the area by a user that is in a particular place (generally the resident) and it measures the ease with which he can reach various destinations from an origin. It is useful in locating settlement decisions.
- Passive accessibility refers to the need for the various opportunities that are located in a certain area of the territory, to be achieved by the various users scattered throughout the study area. In other words, it measures the ease with which individuals, business and the services of a target area of the displacements can be reached by the users concerned. It is useful in the location decisions of public services and economic activities.

Most of the formulations in the literature refer to an urban accessibility of active type, whose indicator, in analytical terms, is generally a function of the number of spatial opportunities and the generalized transport cost. In particular, the accessibility indices based on gravitational models provide a measure of the continuous type which weighs the value of the opportunities with respect to a spatial impedance function. The impedance function reflects the effect of decreasing accessibility due to the increase of distance, travel time, or in general of the generalized cost of shipping.

The first application of the gravity model to accessibility measures is attributed to Hansen (1959), which suggested that accessibility across regions was directly proportional to the attractiveness factors (jobs, shops, sports centers, etc.) and inversely proportional to the travel time between the zones, which represents the cost of moving. The Hansen's index has the following form:

$$A_i = \sum_j^n O_j \cdot f(C_{ij}) \tag{1}$$

Where Oj is the number of opportunities in the zone j and f(Cij) the impedance function among zones i and j. A negative exponential impedance is often used, such as:

$$f(C_{ij}) = e^{-\beta \cdot f(C_{ij})} \tag{2}$$

With C_{ij} generalized cost of travel among *i* and *j* zone and β is a parameter related to the cost, estimated by choosing a destination model. The generic measure of cumulative opportunities can be considered a special case where $f(C_{ij})$ is equal to 1 if C_{ij} is less than the predetermined threshold; it is equal to 0 otherwise.

This type of indicators offers the advantage of requiring a relatively small amount of data (ease of processing and calculation), allowing to differentiate the areas of study and to derive the accessibility indices for each of them. They are particularly useful for assessing the potential of suburban residential areas in allowing access to activities such as shops, schools, workplaces, health care and other services.

2.3. Lorenz curve and Gini index

If we assume the existence of a correlation between accessibility and social exclusion, accessibility indicators can be linked to an economic index, such as the Gini coefficient (which can be calculated as a result of the Lorenz curve tracing) in order to verify the social equity of its improvements.

The Lorenz curve is a simple and effective graphical representation of horizontal inequality, since it was created as an aggregate measure of the distribution of wealth within the population. It lends itself to many applications, from education to biodiversity, quantities that can be combined through the population.

The horizontal axis (Fig. 1) shows the cumulative percentage of the population under examination (from 0 to 100%), sorted according to the increasing value of the indicator, while the vertical axis shows the cumulative percentage same indicator. In the economic field, it is mainly used as a graphical tool for the analysis of inequality of income distribution.

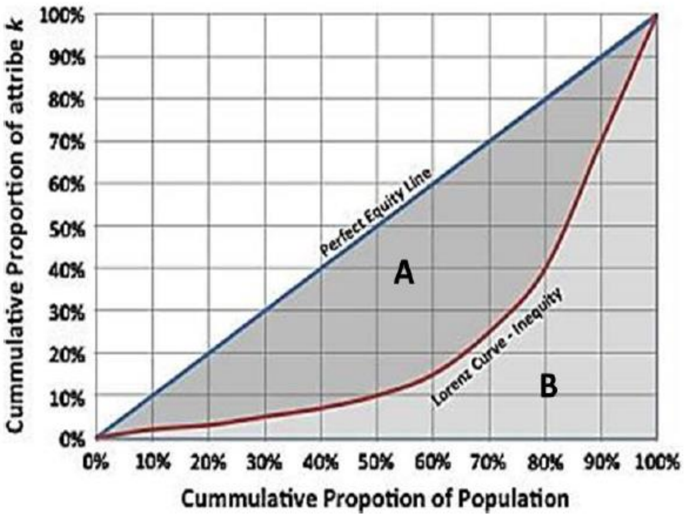

Fig. 1.
Lorenz Curve for a generic attribute k
Source: (Rofé et al., 2015)

In the transport field, social equity considerations are complicated by the fact that not only income plays a role, but also factors such as age, occupation, physical condition and the level of accessibility to services.
In this regard, the use of the Lorenz curve represents an original approach to provide a measure of overall accessibility compared to the entire population (Delbosc and Currie, 2011).
Basing on Fig. 2, Lorenz curve (in red) describes the actual accessibility distribution: each point of the curve indicates the percentage of accessibility owned by a given percentage of population. The blue line at 45° represents the line of equal distribution, i.e. the one corresponding to a perfect distribution of the same attribute. The more the Lorenz curve deviates from the straight line of equal distribution, the higher is the inequality of the distribution of accessibility in the population.
The Gini coefficient, introduced in 1912 by the Italian statistician Corrado Gini, is a mathematical measure of the degree of inequality, related to the area between the Lorenz curve and the straight line of equal distribution (indicated with the letter A in Figure 2). The relationship between this area and the area below the line of perfect equality (A + B in Fig. 2) is the Gini coefficient, which can be mathematically calculated using the following approximate formula in (3):

$$G = 1 - \sum_{k=1}^{n} (X_k - X_{k.-1}) \cdot (Y_k + Y_{k-1}) \tag{3}$$

where X_k is the generic interval of the cumulative percentage of the population variable and Y_k is the corresponding interval of accessibility cumulative percentage, for $k = 1, ..., n$ and $Y_0 = 0$, $Y_n = 1$.
Gini coefficient can take any value between 0 and 1. A value of 0 implies a situation of complete equality, while a value of 1 corresponds to complete inequality. The lower the coefficient, the lower the inequality of the distribution concerned.
The method described above is useful to analyze the changes over time of the distribution of accessibility in a given region, making it possible to see if inequality is increasing or decreasing. In addition, the Gini coefficient can be compared between different urban realities, obviously using the same methodology for the calculation of accessibility.
However, like any index of its type, it has the limit to remain unchanged if the accessibility of all individuals increases in the same proportion. In fact, being calculated from the relationship between two quantities, it cannot take into account the difference between the absolute values.

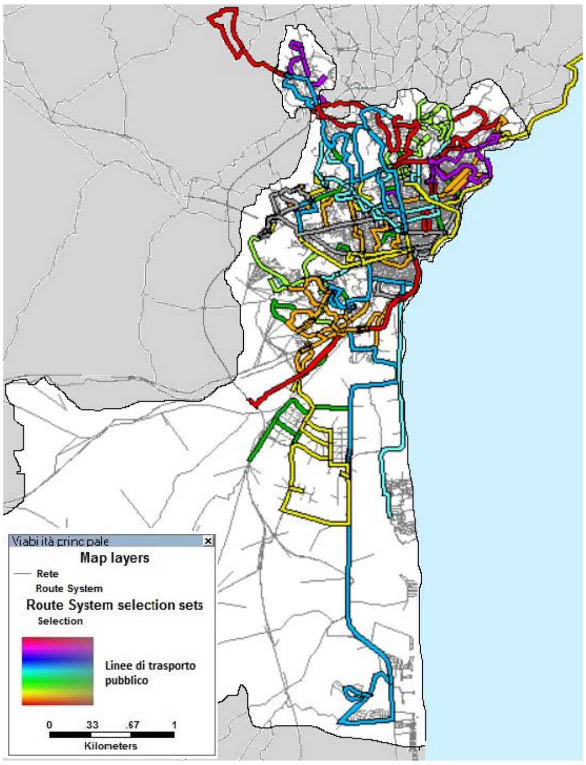
3. Case study

3.1. Territorial framework and transport supply

Catania is a city of about 300.000 inhabitants, located in the eastern part of Sicily (Southern Italy); it has an area of about 183 km*2* and a population density of 1.754,54 inhabitants / km^2 (Istat, 2015b). It's part of a greater Metropolitan Area (750.000 inhabitants), which includes the main municipality and 26 surrounding urban centers, some of which constitute a whole urban fabric with Catania. The main city contains most of the working activities, mixed with residential areas. With reference to the urban area, the transport service is provided by 51 bus lines, a Shuttle line (ALIBUS) connecting the city center with the airport and a second fast bus (called BRT1) connecting a park-and-ride facility on the northern periphery (Due Obelischi) to the city centre (Stesicoro Square). BRT1 is the first of three lines provided by the City of Catania with equipped lanes protected by curbs on the majority of their path and was promoted commercially as *Bus Rapid Transit*. In Catania it is also operated an urban subway line that currently connects the station "Porto" with the station "Borgo" from which continues as a surface long-distance railway line. By 2016 it is expected the undergrounding of the line until the station “Nesima” and it’s also planned the opening of a branch linking the station “Galatea” to Piazza Stesicoro.

3.2. Transport model and scenarios

A mathematical representation of the transport system has been built by the TransCAD modelling tool, a software which combines a Geographic Information System and a set of transport models in one integrated environment.
The zonation used for the city is the one given by ISTAT, which divides the study area in 2480 CENSUS sections. Three different scenarios have been analyzed. The first one, called Scenario 0 (Fig.2), includes 51 bus lines with a speed of 15 km/h; this will be considered as the current scenario and will be taken as base for the comparison with the other two transport solutions. The second one, called Scenario 1, provides for the introduction of three BRT lines and the subway line with the new extension from Borgo Station to Nesima station. The last one called Scenario 2, provides for an improvement of all bus lines speed from 15 km/h to 18 km/h.



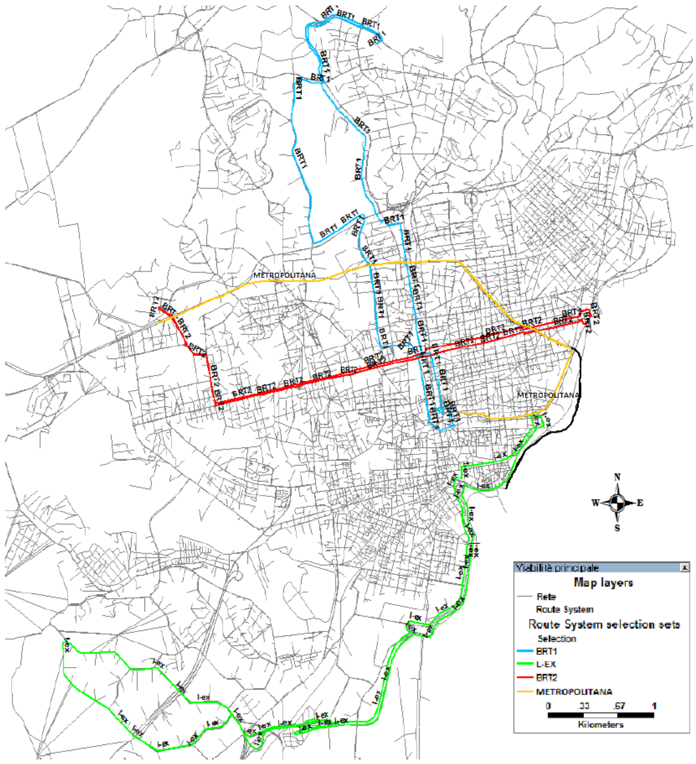


Fig. 2.
Scenario 0 on the left and improvements in the transport system of Scenario 1 on the right

3.3. Accessibility measures

Through the use of TransCAD software, Hansen accessibility measures have been evaluated for the three different scenarios.
The opportunities considered in the analysis include the accessibility of goods and services classified into: Health (hospitals, pharmacies); Education (University, schools, libraries); Places of worship (churches); Entertainment (theaters, cinemas, museums); Restaurants (Restaurants, bars, fast food); Transport services (metro, train station, bus stops). The Hansen Index has been evaluated considering as impedance a function based on the generalized cost of transport and taking into account parameters such as travel time, the cost of travel time, the number of transfers and considering a flat travel fare. The software provides standard values for deterrence index β, based on the selected transport mode and type of opportunities at destination. Values for our study are indicated in Table 3.

Table 3
Deterrence parameter for Hansen Accessibility Index calculation

Scenario	Mode	Destination	β Value
Scenario 0	Bus	Local Centers (No car)	0.082
Scenario 1 and 2		Local Centers (No car)	0.079

The active accessibility of the 2480 zones of the case study has been calculated for the 3 scenarios. Results show that the introduction of the improvements both in Scenario 1 and Scenario 2 provide an increase of accessibility; the amount of improvement for each zone can be deducted by the comparison of maps in Fig. 3, Fig. 4 and Fig. 5. The caption of the maps shows in brackets the number of zones that benefit from increased accessibility.

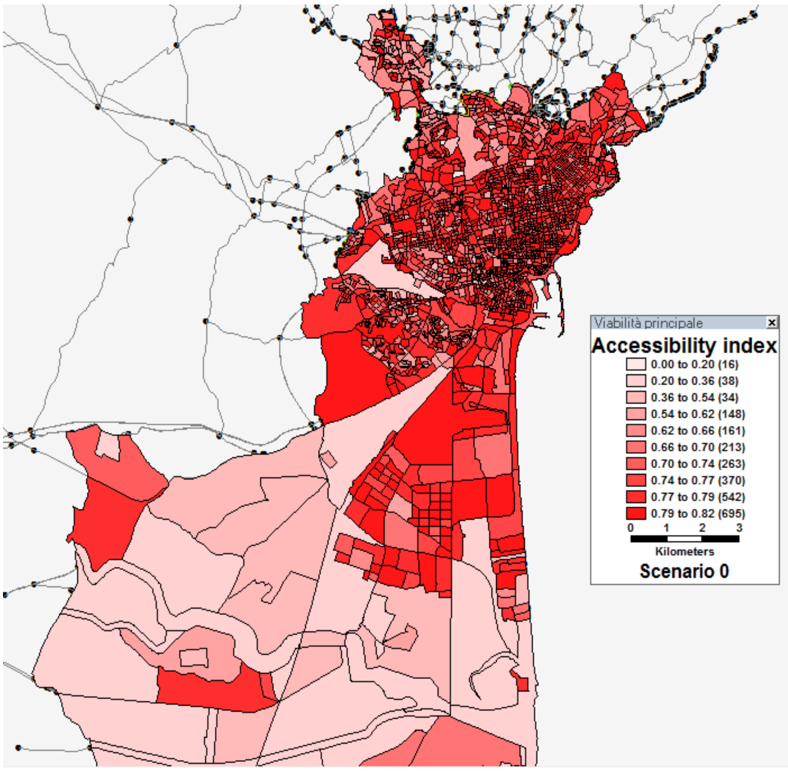

Fig. 3.
Accessibility Map for Scenario 0

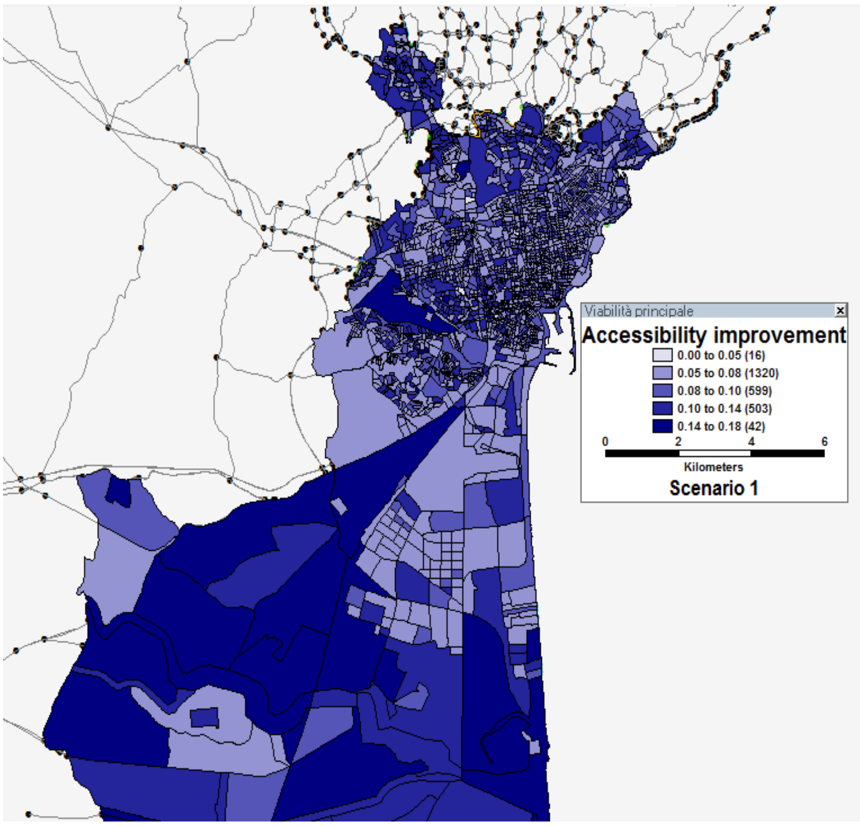

Fig. 4.
Accessibility Improvement Map for Scenario 1

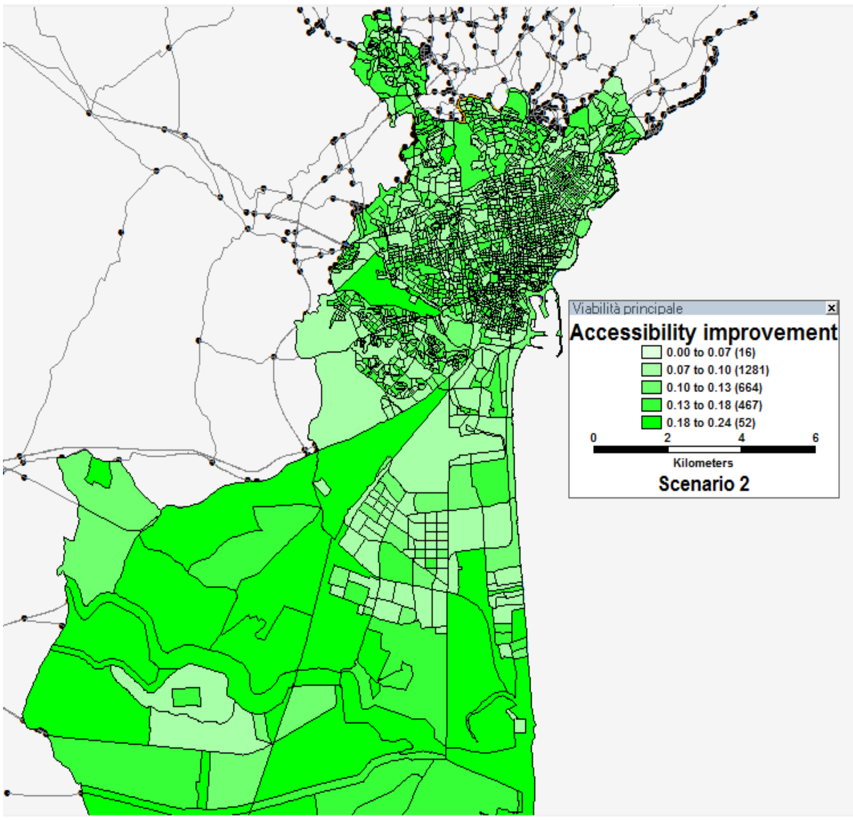

Fig. 5.
Accessibility Improvement Map for Scenario 2

3.4 Lorenz Curve and Gini Index

Lorenz Curve and Gini Index based on Hansen Accessibility measures have been calculated under the 3 scenarios. A graphical representation of Lorenz curves is shown in Fig. 6.
The Lorenz curves for all scenarios are close the perfect equality line (bisector). This does not imply a high level of service public transport, but a low inequality due to a quite uniform service coverage of the whole urban area. Both scenario 1 and 2 produce a significant improvement of equality as it is visible from the increased proximity of each Scenario's curve to the perfect equity line. The distribution of accessibility is quite the same for scenarios 1 and 2, so the relevant curves overlay each other.

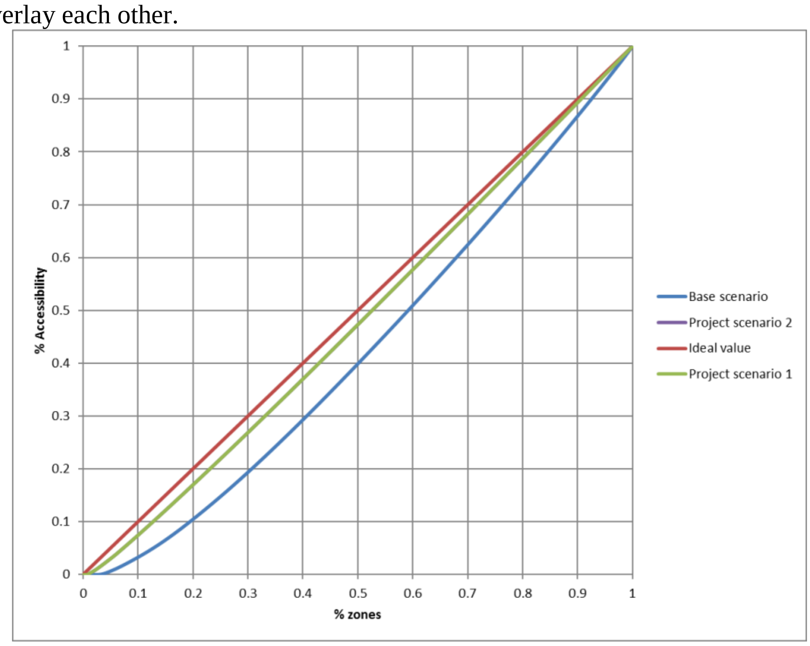

Fig. 6.
Comparison among Lorenz Curve for Scenario 0 and 2

Evaluation of Gini indices, which results are showed in Table 4, confirms the previous results and moreover underlines how Scenario 2 shows slightly better improvements than Scenario 1.

Table 4
Gini Index for the three different scenarios

Scenarios	Gini Index
Scenario 0	0.148485562
Scenario 1	0.046431085
Scenario 2	0.041428445

4. Conclusion

The ability to move and reach places even at great distances, has become an indispensable condition to live well and to integrate into today's society. Mobility is no longer just an option but has become a necessity. However, there are still many citizens who have limited resources or fewer resources than others, and the aim of social inclusion policies is to improve the quality of life of such the weakest sections of the population, in order to reduce exclusion.
Social inclusion is linked to the level of accessibility perceived by the individual, assessed according to the ease of reach of different places, with different availability of transport system. Accessibility awareness by citizens is a key element to coordinate the intervention measures in the field of transport and public services, but also to foster social receptiveness of such measures.
In this paper three different transport accessibility scenarios have been evaluated for the city of Catania. The application of an approach based on Lorenz Curve and Gini Index has showed that the proposed changes in the public transport network design corresponds both to an accessibility improvement and to a major equity of accessibility distribution as well. The methodology described seems to suit well to take decision in transport planning when both accessibility improvement and equity magnitude is crucial the address land use and transport decisions.

NETWORK DESIGN AND PLANNING: SUCCESS FACTORS FOR HIGH QUALITY PUBLIC TRANSPORT

Slaven M. Tica[1], Predrag Živanović[2], Stanko Bajčetić[3], Branko Milovanović[4], Andrea Nađ[5]
[1,2,3,4,5] University of Belgrade, Faculty of Transport and Traffic Engineering, Vojvode Stepe 305, 11000 Belgrade, Serbia

Abstract: Public transport network generally refers to a set of links, nodes, and lines that represent the infrastructure or supply side of the public transport system. Public transport network design depends on various factors, i.e. the city structure, the city transport network and infrastructure, geographical and climatic characteristics of the city, the structure of the public transport system, etc. Improving public transport network is one of the key steps in the process of creating high-quality and efficient mobility service. This paper deals with design of public transport network in urban areas. Emphasis is put on basic concepts and success factors in order to create high quality public transport services. Methodology for public transport network design and improvement, based on real transport demands and user requirements, is presented herein. The methodology represents a modern approach, which enables a continuous process of adaptation of the system in a changing environment. The proposed approach supports the realization of the efficient mobility of all categories of users, while at same time, increases system efficiency and effectiveness. The success in achieving these goals is measured using specific key performance indicators (KPI) for public transport network evaluation, which are defined herein. Proposed methodology is applied on the public transport system in Belgrade.

Keywords: public transport, network, key performance indicators (KPI).

1. Introduction

A vicious circle of the expansion of urban areas, overpopulation, and a lack of a quality life space smothers the cities and leads to a poorer quality of life. According to the official data of the UN, a staggering increase in urban population is expected in the next 30 years. Consequently, cities will face the inevitable socioeconomic, logistic and ecological challenges which will in turn make many commuters move from cities to suburbs causing the intensity of transport needs and transport demands to increase suddenly with respect to all modes of transport. While local authorities call for solutions aimed at the creation of livable cities (Vuchic, 1999), the time has come to recognize a long suppressed truth that public transport is by far the most efficient solution as regards the necessary quality of life and sustainable development of cities, and it is the key element of an efficient urban transport system (UITP, 2011).

Public transport (PT) system with its performances, technology, quality, costs and effects on the environment is one of the important factors which can influence size and structure of modern cities, their economy and sustainable development. The high quality PT system is foreseen to be the one of the key elements in the process of creating livable cities, because of its' ability to replace car use. Public transport is required to serve a range of objectives – from providing mobility to the disadvantaged through to alleviating traffic congestion – while also enabling efficient use of financial resources (Mees et al. 2010). These different objectives often conflict.

One of the basic elements of PT structure is transport network which presents, at the same time, the basis of transport system supply. Line network development is one of the first steps in the process of generating quality and efficient public service of citizens' mobility. Line network depends on the city structure, city transport network and its infrastructure (street network), PT subsystems structure, geographical and climate city region features, etc. General requests which urban public transport network should comply deriving from general PT system objectives refer to maximization of production and economic efficiency and system effectiveness and alignment of transport capacities with transport demand (utilization of the resources). Moreover, a high quality service to the passengers is required.

While there is an extensive literature focusing on PT systems economics and operation, the literature on the successful public transport network design and planning is relatively poorly documented. Furthermore, it mainly relates to the improvement of PT network on tactical and operational level. Therefore, urban and mobility planners are not well informed on the advantages of PT network planning and design and its' possibility to make a very significant contribution towards all above mentioned PT system objectives. Current practices reveal that there is a thin line between success and failure. The final outcome depends on the making the right or wrong choices on strategic level.

This paper outlines some basic principles of PT network design and planning. We aim to show that network planning and design can be a decisive factor for PT success. A methodology for public transport network design and improvement, based on real transport demands and user requirements, is presented herein. Proposed methodology is applied on the public transport system in Belgrade.

The remainder of this paper is divided in four sections. In the first section we concentrate on network planning philosophy and design principles. We continue with presenting the methodology for public transport network design and improvement. The methodology is applied in the PT system in Belgrade. The success in achieving PT network planning and design objectives is measured using specific key performance indicators (KPI) for public transport network evaluation, which are defined herein. Finally, some conclusions are presented. We also recommend some important planning and design principles (key lessons learned) for the public transport network.

2. Transport network planning and design overview

Urban public transport network or line network of urban public transport (PTN) is a sub-system of city transport network and it comprises lines network of all sub-systems (modes) of PT. The structure of the line network of the PT comprises static and dynamic elements. Static elements are the infrastructure of urban public transport network: routes, stops, terminal stops, stop distances and line lengths (network structure). Dynamic elements of PTN are the operation elements: times, speeds, number of vehicles, headways, frequency, capacity (scheduling) etc.

Thompson (1977) provided some early insights into the PT network planning. Furthermore, this issue has been analysed in detail by Mees (2000; 2010), Nielsen et al. (2005), Vuchic (2005), Dodson et al. (2011) and TRB (2015). Ronda and Mulley (2012) argued that influence of topography is often neglected in PT network planning. They claim that including this factor could led to better measuring the nature of the walk access; ensuring that planning guidelines measure walking access realistically; and choosing the most efficient mode topographically while ensuring that other policies support multimodal networks. Other group of researches focuses on scheduling problems in public transport systems rather than network strategy, structure and connectivity questions. A comprehensive overview this scheduling based network design and planning is given by Guihare and Hao (2008).

The essential purpose of PT is to carry a group of people with different trip origins and destinations in the same vehicle. As homes and workplaces become more and more dispersed, public transport faces an increasing challenge regarding the range of trip origins and destinations. It is a common assumption that public transport planning must be able to fulfill all these different users' travel demands and therefore it should be based on a very understanding of the different segments of the market. However, Mees (2000) have shown that this *demand-oriented public transport planning* might lead to some serious misconceptions. He names them the 'Bangkok' model of urban transport planning, which he connects with the idea of a liberal, deregulated PT market.

This have raised a question on whether the PT system should be planned as a widely distributed integrated transport network to support seamless multi-destination travel rather than as dedicated routes to meet specific passenger cohort demands (Dodson et al. 2011). Mees (2000; 2010) has demonstrated that the first concept (i.e. public transport systems as integrated networks) can generate higher levels of patronage than the planning of individual routes. This is due to the unexpected trip making behaviour that the network can support and which planners might not have predicted. Mees calls this phenomenon the 'network effect'. This new approach in public transport planning is often called *the supply-oriented planning*. Mees (2000) recommends the development of the public transport system according to the supply-oriented planning model of the Zürich region. Neilsen et al. (2005) gave guidelines on the strategies and tactics that can be applied to PT networks in order to achieve the 'network effect', based on analysis of some success and pitfalls in network planning. Dodson et al. (2011) distinct two basic principles underpinning the network effect. The first principle is to provide a simple and stable inter-connected network of public transport lines throughout the day with a structure and timetable that is easy for users to learn and understand (Nielsen et al. 2005). The second principle is to accept and support the fact that many of travelers will need to transfer between lines to access their selected destination. It can be said that transfers are the key to the 'network effect'.

Dodson et al. (2011) argues that planning public transport systems as seamless integrated networks, rather than as a series of individual routes serving a specified set of origin-destination pairs, is a critical task for metropolitan transport planning agencies. Although benefits of the supply-oriented planning model are undeniable, this approach can be economically unfeasible. Increasing frequencies implies additional vehicle fleet, more driver working hours etc. Therefore, cities with limited financial resources must look for modified solutions. Sustainable PT network development requires finding the right balance between demand and supply oriented planning. The choice of balance should reflect the major objectives of PT system, as well as the city objectives.

Throughout the years two different strategies in network design have emerged driven by the same currents as for PT planning (see above). The first approach is to provide 'tailor-made' services for different travel markets (express buses for peak hour trips; flexible paratransit for low-demand corridors and times, taxi for door-to-door demands etc.). The problem with this approach is that the more public transport is tailor-made, the more it surrenders its environmental and economic advantages (Mees et al. 2010).

The other alternative is the introduction of transfers can enable the provision of a 'ready-made' service. This approach enables 'anywhere-to-anywhere' travel, with high occupancy rates, by carrying different kinds of travelers on the same services (Mees et al. 2010).

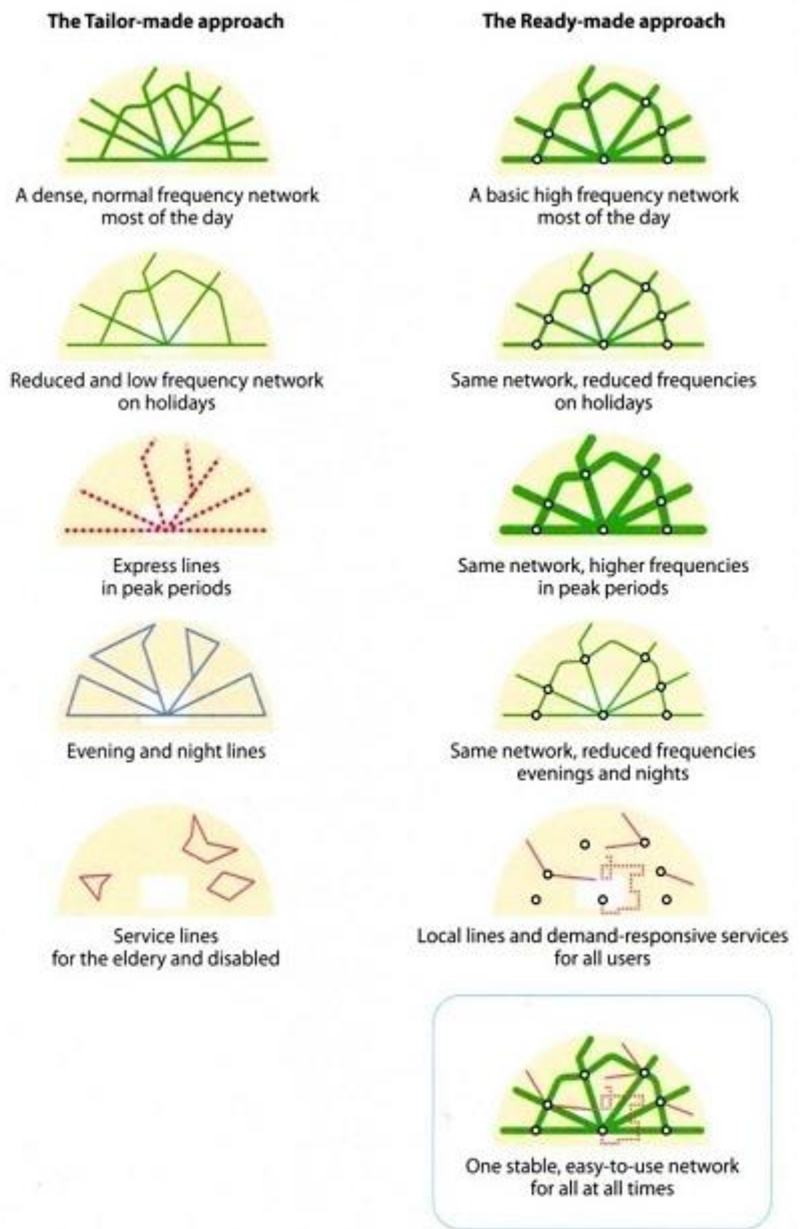

Fig. 1.
Two different approaches to network design
Source: Nielsen et al. (2005, p35)

The conventional PT network strategy is the one with radial links (Thompson 1977; Thompson and Madoff 2003). However, this strategy has some shortcomings. All trips are made via city center even though origin and destination might be in city suburbs. Thompson (1977) estimated that radially organised public transport systems in dispersed suburbanized cities can cater only to around 10 per cent of regional trips. An alternative strategy to the radial approach is the multi-directional network design approach (Newman and Kenworth 1999). Basic idea of this approach is to provide a seamless grid of mobility across as wide a proportion of the urban area as possible. Although performance level of these networks is higher compared to the simple radial ones, some disadvantages remain. To mitigate and/or overcome these shortcomings different kind of diametric PT networks, i.e. a network of pendulum lines running between areas on either side of the city centre. Bell (2016) identifies the benefits of the "network effect" and concludes that that the radial nature and centrality of PT networks in Australian cities may be more easily transitioned to a triangular rather than square geometry. Nevertheless, it is very unlikely to have a uniform type network in real urban systems. The same goes for the City of Belgrade (for details see following chapters).

3. The proposed methodology

Fig. 2 shows specific methodology for PT network planning and design. Developed methodology applies the system approach with real system data as basic inputs. Methodology represents a modern approach in designing the urban public transport basic elements which enables continuous process of constant adaptation to changeable environment. It comprises a number of steps and enables conditions for gradual changes in the system without leaps of sudden changes. The methodology was developed primary for the City of Belgrade, but is applicable to any PT system. Proposed methodology for PT network design and planning can be placed between the two previously indicated approaches (see Fig. 1). It follows the idea of high frequency urban and suburban transport network most of the day with reduced capacity on weekends and holidays. Basic network is supported with a network of local lines to cater to the diverse needs of passengers in suburban municipalities. After midnight until early morning hours a network of night lines completes the supply. This network runs through high-demand corridors and it is logically integrated with daily PT network (line numbers are the same, letter "N" is added to mark them as night lines). This has resulted in one stable, easy-to-use public transport network.

STEP 1: The first step of the methodology is the definition of objectives for PT network planning and design. PT system objectives can differ from city to city. Nevertheless, these objectives must be in line with the city's objectives. For the City of Belgrade and its' PT system target function is set as: "to cater all transport demand in terms of volume and quality for a defined level of costs (economic efficiency), with a maximum productivity of the system and the minimum negative impact on the environment".

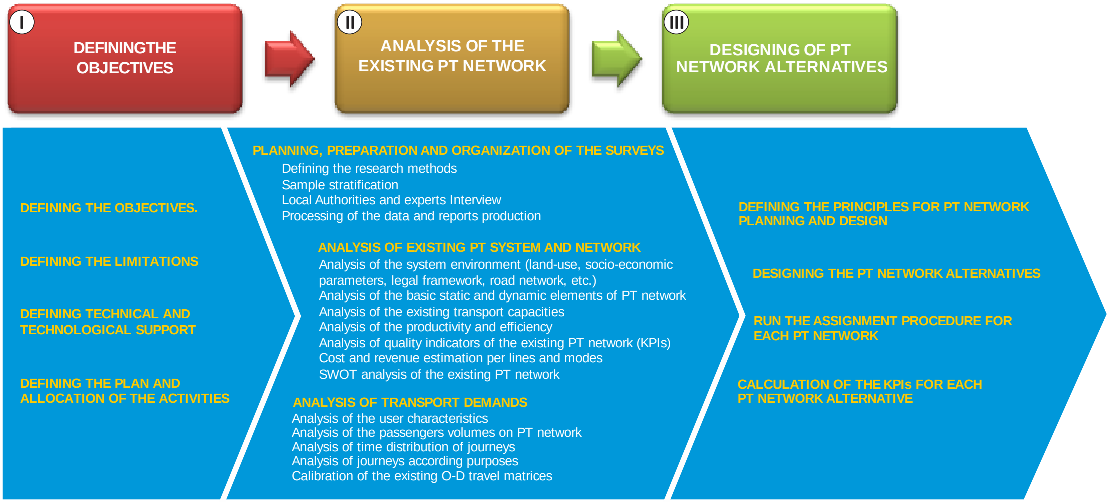

Fig. 2.
Methodology for PT network planning and design

STEP 2: The task of planning and design a PT network from scratch is rarely presented. Most cities have some form of PT system and the main challenge is to define the key strategies and tactics to improve PT network. Therefore, the second step of proposed methodology is the analysis of existing PT network and the research of transport demand. Output of this step should shed a light on improvement and re-design possibilities.

The analysis of existing PT system in the broader sense comprises also the basic elements of urban land planning, demographic and socio-economic characteristics, as well as the analysis of the existing street network. Additionally, attitude of stakeholder groups (users, local authorities, operators, experts) and transport demand are researched. This requires a wide set of different methods presented in the following table.

Table 1
The analysis of existing PT system in Belgrade – applied methods

No	Analysed element	Method	Data source
1	System environment	Desk research	General plan, Master plan, etc.
2	Historic development	Desk research	Studies, projects, expertise
3	Transport network	Desk research	N/A
4	PT system (static and dynamic elements, network KPI, costs, …)	Desk research	Data from Directorate for Public Transport City of Belgrade, Reports from electronic vehicle management system (BusPlus), etc.
5	Transport demand and users' characteristics	Survey - Passenger counting and users' interviews	N/A
6	Personal attitude of local authorities, operators and experts	Survey - Direct interview	N/A

STEP 3: Final step is the designing of the new PT network. To achieve goals set in Step 1 one must define a list of key principles for network planning and design. The more complex PT system is the more specific principles are. For PT network planning and design in Belgrade key principles defined are:

- *Plan and design PT network in alignment with land-use planning and socio-economic development.*
  Very often the requirements of PT system are neglected in planning of land-use and this is often said to be one of major pitfalls of PT systems. Integrated approach might lead to mutual benefits both for the city and its PT system.
- *Create integrated transport network to support seamless multi-destination travel while meeting the specific passenger origin-destination demands to insure reasonable number of transfer per one journey.*
  The duality in PT planning regarding tailor-based and ready-made approach is analyzed in previous chapter of this paper. We propose balanced approach: integration of all transport services to support "anywhere-to-anywhere" journeys with optimized number of transfers. It is important to always have on mind a complete PT network not a piecemeal changes of some parts of it (sections, lines, modes), i.e. system approach is crucial.
- *Retain at the greatest possible extent the existing user habits and recognizable image of the existing PT network.*
  Most cities have some form of PT system the users are familiar with. The main challenge is to define the key strategies and tactics to improve PT network while retaining its positive features.
- *Plan a hierarchy of lines into a network.*
  The basic element of PT network is the line. Clear understanding of the line and its elements is needed but not sufficient condition for achieving the "network effect". Each line must have a clearly defined role in network hierarchy. Lines should have consistent stopping patterns throughout all operating hours and reliable timetables.
- *Increase journey speed and system reliability.*
  Journey time is one of the most important factors for passengers in transport mode selection. Public transport planning should aim for travel speeds comparable to or faster than door-to-door travel times that can be achieved by car (Nielsen et al 2005; Mees 2000, 2010). Another important factor is the system reliability. Service reliability can be defined in terms of the variability of service attributes and its effects on passenger behavior and on operator performance (Abkowitz et al. 1978). Providing reliable service means keeping vehicles on schedule, maintaining uniform headways and minimizing the variance of maximum passenger loads (Levinson 1991). Importance of travel time and service reliability must be acknowledged in PT network planning and design.
- *Maximize the volume/capacity ratio - optimal network frequencies.*
  Some parts of existing PT network, usually suburban and local lines, have low frequencies making PT less attractive comparing to passenger cars. On the other hand, other network sections have so high frequencies resulting in congestion and unreliability, which may cancel the positive effects from shorten dwell times. Optimization of transport supply (frequencies and capacities) based on transport demand will result in higher utilization of resources, cost reduction and increase in overall quality of service.
- *Minimize No of terminals in the city centre – replace radial lines with a network of pendulum (diametric) lines.*
  The City of Belgrade has a problem of many PT line terminating in the city centre. There are many similar examples in other cities worldwide. Radial PT lines should be replaced with a network of pendulum (diametric) lines running between suburban centres via city centre. This will improve the efficiency of the system and quality of service for passengers while at the same time highly attractive areas in city centre are left for other use, e.g. the City of Belgrade is turning a wider central area into a pedestrian zone.
- *Coordination of convenient, fast and easy transfers.*
  Create integrated transport network to support seamless multi-destination travel results in higher transfer rate in the PT system. Fast and easy transfers support fast journeys to dispersed destinations within a public transport network (Nielsen). Therefore, this is an important element in creating high quality PT system. However, one can argue about the definition of "fast and easy transfers". Nielsen et al 2005 claim that at interchanges walking distances between services should be very short - preferably no more than 10 metres. This is very hard to achieve in real PT systems.
- *A shift to more environment friendly PT modes.*
  The positive effects on the environment which PT has comparing to cars are well known. However, some PT modes (e-bus, trams, trolleybus) are more environment friendly then others. Favoring those transport modes will have notable effects on overall quality of life in the catchment area as well as throughout the city.
- *Make the system economically sustainable.*
  The explicit request from the City of Belgrade was to reduce operating costs of PT system. This can be an important principle for the systems with limited financial resources.

Turning principles into operational actions is not always straightforward, particularly where multiple further factors enter consideration (Dodson et al 2011). Yet consistent, continuous and determined application of these principles can improve PT network functioning.

Some network design principles are opposed to the others. Therefore, this phase continues with the definition of the alternative PT networks satisfying all the principles to some extent. The level of meeting the principles is evaluated using KPIs.

Complete list of the KPIs for network analysis is given in the following table. A special emphasis is put on the volume/capacity ratio analysis and analysis of the efficiency indicators. To calculate the values of KPIs for each alternative network it is necessary to run the assignment procedure first. The assignment procedure was selected based on the potential demand analysis ("desired lines network").

Table 3
PT network KPIs

No	KPI name	Measuring unit
1	*Construction network length*	[km]
2	*Exploitation network length*	[km]
3	*Coef. of Line network overlapping (branching)*	[km/km]
4	*Coef. of Line network complexity*	[--]
5	*Coef. of Stops density*	[stops/km]
6	*Coef. of Line network availability*	[km/inhabitant]
7	*Coef. of Line network density*	[km/km^2]
8	*Line coefficient*	[km/km]
9	*Coef. of Line network adaptability*	[--]
10	*Coef. of Line network directness*	[--]
11	*Coef. of Line network utilization*	[passengers/km]
12	*Stop catchment area*	[km^2/km^2]
13	*Average stop distance*	[km]
14	*Coef. of Physical integration (number of multimodal stops)*	[stops]
15	*Coef. of Environmental friendliness*	[%]
16	*Production efficiency*	[vehiclekm/vehicle]
17	*Economic efficiency*	[RSD / RSD]
18	*Cost efficiency*	[RSD/departure]
19	*Average number of transfers*	[--]
20	*Journey speed*	[km/h]
21	*Average travel length*	[km]
22	*Gross transport work on line network*	[vehicle·km]

Analysis of such a complex PT system such as Belgrade's requires appropriate tools. Transport demand data processing is done in the *Public Transport Demand Analysis Tool – PTD,* a specialized software package designed by the authors of this paper. The entire computer-aided procedure of modelling and designing for PT system in Belgrade was done in *PTV VISUM Expert* software package, version 14.00 which comprises also modules: Timetable management, Line costing and revenue calculation, Detailed line blocking, Public transport interface package, Schematic line diagram and Passenger onboard survey and e-ticketing data. The package size is "2" which comprises 1.000 zones, 30.000 time profiles with unlimited number of links and nodes/stops.

4. Discussion and conclusions

This paper deals with the design and planning of PT network and key success factors in order to create high quality public transport services. We propose a simple three-step and easy to apply methodology, which was successfully implemented in PT system in Belgrade. Looking at the KPIs some of the main benefits of the new PT network in Belgrade are:

- ✓ Increased travel speed +**7,49 %;**
- ✓ Decreased network overlapping - **5,10 %;**
- ✓ Increased network adaptability (ration between journey time and in-vehicle time) **22,06%**;
- ✓ Increased stop chatchment area +**3,49%;**
- ✓ Increased cost efficiency +**1,7%** for the same productivity level**;**
- ✓ Decrease in operating costs **-9,38 %,**
- ✓ Modal shift to environment friendly PT modes (introduction of the two new tram lines, introduction of the first e-bus line and introduction of the second urban rail line)– Increased coefficient *of environmental friendliness* **+12,19 %.**

The lessons learned during PT network planning and designing in order to create high quality PT services are as follows:

- *The system approach is crucial* - always have on mind a complete PT network, not piecemeal changes to individual sections, lines or modes.
- *Always plan and design PT network in alignment with land-use planning and socio-economic development*. PT system is subsystem of a city, not a self living system.

- *Planning and design of PT network requires extensive involvement of all stakeholders and users* at all stages of the process. This requires various research methods for collecting their inputs.
- *Respect the existing user habits and recognizable image of the existing PT network*.
- *Plan for speed and reliability, but also for maximum productivity and cost efficiency.*
- *Optimization of all network parameters is key to success rather then max/min strategies*. This often means some kind of trade-off between opposite requests (e.g. passengers might accept additional transfer if journey speed in increased because of an increase in frequency etc.)
- *Evaluation of the effects requires a set of clearly defined KPIs*.

There are few possibilities for further research. Finding the optimal values of network parameters for specific conditions and constraints is one of the biggest challenges in front of the future PT network planners and designers. The second line of research could follow further consolidation of the KPIs, making them simpler and easier to apply. The other approach could be adjustment of the methodology to make it applicable in regional and intercity transport.
Finally, we can conclude that the success depends on high quality PT network planning and design with the users in focus. High tech is not a critical factor, although it can make this process even faster and simpler.

Acknowledgements

This paper is based on the project TR36027: "Software development and national database for strategic management and development of transportation means and infrastructure in road, rail, air and inland waterways transport using the European transport network models" which is supported by the Ministry of science and technological development of Republic of Serbia (2011-2016).
The proposed model was developed by the Authors within the project “MassTransNet: Urban public transport line network and definition of required capacities in Belgrade (ITS-1)”, which is supported by the City of Belgrade (March – July 2015).

MEGLIO MUOVERSI. THE SUSTAINABLE MOBILITY IN THE PROVINCE OF REGGIO CALABRIA

Domenica Catalfamo[1], Giuseppe Amante[2], Giovanna Chilà[3], Maria Rosaria Trecozzi[4]
[1,2,3,4] *Provincia of Reggio Calabria, Reggio Calabria, Italy*

Abstract: Meglio Muoversi is a projects realized by the Province of Reggio Calabria in order to realize a process of planning, integrated management and monitoring able to increase the accessibility and to produce a modal shift towards more sustainable transport modes. Two services of advanced mobility flexible in space and time have been activated with Meglio Muoversi: Chiamabus and C'Entro. Chiamabus is a dial-a-ride transport service, C'Entro is a Car-sharing service and provides for the promotion of the Car-pooling. Both services are complementary to the services existing in the territory and are complementary one each other with respect to the offer of transport. Chiamabus and C'Entro are managed by a Provincial Operating Centre making use of the most advanced technological systems for management and monitoring. Below we describe the components of Meglio Muoversi as well as the results of Chiamabus, with particular reference to the services provided between different transport nodes. Finally, we describe find the development perspectives considering both services envisaged, and potentialities of the Provincial Operating Centre that, for the way it is designed, results an open system able to host and manage further services for mobility.

Keywords: dial-a-ride transport service, car sharing, sustainability.

1. Introduction and state of the art

In the last years, sustainable mobility is the object of different strategies at international and national scale.
The General Plan for Transport and Logistics (2001) indicates, among its objectives, the satisfaction of the mobility demand by a transport supply with adequate levels of service, the realization of a safe and sustainable transport system, the efficiency of public spending and the quality of services. Among the transport policy guidelines, in addition to environmental sustainability and safety, the aim is the liberalization and privatization, to mobility in urban areas, to introduce an integrated planning process between transport and land, through intermodal and integrated networks.
As reported in the Action Plan on Urban Mobility (2009), local, regional and national authorities should be geared to the sustainable transport objectives, with a focus on the mobility needs of vulnerable users, including persons with disabilities, the elderly, subjects with economic hardships.
The White Paper - Roadmap to a Single European Transport Area - Towards a competitive and resource efficient transport system (COM (2011) 144) shows the addresses to be pursued for obtain a competitive and sustainable transport system.
The Guidelines. Developing and Implementing a Sustainable Urban Mobility Plan, aimed at accelerating the widespread adoption of Sustainable Urban Mobility Plans, as provided for by the Action Plan on urban mobility.
One of sustainable mobility tools implemented in different realities as support to local public transport systems is represented by the call transport systems, also known as Demand Responsive Transport (DRT) or Dial-a-Ride services. The call transport systems generally involve the use of a fleet of vehicles of small dimensions, such as to enable the performance of displacements personalized according to user requests (with source and destination choices from time to time), carrying a number of users at a time and managing the concatenation of paths with a certain level of flexibility to be able to satisfy all the requests.
The DRT system is able to plan the route of each vehicle used according to the requests received. In general, the attempt is to minimize the operating costs that, in the case of maximum flexibility, may increase, and to maximize the level of service offered to the user, proposing the services that are consistent with the requirements. The management of these systems is supported by specific software for the planning and management of the service, GPS satellite systems for vehicle tracking, communication systems, GIS systems for spatial information management.
The activated service models could be:

- Fixed line at booking, with defined paths but ran only performed in the presence of reservations,
- The fixed-line deviations, similar to the previous, but in which small deviations in the default location are authorized,
- The model many to one, which picks up passengers at different points and leads them toward the same destination,
- The model many to many, offering complete flexibility both in origin and in destination.

Regarding the deployment of DRT systems, in Italy the first experiences are those of Imola in the 80s, which later evolve and for large urban areas of Rome, Milan, Genoa, for both small towns and mountain communities, as in services, for example: EccoBus, in the province of Alessandria; StradiBus, in Cremona; Prontobus, made in Sarzana, La Spezia; AllôBus and AllôNuit, in Aosta and the surrounding towns; Provibus and MEBUS, in the province of Turin.
Another example of mobility systems is car sharing, a system of car rent without driver. In Italy, different system of car sharing are diffused in Rome, Firenze, Milano, Torino, …

[1] Corresponding author: domenica.catalfamo@provincia.rc.it

Meglio Muoversi is a Local Integrated Development Programme realized by the Province of Reggio Calabria, thanks to a funding POR Calabria FESR 2007-2013 – Line of Intervention 8.2.1.1, approved with Resolution of the Regional Council 466/2012, concerning the Inter-municipal Mobility Systems. The objective of Meglio Muoversi is the pursuing of the sustainable mobility in its three variations of: social sustainability, economic sustainability and environmental sustainability. The first one aims at reducing the accident rate and the improvement of accessibility, the second one at efficacy and efficiency, the third one at reducing environmental impacts. In this perspective, with Meglio Muoversi we want to realize a process of planning, integrated management and monitoring, of advanced mobility services, aimed at thickening tangible and intangible networks of connection (accessibility), changing the travel behaviours of users to discourage the use of private cars and foster the integration between various modes of transport (safety and environmental impacts, efficiency and efficacy). Two services of advanced mobility flexible in space and time have been activated with Meglio Muoversi: Chiamabus and C'Entro. Chiamabus is a service on demand, C'Entro is a Car-sharing service and provides for the promotion of the Car-pooling. Both services are complementary to the services existing in the territory (e.g. road and rail Public Local Transport) and are complementary one each other with respect to the offer of transport, because they provide different services with different infrastructures, and with respect to the demand, because they aim at satisfying various categories of users.
The components of Meglio Muoversi are described here below as well as the results of Chiamabus, with particular reference to the services provided between different transport nodes. Finally, you can find the development perspectives considering both services envisaged (Chiamabus and C'Entro), and potentialities of the mobility centre that, for the way it is designed, results an open system able to host and manage further services for mobility.

2. Territorial areas and centres attracting of the Province of Reggio Calabria: the analysis of Reggio Calabria basin

The Province of Reggio Calabria is a peninsula washed by the Tyrrhenian Sea and the Ionian Sea and stretches out towards Sicily forming a bridge for links between the Europe and Sicily. The territory is characterized by presence, in the space of a few kilometers, of different environments: in particular, the hinterland is characterized by a morphological structure that is connected with the Aspromonte mountain system, while the coastline is characterized by coastal settlements which have a main development between the shoreline and the coastal roads.
A peculiar place which stands out on its own is the City of Reggio Calabria, the largest city of Calabria and the largest in terms of municipal territory (236 sq km), that is characterized by a considerable extension along the coast (over 10 km) and by a territory with altitudes ranging from sea level to over 1800 metres high. The city, which alone accounts for 70% of the population of the entire area covered by this study, is indeed predominant in relation to other nearby towns and is a real pole of attraction of mobility
Demand mobility in the Province of Reggio Calabria is related to a study area including 576,693 residents and 189,946 families; a percentage of about 47% of these moves for work or study reasons.
Beginning from data available in transport literature and from the application of demand model of transport (Cascetta, 2009), we have estimated the transport demand on a provincial scale in a generic day, for the following reasons:

- Home-work (CL),
- Home-school (CS),
- Home-personal services (CA).

Main results are reported in Catalfamo, Amante, Chilà (2014).
Inland areas of the Province are characterized by low accessibility in terms of infrastructures and services: the privately owned car represents the only modal alternative, especially for specific groups of citizens and in the peak-off time period.
The high percentage of those who use their own private car produces very low levels of environmental quality and energy efficiency, a low level of both accessibility and attractiveness of areas.
Accessibility has always been a decisive factor in economic development: improving accessibility allows a change of economic activities, increasing the economic surplus and the levels of local employment.
The aim of this work is to implement a flexible transport service in order to improve the accessibility of the specific area of the Province of Reggio Calabria and to promote a modal shift towards more sustainable alternative transport.
In order to optimize the transport service on demand provided for within the CHI-AMA BUS operation, the provincial territory has been divided into mobility territorial areas, by identifying centres attracting the service as main destinations of the connections to be activated, classified as:

- Local attracting centres, defined for every territorial area,
- Provincial attracting centres, valid for the whole Province.

As regards the local attracting centres, they are defined according to territorial area, representing the main destination of movements and, therefore, of the connections to be activated with CHI-AMA Bus (mainly but not exclusively many-to-one service). The division of the Province into territorial areas was carried out starting from the analysis of the demand of mobility, in order to maximize, within each area, according to the canonical definition of study area (Cascetta,2009) the effects of the interventions planned, considering transport and socio-economic elements.

The study has led to an organization of the service based on 8 mobility territorial areas, identified by the Municipality, that within the area, represents the main destination of movements and that, therefore, is classified as local attracting centre (Table 1).

Table 1
Territorial areas

Territorial Area	Municipalities
Reggio Calabria	Reggio Calabria, Calanna, Campo Calabro, Fiumara, Villa San Giovanni, Laganadi, San Roberto, Sant'Alessio in Aspromonte, Santo Stefano in Aspromonte, Motta San Giovanni, Cardeto
Melito di Porto Salvo	Bova Marina, Brancaleone, Condofuri, Palizzi, Africo, Bagaladi, Bova, Roccaforte del Greco, Roghudi, San Lorenzo, Staiti, Melito Porto Salvo, Montebello Ionico
Bovalino	Ardore, Benestare, Bianco, Bovalino, Bruzzano Zeffirio, Caraffa del Bianco, Casignana, Ferruzzano, Sant'Agata del Bianco, Careri, Platì, Samo, San Luca
Locri	Locri, Portigliola, Sant'Ilario dello Ionio, Siderno, Agnana Calabra, Antonimina, Canolo, Ciminà, Gerace, Mammola
Roccella Ionica	Caulonia, Gioiosa Ionica, Grotteria, Marina di Gioiosa Ionica, Martone, Roccella Ionica, San Giovanni di Gerace, Camini, Monasterace, Riace, Stignano, Stilo, Bivongi, Pazzano , Placanica
Gioia Tauro	Gioia Tauro, Rizziconi, Rosarno, San Ferdinando, Molochio, Oppido Mamertina, Taurianova, Terranova Sappo Minulio, Varapodio
Polistena	Anoia, Candidoni, Cinquefrondi, Cittanova, Feroleto della Chiesa, Galatro, Giffone, Laureana di Borrello, Maropati, Melicucco, Polistena, San Giorgio Morgeto, San Pietro di Caridà, Serrata
Palmi	Bagnara Calabra, Palmi, Scilla, Seminara, Cosoleto, Delianuova, Melicuccà, San Procopio, Santa Cristina d'Aspromonte, Sant'Eufemia d'Aspromonte, Scido, Sinopoli

The local attracting centres identified for every territorial area are: Reggio Calabria (to be considered in terms of conurbation system Reggio Calabria - Villa San Giovanni); Palmi; Gioia Tauro (to be considered in terms of conurbation system Gioia Tauro – Rosarno); Polistena; Roccella Ionica, Locri (to be considered in terms of conurbation system Locri – Siderno); Bovalino; Melito di Porto Salvo.
In every local attracting centre, the service is supported, as provided for by the project, by the installation of infotainment stands performing the double function of information to users and booking service.
As regards the provincial attracting centres of movements, to be considered valid for every territorial area, the preferential destination of the connections activated, are listed below:

- Tito Minniti Airport of Reggio Calabria,
- Ports of Reggio Calabria and Villa San Giovanni,
- Main railway stations,
- Hospitals and Hospital facilities,
- Provincial healthcare facilities,
- Universities,
- Provincial administrative and judicial centres.

3. The Chi-Ama Bus service: management and exercise data

The transport services on demand and car-sharing services are managed by a mobility centre making use of the most advanced technological systems for management and monitoring. The Provincial Operating Centre is described in the below.

3.1. Provincial Operating Centre

The transport services on demand and car-sharing services are managed by a mobility centre making use of the most advanced technological systems for management and monitoring. The mobility centre rules the relationships with the users for reception and management of bookings, the relationships with the operators of Chiamabus to transfer the bookings, the relationships with the on-board devices of the cars of C'Entro to authorize withdrawal and delivery.
The Operating centre comprises two main units: Earth system and Transmission system.
The earth system is the functional block at the Operating centre including all the functionalities necessary to provide the bus service on demand and car-sharing service. There are both back-end functionalities, namely concerning the computational part and data processing to provide the service, and front-end functionalities, or rather the service provided to the user and necessary to accede to and use the service.

The back-end processes include all those macro-services, defined as modules, designed to collect real-time the requests of the users (booking request, changes, users' registration) and data coming from in-service means. The earth system shall process the collection paths and the service planning, both planned and real-time, after the requests of the users. This part includes also all those functionalities that need data from vehicles with the purposes to control and monitor the service. The earth system comprises the parts described in brief here below.

- System Engine, the infrastructure of the operating centre, designated to manage the support functionalities, aimed at guaranteeing the functionality of the services provided. It guarantees the real-time data acquisition and their filing,
- Management and filing of OBD data (On Board Data) arising from the OBU workstations of vehicles, through a network manager system, representing the control tool which supports the rest of the processes of the platform CHI-AMA bus to provide the services,
- GIS, the component engaged in managing every service linked to the georeferencing, first of all, those designated to display real-time the positions of the means, to display the road graph and points of interest. The component GIS provides for the implementation of a specific Geospatial architecture based on GeoServer, an open source server for the interoperable management of geospatial data, and a monitoring system of vehicles, based on the information collected by the devices of Exercise Data Transmission System installed in the vehicles,
- Booking Form, functional block used by the user to require the use of the service (booking, information request, changes etc.) and to check the status of his/her booking and of the means. This form includes: Account System e Profiling; Charging Form; Payment Form,
- Fleet Management, engaged in managing the fleets of means designated to provide the service, includes all important data concerning means, drivers and planning of rides. It is the management component allowing the integration and planned management of fleets,
- Report management, allowing to generate appropriate final reports on the use of the system (such as show, for every vehicle, the kilometres made, the frequency of use, the number of users served etc.). The form allows to carry out specific analyses concerning the assessment of indicators of service, and more in general a series of analyses carried out on the basis of keys and filters selected by the operators,
- Interaction channels.

The platform CHI-AMA Bus allows the user making use of the services provided through the use of the following interaction channels: Web portal; Mobile Application; Call centre, interactive Infotainment Stands.
The modular services of fleet management, GIS, report management, payment for the transport service on demand shall be also functional to the implementation of the car-sharing service.
In particular, through the Operating centre it will be possible: register users and fill in on-line the subscription forms; manage bookings; accede via web, PC, tablet, smartphone, other devices and via mobile Apps; manage the payments, according to different forms of charging, and invoicing; manage the opening of doors and start of the engine; manage the maintenance of the fleet; monitor the range of diesel and electric vehicles of the fleet; receive and store data concerning the positioning of the Car Sharing fleet, coming from the OBU, dedicated to the Car Sharing, through interfacing with the data reception system of positioning of the Car Sharing system (therefore not through direct interfacing with the OBUs); display on the GIS component data concerning the positioning of the Car Sharing fleet and the status of the means; extend the use of the Fleet Management system also to the means of the Car Sharing fleet, with concurrent allocation of the OBU; manage the reallocation of vehicles depending on bookings; carry out the report management of data concerning the use of Car Sharing means; expose data of report management through web services; have accounts available with appropriate profiling.

3. 2. Exercise data for Chi-Ama Bus

Chiamabus, active as of 20th July 2015, is executed by private operators, having subscribed a Framework Agreement through public procurement, with means having a variable capacity from 8 to 50 seats. The service mainly collects requests in urban and metropolitan areas, but performs also services with origin and destinations in the rest of Italy. At the moment there are 5 transport operators:

- Operator 1, with headquarters in Reggio Calabria operating with a 8-seat vehicle (excluding the driver),
- Operator 2, with headquarters in Villa San Giovanni, operating with a 8-seat vehicle (excluding the driver) and a 50-seat bus, and that, compared to the fleet of the Province of Reggio Calabria, has also made available: a further 8-seat vehicle, a 25-seat bus, a 35-seat bus, a 50-seat bus,
- Operator 3, with headquarters in Stilo, operating with a 7-seat vehicle + 1 seat for disabled person (excluding the driver),
- Operator 4, with headquarters in Reggio Calabria, operating with a 8-seat vehicle (excluding the driver).

As of 26th October it represents an effective service in support of the integration between both banks of the Area of the Strait to improve the connections having as origin and destination the Airport of Reggio Calabria. Several requests are

registered everyday by passengers from Messina using Chiamabus that coincide with every arriving and departing flight.
With reference to the last available data, we refer here below a comparative table of the main indicators detected on 31th July 2016 (Table 2). According to this data (July, 31, 2016), about 16.000 passengers have been users of Chi-Ama Bus, of which 57 % with 8-seat vehicles. A percentage about 90% of total of transport services have been realized with 8 seats-vehicles, with a 3,5 pax for travel and a rate of occupancy about 0,44. In effect, Chi-Ama bus allow to satisfy weak demand, during off – peak hours, as support of the local public transport. In relation to aggregate data concerning the travels carried out to and from the Tito Minniti airport of Reggio Calabria, we highlight that they represent in the aggregate almost 70% of the Chi-Ama Bus services.
Other attracting centres are the healthcare facilities part of the national healthcare service, schools of all levels and Universities, and the tourist resort of Gambarie, privileged destination during the plentiful snowfalls of January.

Table 2
Aggregate exercise data

Indicator	Value
Tot. no. of travels	2.864
Tot no. of travels – 8 seats	2.616
Tot no. of travels –> 8 seats	248
Tot no. of passengers carried	15.903
Tot. no. of passengers carried – 8 seats	9.128
8-seat vehicle average occupancy rate	0,44
Tot. no. of passengers carried –> 8 seats	6.775
Tot. no. Km made	91.240
Pass./km	0,17
No. travels with O Tito Minniti Airport	800
No. travels with D Tito Minniti Airport	950
No. Travels With O or D Tito Minniti Airport	1.750
% travels with O or D Tito Minniti Airport	61%
Tot. no. of passengers carried towards Tito Minniti Airport	2.540
Tot. no. of passengers carried from Tito Minniti Airport	2.624
Tot. no. of passengers carried towards or from Tito Minniti Airport	5.164
No. travels with O a transport node	1.893
No. travels with D a transport node	1.152
No. travels with O and D a transport node	1.116
No. travels with O or D a transport node	1.929
% of travels with O or D a transport node	67%
No. of passengers carried towards O a transport node	5.767
No. of passengers carried from D a transport node	3.165

Table 3 shows synthetic data service Chi-Ama Bus on the first year of service activation, and MEBUS, in the area called service Turin metro, for 2013, the first year from which data are made available and useful for the comparison. The MEBUS is a DRT service that is activated by reservation. To use it, a telephone reservation toll on the area of interest, indicating the day and time in which the service is used, the source and destination. The service was set up for the first time in April 2008 in the North East area and expanded later to North West Basin, the South West Basin and the Hill Chierese. Data show that Chi-Ama bus is characterized by a more higher value for the parameter *Number of pax/travel*; the other parameters are similar.

Table 3
Comparison between Chi-Ama Bus and MeBus

Indicator	MeBus (2013)	Chi-Ama Bus (July 2015 – July 2016)
Tot. no. of passengers carried	15.000	15.900
Tot. no. Km made	104.000	91.000
Tot no. of travels	11.000	2.864
No. pax/travel (average value)	1,4	5,5

3. 3. C'Entro

C'Entro is the Car Sharing service, the activation of which is scheduled for next autumn, it will be completed with 18 diesel cars and three electric cars that can be rented in 5 municipalities of the province: Reggio C., Villa SG, Joy T ., Locri and Siderno. Have been reserved 40 stalls at the main pole attractors (transportation hubs, hospitals, etc.,), and were reserved another 12 stalls further 6 municipalities to ensure the break during the rental in highly attractive areas.

4. Conclusions

For a better efficiency and efficacy of the service, the subscription of a higher number of operators is desirable, with more headquarters spread in the provincial territory: the objective is the creation of a denser network of tangible and intangible connections, allowing to optimize the services in the urban centres, and, concurrently, the creation of valid and sustainable modal alternatives in the most interior and less accessible areas of the Province of Reggio Calabria.

EVALUATING COSTS AND BENEFITS OF POSSIBILITIES OF MODAL SPLIT CHANGE - EXAMPLE OF BASIC TRIP GENERATOR

Milos Pavlovic[1]
[1] *Highway Institute, Belgrade, Serbia*

Abstract: Shops and markets in modern life represent a significant generator of travel, whereby contribute to the temporal, spatial distribution and modal split travel. This paperwork is focused on research, evaluating the benefits and costs based on a comparison modal split distributions and trips that are aimed at going into a hyper market. The study was done during the weekend in the city of Pozarevac, and as a research subject was shop - hyper market on the periphery of town. Basically, that are indicators that describe the costs and benefits incurred during a single trip. Such a simple example shows the possible savings based on the selection of the mode of transport when going to purchase, in accordance with the consumer basket, i.e. the size of the average purchase price, weight of purchased goods, the distance traveled, and travel time. We are witnesses of today that the sources attractions such as hypermarkets, primarily generate passenger travel made by car. The intention of the author in this paperwork is to point out the current modal split distribution and the possibilities of future traffic; accelerate, motivate and popularize the development of other modes of transport in accordance with the basic principles of sustainable mobility, especially when it comes to developing countries. Prediction and prevention in such cases can significantly affect the future development of transport infrastructure. Thus, changing the mode of transport, possible multiplied savings needs to justify and change the awareness of today's stagnant local society. Multicriteria evaluation of the effects of a basic trip regarded through the economic, health, social and other benefits may change the current modal split travel. The strategic approach observed through acts, legislation and principles and implemented through a significant number of programs (discounts, benefits, etc.) must have unequivocal support of the authorities and the local community, in order to progress towards sustainable development.

Keywords: cost and benefits, evaluating urban transport, modal split, sustainable transport, spatial and transport planning.

1. Introduction – Sustainable Progress

Transition towns and technological development of urban areas modify the existing environment and urban area, thereby leaving a mark on people and the environment. Steady progress has generated a number of factors pushing the burden on residents, also mixing them in quality of life. Experience are valuable heritage, which can be of invaluable importance to the proper application. The practice in urban planning takes into account the integration, participatory, and evaluation principles to satisfy current and future needs of urban residents for mobility, and to ensure a better quality of life in cities and their surroundings. Sustainable Urban Mobility Plan is to create a sustainable transport system means ensuring the availability of jobs and services to all, improve safety and security, reduce pollution, greenhouse gas emissions and energy consumption, increase efficiency and effectiveness in the transport of people and goods, the scaling up of attractiveness and the quality of the urban environment. It is important to develop a common understanding among key stakeholders of what sustainability and sustainable mobility means for a city and its surroundings. In development of sustainable mobility, with transport and mobility should take into account social, economic and political-institutional criteria. The plan should be based on a long-term vision for the development of transport and mobility for the entire city agglomeration, both at macro and micro level.

A set of different measures in all urban structural units create conditions for improving the street scene, the natural environment and living environment.

One of the applied measures found a foothold in the modal split as one of the most important factors and parameters of the quality of community life and urban sustainability. The chance is reflected in the application of international experience and the rate of custom attributes and characteristics of the local community.

2. Environment

Pozarevac is a city with about 70,000 residents. Transportation network of the city burden for our conditions a large number of vehicles (a high degree of motorization in the city and municipality of about 1: 5). It stipulates that during the day citywide found in the dynamic and stationary traffic around 9,000 domicile vehicles, with about 7,000 base state roads I and II, and about 4,000 of the catchment area (municipality - city). This points to the city during the day there are around 20,000 vehicles, the stationary, as in the dynamic state. Almost 50% of these vehicles burdens of the city center.

3. Research – basic trip generator

This feature provides a summary of a study trip generation prepared for a major hyper market company by looking at traffic conditions related to shopping and buying.

The study was done during the weekend and city of Pozarevac, and as a research subject was shop - hyper market on the periphery of town. Number of visitors, buyers that use a hyper market as main source of supply and use different

[1] Corresponding author: milosapavlovic@gmail.com

ways of transportation to get to the desired destination. Today, hyper markets represent a significant generator of travel. They contribute to the temporal, spatial distribution and modal split travel.

Fig. 1.
Hypermarket location
Source: (www.google.com/earth)

It is important to note that there is parking in front of the hypermarket. Parking lots, are not marked on the asphalt, but regardless of this, capacity of parking amount are approximately 60 cars.
As mentioned earlier, the study was done during the weekend days. During the study 600 people were interviewed during the both days. During the study it was registered that weekend days have peak hours between 11-14 am and 15-19 pm. Sample has been taken from both, from 150 morning and 150 afternoon from peak hours, so it could be analyzed distribution timeline.
selection of the modal split, way of transportation has important role in every day life of average person.
Analyze of data collected from parking, shown us that unique average time spent on parking lot amount 1 hour and 12 minutes. Following an examining the arrivals of people at hyper market, it was found that 98.2% of people arrive by a passenger car, 0.4% came by bus and a 0.3% by taxi, and 1.1% by some other mode of transportation (bicycle, walking, etc.).
One of the main questions in the survey was about frequency of visiting a hyper market, where 88.6% of the respondents said that they go to hyper weekend market at 7.2% said that they go to hyper market at weekend and work day and 4.2% said that they only work at the moment.
62.8% of the respondents said that go to the weekly supply shopping at the hyper market (every week - 4 times at month), 23.9% two or three times during the month, 12.1% in one month time, 1.2% - have answered other frequency departures.
Cities to develop their transport networks, thus modal split as inseparable components of expressed needs and demands of a quality living environment, habitat, often cultural and historical heritage - heritage is one of the main causes of the problem. Like most cities around the world, so the city of Pozarevac outlines of its network was in earlier periods, which to this day remain unchanged. City as a unit of the demographic characteristics of the one nation, certainly shares the fate of their country. General known historical events during the previous period and the current economic situation. Development and technological progress is hampered by the disabled during the previous decades. Purchase and finance of the company is at a low level, leaving the consequences and the degree of motorization also reflecting on the functioning of all the city's structural whole, including the modal split.
Average travel distance that exceed customers is 4.1km while average travel time 19.2min amount.
Consumer basket has a crucial role in the life of the average man. This applies particularly to the developing countries. The survey also included a questions about average amount of purchases that take place in the market. They are divided into categories according to the amount of money:

1. Less than 5000 dinars,
2. From 5000-10000 dinars,
3. From 10000-25000 dinars,
4. Over 25000 dinars.

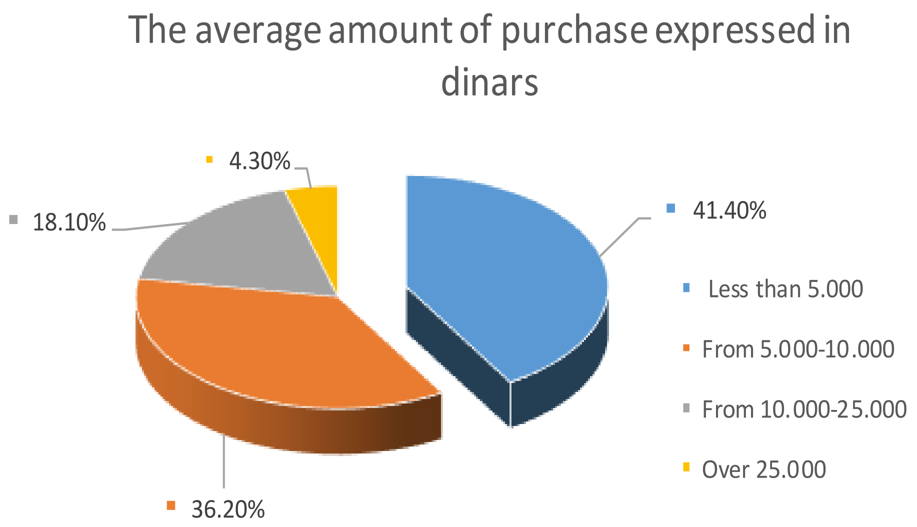

Fig. 2.
The average amount of purchase - dinars
Source: (Author)

Average purchases during the investigation amounted to 12,369.00 dinars. If we consider distribution, 4.3% of consumers belonging to the group of four, 18.1% belongs to a group of three. Only 36.2% of consumers can afford sums of category 2, while the largest part belongs to group one. These results speak volumes about the purchasing power of the population. Why is such a synthesis is made? Just to highlight the weak purchasing power and determine the appropriate measures that would create a different distribution, and as a result we have a different modal split. It should not be forgotten that the arrival of the passenger car market entails fuel consumption, as well.
Also, research included weight of the goods purchased, where customers were asked to measure the weight of their goods on a digital scale. Similarly as in the previous case, the results were divided into categories:
CTM theory, first two types of traffic flow transmission between cells can be used in lane blockage analysis. These two types can be classified as given below (Gomes and Horowitz, 2006; Gomes et al., 2008; Dong et al., 2012):

- Less than 3 kg,
- From 3 - 5 kg,
- 5 - 10 kg,
- Over 10 kg.

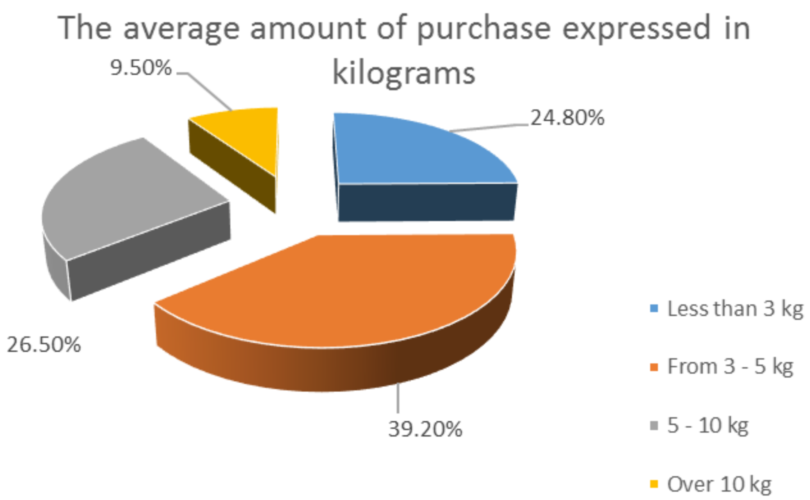

Fig. 3.
The average amount of purchase - kilograms
Source: (Author)

Most individual purchases had a weight of 3 - 5 kg (39.2%), followed by (26.5%) of 5 - 10 kg. The weight of the goods purchased less than 3 kg 24.8%, while over 10 kg bought only 9.5% of customers. By analyzing this data the information is that more than 60% of customers can switch to a different mode of transportation, and points to the fact that passenger car is not necessary.

4. Policy and measures for motivating modal split

Significant contribution to changing preset picture off modal split distribution and spatial distribution can also be made from many different views. Target group of citizens could be always detected, the largest individuals in today's society - the average citizen who lives on the edge of existence. Quality designed strategies and programs could modify the everyday life of residents of the city, thereby influencing the behavior and habits of people. What we can definitely feel in everyday life is that it is necessary to make a remarkable number of decisions. Decisions taken at a given moment are caused by a number of factors, in order to make the best one. Economy, finance and money today play an important role in the life of man, often existential. Accordingly man during life is often driven by economic motives administration. Often giving a discount, as well as the introduction of fees for certain things can significantly affect the outcome of making decisions and exercising other choices in all aspects of life of one individual. In the same way, can influence the purchasing decision in a particular place, the amount of purchase, mode of arrival and departure, and the initial and final point of the trip. Measures to be taken in order to achieve the desired result may not always be a criminal-related. Increasingly, his execution around the world are experiencing a variety of programs aimed at encouragement and motivation of certain forms of behavior, through subsidies, rebates and other allowances. Why? The answer lies in the opportunity to position themselves well on the available market male incentives can provide greater benefits - both sides, but the implementation of penal policy. An example given is an experiment that was conducted during this study. Specifically, during the survey, respondents were asked questions related to potential policy benefits that supermarket could implement in the future, or the questions that refer to the close link grant discounts in relation to the choice of means of transport which carried purpose of the trip - shopping. Thus, the program would address the following: a discount on the purchase amount would be given to all who come by bike to super market, or those who choose to instead passenger car, do the shopping by bicycle. The results show the following:
For discount of 5% on the amount of the purchase price, 19.4% of which amount would agree to change the mode of transport, and it would have happened by bicycle. Discount of 5-10% results in a group of 33.7% which makes subjects who came by bicycle. 15% discount to attract 42.1% of what is already. This percentage represents a significant number of people who are ready to change habits, motivated by financial objectives. Discount of 15% generally speaking not from excessive savings. However, this is an indication of the difficult economic and social situation of society. The result obtained is not a surprise when it comes to developing countries, especially the smaller communities within the same, where the amount is less consumer basket. Otherwise, the implementation of such a program would be implemented through the registration and obtaining the numbers in the parking lot for bicycles, with the help of which they can at the ticket offices exercise the right to a discount. We should not forget that in addition to savings in the purchase of the achievement of the right to a discount, additional savings would be achieved in fuel consumption, given the choice of a new means of transport.

5. Hidden Benefits

5.1. Parking space

Compared to cars, cyclists need a little room to move, maneuvering and parking. Busy area viewed through stationary traffic leads to permanent seizure and usurpation of available space, which can be measured and compared. Average parking place for cars, can be replaced with a 7-9 cycling city. Construction of standard parking spaces for cars costing between 4,000 - 8,000 €, and the construction of covered places, or in the underground garage will cost about 16,000 €. Compared with these facts, the construction of a standard parking surface on which can accommodate 8-10 bikes cost about 1,000 € (von Harten and Sorof, 2012).

5.2. Health benefits

The benefits can be quantified and in terms of human health. Regular physical activity contributes to health and improving the quality of life of all people. The World Health Organization recommends at least 150 minutes of cardiovascular exercise during the day, such as. walking or riding a bike, in addition to strength training. According to the same alleged use of bicycles as a mode of transport, can be compared with the daily intense training of 150 minutes during the entire week (Cavill and Kahlmeier, 2008). The benefits in the cardiovascular system are achieved with a 10-minute drive away. The benefits that are associated with the use of bicycles include personal (personal) is used, then uses the community as well as social benefits. Consequences of physical activity are manifested through:

- Reducing the risk of cardiovascular disease and diabetes,
- Reduces the risk of many types of cancer,
- Reduces the number of affected by asthma,
- Control and reduction of body weight,
- Improves mood and mental health,
- Reduces the cost of health care,
- Reduces the risk of stroke and premature death.

Over the last decade, there is major recognition of the impact of the election mode of transport on health. Many of these impacts are directly related to public health expenditures; as well as the loss of productivity in the course of the disease and the inability to operate. If the health of the population can be improved through increasing non-motorized modes of transport, personal, private and public - state costs can be reduced. The study, which investigated 2,400 adults showed that those who used the bicycle as a means of transport to work were leaner, were in a better mood, they had better triglyceride levels, blood pressure and insulin levels, as opposed to those who have used "passive "carriage, respectively for transport by car.
Also, another interesting benefit of using a bicycle that appeared in recent years is that with growing popularity and increasing security. The study of accidents at an intersection, or crash of 2004, considering the account of traffic accidents involving cyclists, shows that the greater the number of cyclists who appears on an individual junction, the risk of an accident, or impact by a motor vehicle, is often lower at intersections where cyclists higher, even if such intersections recorded a higher number of accidents or collisions.

5.3. Environmental Benefits

Cycling does not use fossil fuels and is a means of transport that absolutely does not pollute the environment. Bicycles lessen the need for production, service, maintenance, and finally removing the cars.
The daily ride from 10 km saves about 1500 kg pollutant emissions of greenhouse gases annually. This applies particularly to weather losses and delays in traffic flows, where the vehicle during standstill in major European cities emit 10-13 million tons of harmful emissions annually. Increased bicycle use, especially during peak hours, will contribute to further reduction of emissions and pollutants, as well as improving traffic flow.

6. Conclusion

Recent socio-economic and cultural trends show a high level of requests for communities adapted to pedestrians and cyclists. However, a large number of towns in the absence of adequate infrastructure for safe walking and cycling. Creating a friendly community to non-motorized traffic starts building environments: connecting destinations close to each other, such as schools, parks, adequate public facilities, etc. while allowing the possibility of joint use space and land use, then the construction of buildings intended for transit, commercial implementation districts where access is enabled and adapted to cyclists, pedestrians and people with disabilities.
The compound of the planned land use and transport - traffic planning is crucial for the safe and efficient adjustment of different travel modes of transport, such as cycling and walking. Studies have shown that the infrastructure and facilities such as separate bike paths, priority at intersections, sidewalks and benches closely linked to security and active travel. Through the design and redesign and reconstruction of the environment and the environment, in order to make walking and cycling more pleasant, planners and engineers can help assist people of all ages to get the exercise they need to live longer and healthier lives. Construction of a new road could cost tens of millions of euros, as opposed to the many walking and cycling infrastructure projects, which have extremely low investment cost. Although the case of the city shows that the majority of indirect benefit is not quantifiable primarily due to lack of appropriate data bases, however, are noticeable signs of the first moves towards change and betterment for cycling flows. Unified Infrastructure guidelines in this document are aimed at encouraging and improving construction environment adapted primarily to non-motorized traffic flows - cyclists and pedestrians.

COMBINED EXPERT, STAKEHOLDER AND CITIZEN INVOLVEMENT FOR PRIORITY SETTING OF CYCLING MOBILITY STRATEGIES USING ANALYTIC HIERARCHY PROCESS

Michela Le Pira[1], Giuseppe Inturri[2], Matteo Ignaccolo[3]

[1] *University of Roma Tre, Roma, Italy*
[2,3] *University of Catania, Catania, Italy*

Abstract: Transport planning is not a simple task, in particular at the urban scale, because it implies decisions that (1) affect stakeholders with conflicting interests and (2) needs to be evaluated considering different criteria. Involving stakeholders and citizens in the decision-making process is a necessary condition for reaching consensus, while guarantying transparency and pursuing sustainability. The use of sound Multi-Criteria Decision-Making (MCDM) methods can support the decision-making process characterized by multiple criteria and multiple points of view. This paper presents an approach based on the MCDM method called Analytic Hierarchy Process (AHP) to support a public participated planning process where experts, stakeholders and citizens were involved in setting the priorities for cycling mobility in an urban context. AHP hierarchy was built by a panel of experts and stakeholders engaged in an evaluation process where their opinions' convergence was facilitated by the Delphi method. A simplified online questionnaire based on the AHP hierarchy was used to involve the general public by eliciting their preferences. The ranking of alternatives derived from citizens was significantly different from the one derived from the panel, showing that they have diverse views about the priorities for cycling mobility. A small test sample represented by students was also asked to answer to both questionnaires (AHP and simplified) to investigate the robustness of their judgments and see if there are any differences in the results obtained. The collective ranking obtained with the simplified questionnaire is more in line with individual preferences, suggesting that a simpler, easier to understand questionnaire is to be preferred when a non-expert audience is involved. In conclusion, a tailored approach is needed to elicit experts, stakeholders and citizens' preferences, while using solid decision-support methods. The proposed AHP-based approach proves to be a useful tool for decision-makers and planners to support them when dealing with public decisions affecting multiple stakeholders and to guide them in planning effective participation process.

Keywords: participatory transport planning, multi-criteria decision-making methods, consensus building.

1. Introduction

Transport systems are regarded as complex systems that include multiple agents making decision and where some characteristics emerge from the aggregation of individual behaviors (Ettema, 2015).
In this context, transport planning is not a simple task, in particular at the urban scale, because it involves decisions that affect multiple actors with conflicting interests, such as the users of the transport systems, the citizens, the transport operators, and all those who have an interest or hold a stake in that particular decision: the so called "stakeholders". If they are not properly involved since the early stages of the decision-making process, this can cause protests and even the plan failures, wasting money and time.
Nowadays it is widely recognized the importance of involving citizens and stakeholders in a participatory planning process with different levels of growing involvement (Wefering et al., 2014; Cascetta et al., 2015). The participatory approach helps to have better decisions supported by the public and to increase the transparency of the whole process, but still we are far from a comprehensive knowledge of effective participation techniques and procedures and from a satisfactory inclusion of them in the transport planning process as well.
Identifying all the relevant stakeholders and decision context plays a fundamental role in understanding who to involve, therefore a good knowledge of it is required.
Stakeholders can be represented in a pyramid according to the level of competence and public interest: the "experts" (key informants), with high competence but low stake, the "stakeholders" in strict sense (e.g. institutions, groups, environmental associations, transport companies), with competence and high stake, and the "citizens", with low competence but that act in the public interest (Le Pira et al., 2016a). The decision-maker(s) is bounded with them and should take into consideration all the different points of view.
Many guidelines describing techniques for stakeholder involvement are available in literature (e.g. Wilcox, 1994; Rowe and Frewer, 2000; Kelly et al., 2004). They can be based on vis-à-vis meetings, interviews, focus groups, but there also online engagement tools (Rucker et al., 2014).
Among the variety of available methods, those that focus on the convergence of opinions among stakeholders through interaction and communication (e.g. consensus conferences, deliberative polls), even if "anonymous" and "asynchronous" as in the Delphi method (Dalkey and Helmer, 1963), deserve a particular attention. In fact, it has been demonstrated through a variety of qualitative and quantitative methods that interaction and deliberation can change stakeholders' mind about public policy problems (Quick et al., 2015). Besides, there is also a learning effect due to interaction and participation, since participants have increased their knowledge and understanding of problems at the end of the process (Franceschini and Marletto, 2015).

[1] Corresponding author: michela.lepira@uniroma3.it

Whatever the approach used, participation experiences should be supported by the results of models and simulations that can help to plan and design them. In this respect, agent-based models can be used to reproduce the opinion dynamics on stakeholders' networks considering different type of interactions and relationship among them (Le Pira et al., 2015; 2016a).
Besides, complex decision-making in transport planning, when multiple criteria and multiple stakeholders are involved, can benefit from the use of adequate decision-support methods and procedures, such as Multi-Criteria Decision-Making (MCDM) methods. Analytic Hierarchy Process (AHP) by Saaty (1980) is a well consolidated technique to structure a multi-criteria decision-making process into a tree decision including a general goal, a set of specific objectives, evaluation criteria (and possible sub-criteria) and to finally select the best alternatives to achieve the general goal. Though AHP is generally used to elicit the choice of a single decision-maker, it can be extended to group decision-making.
Based on this premise, in this paper we propose an AHP-based procedure to support experts, stakeholders and citizens' involvement in setting the priorities for cycling mobility in an urban context. AHP hierarchy was built with the help of a panel of experts and stakeholders, that were then involved in the evaluation process trying to make their opinions converge using the Delphi method. A simplified online questionnaire based on the AHP hierarchy was used to involve citizens by eliciting their preferences.
The aim is to propose a custom-made procedure that can be used to involve different categories of stakeholders with different interests and competences.
The remainder of the paper is organized as follows. Section 2 illustrates the materials and methods used to structure the participatory decision-making process; section 3 shows the case study with the involvement of experts, citizens and stakeholders, while section 4 presents and discusses the results of the procedure; section 5 concludes by summarizing the main findings of the paper.

2. Materials and methods

The proposed procedure makes use of different methods and tools in order to be suitable to support expert, citizen and stakeholder involvement in the decision-making process. In particular:

- AHP is here presented to (i) structure the problem into a hierarchy, (ii) elicit stakeholders' preferences and (iii) aggregate them in a collective ranking,
- The Delphi method allows to build consensus among the experts,
- A public meeting is used for information giving and interest gathering,
- An online survey based on AHP hierarchy is made to elicit citizens' preferences.

In the following, AHP and the Delphi method will be explained more in details, while the phases of public meeting and online survey will be illustrated in section 3 with reference to the case study.

2.1. Analytic Hierarchy Process (AHP) for problem structuring

AHP was developed by Thomas Saaty (1980) and it is a process based on pairwise comparisons through the building of matrixes to derive priority scales and weights.
The use of AHP in transport planning is based on the decomposition of a decision-making problem into a tree structured decisions' hierarchy that contains: the general goal of the plan, a set of specific objectives represented by evaluation criteria (and possible sub-criteria) and finally the decision alternatives aimed at achieving the general goal. In general, the problem structure derives from brainstorming sessions with experts or from the analysis or similar problems. A set of pairwise comparison matrices is built by comparing couples of elements at the same level, with respect to the elements of the upper level. The pairwise comparison is made expressing a judgment on a qualitative scale that is turned into a quantitative one (Saaty, 1980). At each level of the problem structure the pairwise matrices can be transformed into a set of local priority vectors using different methods (Saaty and Hu, 1998), e.g. the approximate method, the eigenvalue method, the geometric mean method (Ishizaka and Nemery, 2013). Finally, a ranking of alternatives is obtained by combining all the levels into a global priority vector.
It is known that pairwise comparisons can lead to some inconsistency, meaning that individual judgments can be affected by lack of rationality and violate the consistency condition of the matrix. The inconsistency can be measured (and, therefore, monitored) through the comparison between a Consistency Index derived by the matrix elements with the one obtained by purely random judgments (Saaty, 1980). In general, an inconsistency less than 10% is accepted.
AHP is widely used in transport planning and management (Piantanakulchai and Saengkhao, 2003; Sivilevičius and Maskeliūnaite, 2010; Mahmoud and Hine, 2013; De Luca, 2014). When AHP is used to elicit single decision-maker opinions, the only condition to respect is judgments' consistency; when its use is extended to group decision-making an appropriate procedure to aggregate the individual judgments has to be defined (Dong et al., 2010).
In general, there are four ways to combine multiple preferences into a consensus rating (Ishizaka and Nemery, 2013), according to the level of aggregation (from judgments or from priorities) and the type of aggregation (mathematical or based on consensus vote). The consensus vote can be used when "synergistic" groups are able to agree on the values of the matrices or on the priority vectors. In general, if a consensus cannot be reached, a mathematical aggregation can be

adopted. The problem of aggregation is that the final result consists of an “averaged” ranking that could represent none of the individual points of view.
While mathematical aggregation implies transparency of the calculation and clarity of results but it might not reflect the individual preferences, a consensus vote is a more democratic and fair way to find a group ranking that could have a low rate of acceptance, being supported only by a relative majority.
According to the authors, the optimal solution should be based on a mixed procedure that combines mathematical aggregations with consensus building, through an interaction process among stakeholders that allows a convergence of opinions to increase the acceptability of the final results while at the same time guaranteeing transparency of the decision process (Table 1).

Table 1
Group aggregation procedures.

Type of aggregation	Transparency and reproducibility	Fairness of the process	Probability of acceptance
Mathematical aggregation	✓		low
Consensus vote		✓	low
Consensus building process with the help of mathematical aggregation	✓	✓	high

Source: based on Le Pira (2015)

2.2. Delphi method for consensus building

The Delphi method (Dalkey and Helmer, 1963) is an iterative practice which relies on an anonymous/asynchronous interaction among the participants of a panel performed in different rounds to achieve a convergence of opinions. It has been usually used to elicit experts’ opinions about future trends, but it can be also used as a tool to support consensus building in a group of stakeholders.
A questionnaire is proposed to the members of the panel and at each round of anonymous interaction they are asked to align their opinions within a range where 50% of the opinions stands (between the first and the third quartiles). The iterations are aimed at mitigating radical positions and finding a collective decision which is shared from the panel. The method has been primarily used to elicit experts’ opinions about the future, with the aim to find “real” values, but it can also be used to explore the conditions of consensus building in a group.
Being a practice for the convergence of opinions, it can be combined with other methods aimed at eliciting individual preferences. An interesting approach is the one that combines Delphi practices with multi-criteria decision-making methods, such as AHP (Tavana et al., 1993; Vidal et al., 2011) or ANP (Analytic Network Process) (García-Melón et al., 2012).
In this study, a Delphi procedure is combined with the AHP method, to elicit preferences of experts and stakeholders about sustainable transport strategies and to see if the anonymous interaction could lead to a convergence of opinions. In this respect, there are multiple ways to measure consensus derived from Delphi, some based on qualitative analysis and others on descriptive statistics (von der Gracht, 2012). With AHP, from the judgments in terms of pairwise comparisons, vectors of preferences are derived. In this case, to measure consensus, the overlap between vectors of preferences can be used, being a simple indicator of the similarity between two stakeholders’ opinions (Le Pira et al., 2015). In this study the concept of average overlap will be used to measure the similarity of opinions and to what extent the interaction may affect the degree of achieved consensus towards the final decision.

3. Case study

3.1. Cycling mobility in Catania

In the last years cycling mobility has been receiving more attention from policy-makers as a sustainable and efficient mode of transport in urban areas. Many cities are adapting to introduce facilities and infrastructures for cyclists, but still lots have to be done, in particular in car-addicted cities. The case study refers to a participation experiment with experts, stakeholders and citizens involved in several phases to study strategies to promote cycling mobility in Catania, a medium-sized city (300,000 inhabitants) located in the eastern part of Sicily, Italy. Critical issues related to transport in Catania include road traffic congestion, low public transit ridership, little diffusion of cycling and walking for systematic trips, and high levels of fuel consumption and greenhouse gas emissions per capita (Ignaccolo et al., 2016).
In the last years, the interest for cycling mobility of individual citizens and different associations has been raising, giving birth to several initiatives and exerting pressure on the public administration to increase cycling facilities and improve the safety conditions of cyclists.
For all these reasons, a participation process was performed involving experts, stakeholders and citizens in order to understand the priority of cycling mobility strategies in Catania, paving the way for a more engaging and continuous participation in the transport policy-making process.

3.2. Combined expert, stakeholder and citizen involvement for priority setting of cycling mobility strategies

The whole participatory process is summarized in **Error! Reference source not found.**.

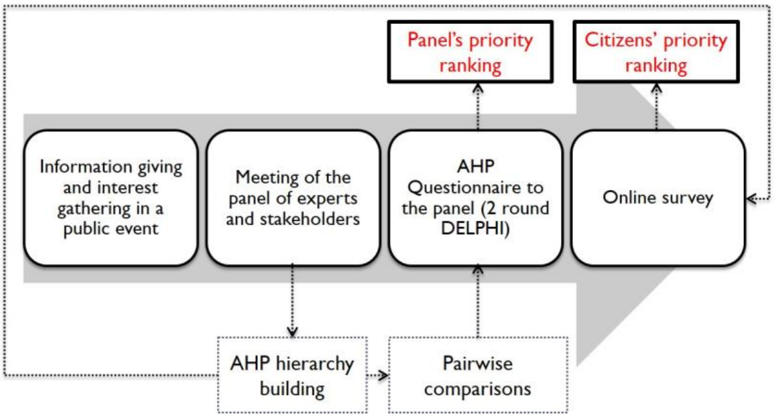

Fig. 1.
Different phases of the participatory process
Source: own setup

The initiative was presented to citizens in a public meeting within the "Catania Bike Festival" (May 2015). Information was given to the audience and interest was gathered by collecting names and contacts of people willing to participate at the initiative.
After this first preliminary phase, a given number of transport experts and stakeholders was involved to identify policy measures that can promote cycling mobility in the city of Catania. The panel of experts and stakeholders met in a brainstorming session (July 2015) to analyze the problem, structuring it into a four-levels hierarchy (Fig. 2). They agreed that four different criteria were necessary to evaluate the alternative measures, i.e. the criteria representing the three dimensions of sustainability (environmental, social and economic) and a transport criterion. Seven indicators were chosen to represent the four criteria and then the alternative measures to promote cycling mobility were identified from the panel:

1. Building a comprehensive cycling network,
2. Setting up extended 30 km/h zones,
3. Making information and education campaigns, to increase public awareness towards pros of cycling mobility,
4. Funding citizens to buy electric bicycles,
5. Establishing a city bike sharing service.

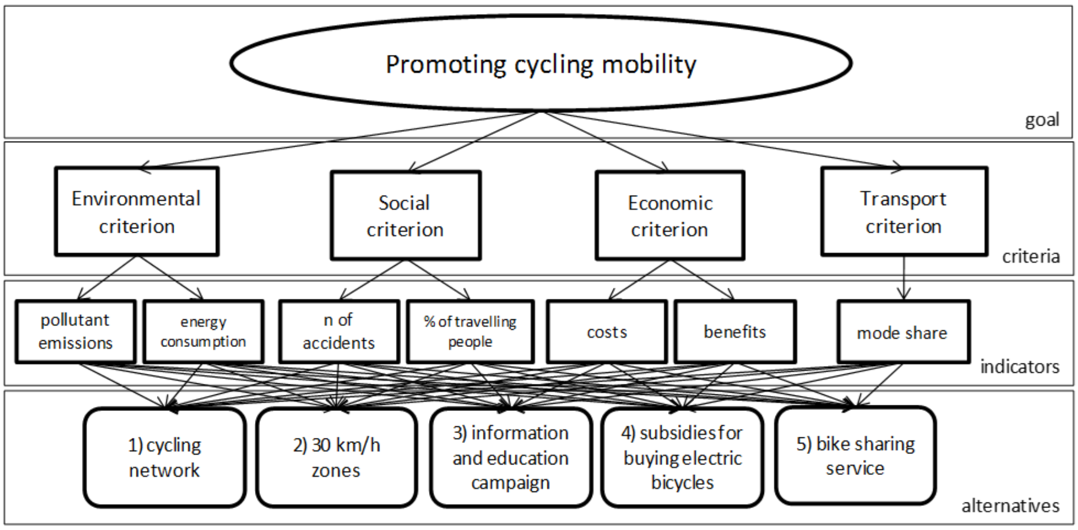

Fig. 2.
Hierarchy of the problem "promoting cycling mobility"
Source: Le Pira et al. (2016b)

After structuring the decision-making problem into a hierarchy, each member of the panel was asked to make judgments in terms of pairwise comparisons between the elements of each level of the hierarchy. Due to the great number of answers they had to give (a total of 79 pairwise comparisons), the facilitator guided them into the whole process paying attention to the consistency of their judgments.

The results derived from AHP were analyzed in order to go on with the first iteration of the Delphi method. In particular, for each pairwise matrix, the local priority vectors were derived, the first quartile (corresponding to the 25% of judgments) and the third quartile (corresponding to the 75% of judgments) were chosen as reference numbers for the members of the panel to “align” their judgments in the second iteration.
By doing this, the results could be expressed in terms of priority vectors for each level of the hierarchy. By aggregating them, the new priority vector for the group was derived, representing the alternative ranking of the panel of experts and stakeholders involved. The whole procedure with the results is described more in details in Le Pira et al. (2016b).
Based on the AHP hierarchy, a simplified questionnaire was structured in order to elicit citizens’ judgments through an only survey (January 2016). In particular, they were asked to rank the four different criteria (environmental, social, economic and transport) with respect to the goal of promoting cycling mobility; then, each alternative was evaluated with respect to the four criteria by stating their relative contribution in achieving the goal (very low, low, average, high, very high). The elements were not compared in pairwise comparisons because of the great number of answers required (as already said, 79 pairwise comparisons).

4. Results and discussion

Results, in terms of collective rankings of alternatives, were obtained in two different ways, according to the questionnaire:

- In the AHP questionnaire the row geometric mean method (RGMM) was used as prioritization procedure and the Aggregation of Individual Priorities (AIP) was used to aggregate the individual rankings (Dong et al., 2010),
- In the simplified online questionnaire, the individual rankings were obtained by transforming the qualitative judgments in quantitative measures (e.g. “very low” corresponds to 1, while “very high” is 5), while the aggregation of individual preferences was done using the Borda rule[2] (Borda, 1781).

The results of the questionnaires in terms of collective rankings (per involved category) and related overlap values are presented in Table 2. It is worthy of notice that the overlap is a measure of the similarity between the individual ranking and the collective one derived from aggregation. Being a simple measure based on the scalar product between vectors of preferences, it assumes a finite value, comprised between -1 (totally different rankings) to +1 (exactly equal). For more details, see Le Pira et al., (2015, 2016b). The first collective ranking resulting from the panel of experts and stakeholders shows very high values of overlap (0.74 compared with the maximum reachable value of 1). This is due to the fact that the actors involved showed more or less the same level of competence and objectives, even if there are some differences in the individual rankings. After the second round of the Delphi method, there is an increase in the convergence of opinions and this confirms the effectiveness of interaction for the consensus building process.
The ranking of alternatives derived from citizens is significantly different from the one derived from the panel of experts and stakeholders, showing that they have diverse views about the priorities for cycling mobility. In particular, while the panel agreed that setting up extended 30 km/h zones is the priority to increase the share of cycling mobility, the priority for citizens is to build a comprehensive cycling network followed by the establishment of a bike sharing service (which is one of the lowest priority interventions according to the panel). The difference in the results is also due to a different level of competence and understanding of the problem: while the members of the panel analyzed the problems together and discussed the different alternatives before expressing their preferences, citizens were only involved via an online questionnaire with a short description of each alternative. In this respect, it can be argued that the involvement of experts and stakeholders was much deeper than the citizens one, i.e. the former participated in the decision-making process, while the latter were only consulted. Besides, citizens overlap is much lower than the panel’s one (0.25 versus 0.80). This is because (a) a higher number of citizens with (b) heterogeneous interests were interviewed and (c) without interacting between each other.
A small sample of University students (13) was also interviewed to test the suitability/adaptability of the two questionnaires. Even though they were involved in Transport Studies they did not analyze the problem before giving their judgments, so their level of interest in the decision (as citizens) can be considered higher than their competence. They were asked to answer to both of the questionnaires (AHP and simplified) and the difference in their judgments was tested. The collective ranking obtained with the simplified questionnaire is more in line with individual preferences, suggesting that a simpler, easier to understand questionnaire is to be preferred when a non-expert/non-informed audience is involved.

[2] With the “Borda Rule” the collective ranking is obtained on the basis of the sum of different scores assigned to each alternative in order to reflect the individual preferences’ ranking (e.g., if there are three alternatives A, B and C and the individual ranking is A>B>C, then A=3, B=2 and C=1).

Table 2
Results.

Stakeholders involved	Number	Online survey	AHP questionnaire	
			I round	II round (Delphi)
Citizens	82	1>5>4>3>2 (overlap 0.25)	-	-
Students (test)	13	1>5>4>2>3 (overlap 0.48)	1>2>5>4>3 (overlap 0.38)	-
Delphi Panel (Experts & stakeholders)	7	-	2>1>3>5>4 (overlap 0.74)	2>1>3>5>4 (overlap 0.80)

Source: own setup

5. Conclusions

A tailored approach is needed to elicit expert, stakeholder and citizen preferences, while using solid decision-support methods. MCDM methods, such as AHP are useful to (1) structure the problem (from the goal(s), to the criteria, indicators and alternatives), together with the experts (and stakeholders), (2) elicit their preferences, e.g. in terms of importance weights about the elements that compose the problem and (3) derive group priority rankings that can aid the decision-making process. Besides, a combination of MCDM with participation methods (i.e. Delphi-AHP method), proved to be suitable to support complex group decision-making processes. In this respect, the cooperation of the panel of experts in structuring the problem and sharing criteria, relevant indicators and alternative measures increased the probability to have a good convergence of opinions after only one step of anonymous interaction. A simplified online questionnaire based on the AHP hierarchy was used to consult citizens by eliciting their preferences. The priority ranking derived from citizens is significantly different from the one derived from the panel, showing that they have diverse views about the priorities for cycling mobility in the city of Catania.
In conclusion, this paper illustrated the first test of a procedure that, in principle, can support a more diffuse involvement of stakeholders in transport decision-making process, considering the heterogeneity of their interests and competences.

A NEW STRATEGY FOR THE DESIGN OF BICYCLE PATHWAYS NETWORKS

Marco Petrelli[1]
[1] *University of Roma Tre, Roma, Italy*

Abstract: In the last years there was an increase of interest of decision makers about bicycle use as alternative travel mode to the predominant auto mode. Starting from these considerations, the objective of the research is the development of a procedure for the definition of bicycle facilities in terms of bicycle pathways. The goal is the increase of the attractiveness of cycling developing a safe and of quality bicycle network for cities characterized by cities with poor level of facilities for bicycle and a very low current bicycle share of trips. A preliminary phase of identification of the bicycle users' needs has been carried out by means of a specific experimentations of 18 months, based on the creation of the travel diary of 30 bicycle users from the city of Rome. Such data are related to the comparison between shortest and observed paths, the use of existing bicycle infrastructures, the characteristics of the links of the road network shared with cars. The design methodology is based on the hypothesis that bicycles are obliged to travel sharing the road sections with other components, using dedicated pathways only for a part of the travel. Such approach permits also to explicitly take into account the significant budget constraints of local administrations.

Keywords: sharing roads, bicycle facilities, road safety, bicycle users behaviour.

1. Introduction

In the last years, the interest of decision makers about bicycle use as alternative travel mode to the prevailing auto mode is more and more increasing. The changes of the urban patterns with a continuous spread of residences and activities, an increasing complexities of the travel behaviour of the people have produced in many urban areas unsustainable urban mobility practices. Negative impacts on sustainability and traffic congestions require new and different policies to promote the use of alternative modes as public transport and cycling.
Based on such issues, this paper presents a new strategy for the definition of the network of bicycle pathways. The objective of the procedure is to build a safe and of quality bicycle network in which traveling from any origin to any destination should be convenient and quick involving a safe and pleasant experience. The proposal for the bicycle network construction is related only to bicycle users with utilitarian purposes (commuters) and should be associated to cities with poor level of facilities for bicycle and a very low current bicycle share of trips. Cities with these characteristics have to be considered a specific case in which the development of cycling infrastructures, following existing standards, should be impossible or ineffective due to the limited number of cyclists. In fact, bicycle lanes come at the expense of restricting the motorists to less space, which may lead to a much worse traffic circulation and hence more severe congestion. This sincere fear has precluded the introduction of bicycle lane in many cities (Alliance for Biking & Walking, 2014). These challenges are really important in congested urban networks. In uncongested urban networks, bicycle lanes cause no congestion and are relatively unproblematic. Instead in congested urban networks, bicycle lanes are more contentious, involving debates about the use of a portion of the road space reserved for cyclists (Bagloee et al., 2016).
The procedure developed is based on the identification of the critical issues and the best planning approach to adopt in these specific cities for designing the bicycle network. In particular, such information are derived from an analysis of literature review, data about bicycle users' needs and safety issues identified for the city of Rome. Taking into account the specific characteristics about mobility (few cyclists and congestion on the road network), this urban area can be considered a valid case of study representative of conditions of many cities all around the world.
The structure of this paper is based on the following different steps: firstly, the state of the art about the development of infrastructures for bicycles and policies to promote cycling is shown. The third section deals with the analysis of these challenges in the specific case of the city of Rome. Finally, the new proposal is illustrated identifying the possible evolution of the bicycle network inside urban areas.

2. Literature review

In literature, especially in the last decade, it is possible to find many contributions about effective measures on promoting bicycling. Many of these contributions highlighted the importance of the presence of infrastructures for cyclists. Nelson and Allen (1997) found a positive association between miles of bicycle pathways per 100,000 residents and the percentage of commuters using bicycle. This result derives from the cross-sectional analysis of 18 US cities data. The successive analysis performed by Dill and Carr (2003) with data from 43 large cities across the US, confirms that higher levels of bicycle infrastructures are positively and significantly correlated with higher rates of bicycle commuting. Pucher et al. (2011) found that cycling rates have risen much faster in the cities that have implemented a wide range of infrastructure and programs to promote cycling and increase cycling safety: expanded and improved bike lanes and paths, traffic calming, parking, bike-transit integration, bike sharing, training programs, and promotional events. Sanders (2016) presents results from an internet survey about perceived comfort while driving and bicycling on

[1] Corresponding author: marco.petrelli@uniroma3.it

various roadways. The roadways with barrier separated bicycle lanes were the most popular among all groups, regardless of bicycling frequency. According to the Collection of Cycle Concepts (Andersen et al., 2012) from Denmark, the combination of hard and soft measures is crucial to bring about a significant change in citizens' transport habits and road safety behaviour. Such considerations are also validated from Vandenbulcke et al. (2011) with an extensive analysis of cycle commuting in Belgium. These found that only a combination of several measures (promotional campaigns, improvement of cycling facilities, etc.) will really lead to an increase in cycle commuting. Munoz et al. (2016) study for understanding the key factors influencing bicycle commuting in an environment characterized as in transition to become a cyclable city. The authors suggest prioritising marketing campaigns and other infrastructure investments (cycleways and bicycle parks) around leisure zones and social and cultural centers to maximise the significant influence of friends on bicycle commuter behaviour. According to these analysis, it is possible to underline that not only facilities but especially active, complementary pro-bicycle policies should be essential to promote the use of the bicycle.

About the experience of European bicycle use, the European Commission report (1999) about cycling indicates that the really incompatible situation for the bicycle's use are few. The presence of strong slopes (6-8% for tens of meters) and some climatic elements as the snow, a thunderstorm or a very hot and sultry day seem to be the only factors that have a dissuasive impact for the use of the bicycle. In many cases, especially where the bicycle use is modest, the main obstacles to boosting the bicycle as a regular mode of transport are safety concerns due to interactions with motorized traffic (Buehler and Dill, 2015; Habib et al., 2014; Menghini et al., 2010). Several studies have shown that it is really emerging the evidence about "safety in numbers". Taking into account data from Amsterdam and Copenhagen, cycling is generally very safe in both cities (Bicycle account, 2012). From 2007-2012, there has been on average five fatalities among cyclists in Amsterdam and three in Copenhagen, which corresponds to the difference in the urban population. Also Jacobsen (2003) suggests that cities with higher bicycling rates also have better road safety records. This study attempts to better understand this phenomenon of lower fatality rates in bike-oriented cities by examining 11 years of road safety data (1997–2007) from 24 California cities. Cities with a high bicycling rate among the population generally show a much lower risk of fatal crashes for all road users when compared to the other cities analysed. The fact that this pattern of low fatality risk is consistent for all classes of road users strongly suggests that the crashes in cities with a high bicycling rate are occurring at lower speeds. According to Marshall and Garrick (2011), motorists adjust their behaviour in the presence of people walking and bicycling. Since it is unlikely that the people walking and bicycling become more cautious if their numbers are larger, it indicates that the behaviour of motorists controls the likelihood of collisions with people walking and bicycling. Policies that increase the numbers of people walking and bicycling appear to be an effective way to improving the safety of people walking and bicycling.

3. Bicycle users' needs and safety issues in Rome

The urban area of Rome is characterized by a population of about 2.9 million and 1.1 million of employees, producing about 550,000 trips in the morning peak hour. Taking into account the built environment, the city should be considered as divided in 4 different circular areas, starting from the historical center to the more external one, outside the GRA (a circular freeway of approximately 68 km of length). The average population density is not so high (about 61.5 persons/ha) but there is a very large variation from center to outside areas. Outside the GRA, in a very large area (about 90,000 ha) the density decreases to very low values, about 6 persons/ha, even if the population of this external area is larger than half a million of persons. In terms of employees, about half of the total amount is distributed in the peripheral districts, also situated outside of the GRA.

About the mobility system, Rome has a very high level of vehicle ownerships (more than 850 for 1,000 persons). The modal share of private vehicles (auto+motorcycle) is more than 65%, the public transport share is estimated to be around 30% while the bicycle share is only 0.6%. Depending on these habits, the road network is frequently characterized by congested conditions. Large part of the historical centre of the city, one of the main point of concentration of activities, is a traffic limited zone (ZTL) and the access in the area is permitted only to the residents' cars. In many districts of the city, there is a relevant lack of space for parking; this trouble is partially offset by the extensive use of motorcycles.

The network of bicycle pathways is currently extended for 125 km (see Fig. 1), with very limited length especially if compared with the extension of the road network (7,530 km). Such situation is also exacerbated by the specific development of the bicycle lanes, generally located in green areas or along the Tiber river with very few sections in the built areas. This lack is due to many, complementary aspects as the presence of not so wide road sections, the high level of congestion in the car network, the widespread use of the road network for the cars parking and the poor level of sidewalks largely used by pedestrians.

A preliminary phase of identification of the bicycle users' behaviour and needs has been carried out by means of a specific experimentations of 18 months of 30 bicycle users from the city of Rome. The users, selected among the students and the employees of the Roma Tre university, have been involved with the creation of their own travel diary. The resulting set of users selected is well representing the commuters actually using the bicycle in the city with a very large prevalence of young males. The analysis of the travel diaries, carried out by the users, have permitted to identify the paths used and the trips characteristics. In 18 months, the 30 bicycle users have travelled for about 29,000 km with an average trip length of 6.01 km. Taking into account each specific trip recorded, on average the chosen paths are 15.4% longer than the shortest paths, involving the use of the bicycle pathways only for 3.3% of the length while the use of multilane roads is 59.2%. Such data permits to underline the behaviour of the cyclists that are very sensitive to travel distance, searching, very often, to reduce travel distance also by adopting unsafe behaviour and not respecting the traffic rules. Such data from travel diaries allows also to observe that in the city of Rome, there is a significant lack of specific solutions for cyclists (for instances routes for avoiding physical and infrastructural obstacles, dedicated rules for the one-way streets, etc). This condition is also confirmed by the observation that longer trips correspond to larger differences between chosen and shortest paths, in many cases derived by the increasing number of obstacles to overcome.

About the safety issues in the city of Rome related with cyclists, the information on collisions experienced by the cyclists over the years from 2005 to 2015 have been collected using accidents database from Rome Mobility Agency. Accidents taken into account are defined as event in which a bicycle is involved regardless of fault and eventual interference with any other object. In the last years, data show that about 300 accidents occurred during a year with 5 bicyclists killed in crashes with motor vehicles. The analysis of the data at disposal from 2005 to 2015 (see Fig. 1 and Table 1) shows that the accidents, people killed and injured are in slight increase, probably due to the increasing number of cyclists in the city. 73% of accidents occur in daylight and they are for the 89%, collisions between car and bicycle. About the people involved in these collisions, male is the 85% of casualties, representing the very large majority of users, while old people are 13.5% of casualties but represents 40% of fatalities. These data show clearly that bicycle users safety issues in the city of Rome are related to the complex and very hard relationships with motorists, involving dangerous conditions especially for older cyclists. As shown by Rasanen and Summala (1998), two common mechanisms, the allocation of attention and the unjustified expectations about the behaviour of others, can be considered essential to understand car-bicycle accidents. In older people, slower reaction time in combination with the two mechanisms already reported should explain the data on fatalities and the unsafe conditions of travel for older cyclists in the road network of Rome.

Fig. 2 shows information about the location of accidents, disaggregated in accidents without fatalities (points in red) and accidents with fatalities (points in purple). The majority of accidents occurred in the city centre, due to higher numbers of people travelling by bicycle, but fatalities are usually located outside the city centre, especially on the multilane roads. Most of the accidents occurred for the 54% on streets, generally on the main roads, and only 37.5% are located on intersections. Similar data are also valid for fatalities: 68% of these are recorded on streets and only 24% on intersections. Most of the studies showed a totally opposite situation in which the intersections are generally known as black spots for cyclists as well as for all road users (Vandenbulcke et al., 2014; Wang and Nihan, 2004; Quddus, 2008). Such places are characterized by an higher risk of having an accident compared to the rest of the network for the presence of many potential conflict points.

About the safety issues for cyclists in the city of Rome, it is possible to undoubtedly highlight that generally can be considered an unsafe environment with a very high number of accidents and fatalities respect to other cities in North of Europe with a totally different number of commuters by bicycle. This is mainly due to the complexity of the traffic situation, the more aggressive driving behaviour and the limited space left to the cyclists. Such differences with other cities are obviously amplified by the lack of facilities for bicycle but also by the negative impacts related to the modest number of cyclists. In fact, such condition involves, for the motorists, the increased risk of collisions with bicycle due to the unexpected presence of cyclists. The risk of accidents is also related to the specific behaviour of cyclists: it is clear that the risk perception and also the attention allocation are devoted especially to the intersections, with an unexpected positive result in terms of accidents. Less attention is instead focused on travelling on the streets where unsafe conditions are mainly due to the lack of dedicated spaces, the motorists behaviour in the shared roads and also the unexpected presence of cyclists.

4. Innovative strategy for the development of pathways network

Taking into account the specific context of the study, cities with poor level of facilities for bicycle and a very low current bicycle share of trips, it is possible to observe that the main critical issues related to bicycle use for commuters are the lack of dedicated facilities not only pathways but also parking spaces. In many cases as in Rome, these problems are enlarged by the ineffective existing pathways, often built where it is possible without subtracting spaces at the other components, so producing the effect that cyclists avoid the use of these for the too long and too slow trips associated. In such context, cyclists are also to consider as vulnerable users of the road network for their “few numbers”. The safety issues are perceived as the main critical point by the potential cyclists especially without a satisfactory development of the pathways network. Past experiences analysed have shown also the limited success of action based only on building new pathways without a more comprehensive policy to really sustain cycling.
The improvement of cycling condition to promote the use of bicycle for commuters requires the involvement and the coordination of many elements in cycling-related infrastructure, operations and services. Through a collaborative effort among these elements it is possible to provide a comprehensive range of strategies in many sectors. Of course, the main controversial point is about the facilities development that can be solved by using a new innovative strategy. The proposal is to stress the concept that bicycle users have to share road section with other components as more as possible, avoiding any request of useless dedicated spaces. In this context, dedicated bicycle pathways have to be realized only where really necessary to travel in a safe and comfortable way. North European best practices about

facilities can represent an ideal target for long term period, after cities transformation in cyclabe cities, but in the short and medium term period, has to be considered an experience not replicable.
The sharing of road section between bicycles and motorists is possible by creating better compatibility conditions. The compatibility of different vehicles or road users is related to their mass and speed. The smaller these differences, the more compatible are road users. In other words, the sharing of road section in safe condition should be possible by achieving the principle of 'homogeneity'. This states that where road users or vehicles with large mass differences use the same traffic space, the speeds should be so low that the most vulnerable road users and transport modes come out of a collision without any severe injuries (Wegman et al., 2012). Several studies have confirmed that there is a threshold around 30 km/h, above which the probability of injury and fatality for cyclists colliding with motorists strongly increases (Kim et al., 2007).
Starting from these consideration, the innovative strategy to follow derives from the development of a combination of new pathways and actions involving the road network management. About the need of dedicated pathways, the selection of this category of pathways is related to two main different aspects: safety and mobility reasons. The first is involving safety issue in multilane roads with speed equal or larger than 50 km/h while the second refers to the bicycle network connection to avoid too long route using road network or in case of presence of physical and infrastructural obstacles. It is also important to minimize the sharing of facilities dedicated to pedestrians because the speed of cyclists and pedestrians are different and because, in many cases, the very large number of pedestrians or the little space at disposal reduce the convenience of sharing spaces.
In conclusion, according to this strategy, it is possible to identify three main categories of pathways:

a) No separation for different road users, the road section is shared with cars without any specific marking. This is the typical condition of narrow street in the historical center or local roads with maximum speed limited to 30 km/h,
b) No separation for different road users, the road section is shared with cars and public transport vehicles but there is the need of bicycle preferentiality using horizontal markings and traffic signs combined with some specific restrictions for cars movement,
c) Segregation of bicycles with the creation of a two-ways or one-way pathway completely separated from other traffic components roads.

The category b) of pathways represents the skeleton of the bicycle network. His design requires the development of a network of links to provide direct, logical and convenient connections combined with actions to manage traffic circulation in the road network. The aim is to divert part of the cars traffic or to reduce average vehicles speed with new restrictions for cars as lower speed limit, narrow lanes increasing parking spaces, reduction of permitted turns at intersections, etc.

5. Conclusion and further developments

This paper presents a new strategy for the definition of the network of bicycle pathways. The objective is to develop a safe and of quality bicycle network for bicycle users with utilitarian purposes in cities with poor level of facilities for bicycle and a very low current bicycle share of trips. The new strategy focuses attention to the concept that bicycle users have to share road section with other components as more as possible, avoiding any request of useless dedicated spaces.
Further efforts have to be done in two different directions. Firstly, it is important to identify the need in terms of management measures and the impact of these to ensure safety condition for sharing spaces. Then, it is necessary to define a procedure for the bicycle pathways network design. Such can be identified by an iterative procedure based on search and selection of shortest paths. The design methodology should be organized as an iterative procedure that, starting from an initial set of pathways composed by the shortest paths, improves the solution proposed by realigning the bicycle pathways, eliminating the less efficient and not necessary ones according to the resulting pathways spatial layout (directness, length, width, possible duplication, etc.) and the characteristics of the road network (traffic volumes and composition, road section and traffic average speed, etc).

SESSION 14: TRANSPORT ECONOMICS, FINANCE AND PRICING

REAL OPTION ANALYSIS APPLIED TO TRANSPORT INVESTMENT PROJECTS

Fabio Pizzutilo[1], Elisabetta Venezia[2]
[1] *Dipartimento di Economia, Management e Diritto dell'impresa – Università degli studi di Bari Aldo Moro, Italy*
[2] *Dipartimento di Scienze economiche e metodi matematici – Università degli studi di Bari Aldo Moro, Italy*

Abstract: Environmental and climatic changes can dramatically affect the long run demand and usefulness of large public transport infrastructures. Migrations, desertification, heavy weather conditions, rising in the sea level, floods, etc., are natural phenomenon difficult to estimate in their extent and timing that in the long run can have a significant impact on the use of highways, harbors, bridges, dams, rails, undergrounds, airports, etc.. Decisions about transport infrastructure projects have to be taken while future developments are uncertain. In general, they are implemented over several years, during which many factors can change significantly: technological advances, political shifts, economic fluctuations and so on. Moreover, transport infrastructure investments are usually highly costly and irreversible (in that the decision to realize the infrastructure involves costs that cannot be recouped, for example a railway track or a motorway). These uncertainties make such kinds of investment highly risky. Project managers and engineers are thus forced in embedding flexibilities in the infrastructures to cope with the increasing long run uncertainty posed by environmental, economic, social and climatic changes. Hence, flexibilities in transport investment projects, if any exist, are appreciable and valuable. Anyway, the traditional large infrastructure assessment process based on the net present value (NPV) is challenged since the value of the flexibility is rarely taken into proper consideration. We here propose to assess the value of the flexibilities any large public transport infrastructure project has through a real option analysis (ROA). A real option (RO) is the possibility that the management has to modify an investment during the course of its life to cope with the on-going development of the business. Differing from a financial option, it has no legal existence but relates directly to the real assets of the investment. From a capital budgeting perspective, coupling the classical NPV analysis with ROA can enhance the public investment decision process and facilitate decision makers' job. In practice, real options are difficult to recognize and to price properly. Since the pioneering work of Myers (1977) ROA for private companies' project valuation has been largely studied from the corporate finance perspective (Trigeorgis and Mason 1987, Ingersoll and Ross 1992, Amram and Kulatilaka 1998, Aguerreve 2003, Grenadier and Malenko 2010, to cite just a few among the copious relevant literature) and taken into proper account by analysts and practitioners of the private sector. Anyway, real options seem not yet to have received the attention that they deserve in the decision process of public infrastructure investment projects, either in theory or in practice. We conclude that coupling the classical NPV analysis with ROA enhance the public investment decision process and facilitate decision makers' job.

Keywords: transport infrastructures, financial analysis, investment decisions.

1. Introduction

Environmental and climatic changes can dramatically affect the long run demand and usefulness of large public transport infrastructures. Migrations, desertification, heavy weather conditions, rising in the sea level, floods, etc., are natural phenomenon difficult to estimate in their extent and timing that in the long run can have a significant impact on the use of highways, harbors, bridges, dams, rails, undergrounds, airports, etc.. Decisions about transport infrastructure projects have to be taken while future developments are uncertain. In general, they are implemented over several years, during which many factors can change significantly: technological advances, political shifts, economic fluctuations and so on. Moreover, transport infrastructure investments are usually highly costly and irreversible (in that the decision to realize the infrastructure involves costs that cannot be recouped, for example a railway track or a motorway). These uncertainties make such kinds of investment highly risky. Project managers and engineers are thus forced in embedding flexibilities in the infrastructures to cope with the increasing long run uncertainty posed by environmental, economic, social and climatic changes. Hence, flexibilities in transport investment projects, if any exist, are appreciable and valuable.

Anyway, the traditional large infrastructure assessment process based on the net present value (NPV) is challenged since the value of the flexibility is rarely taken into proper consideration. We here propose to assess the value of the flexibilities any large public transport infrastructure project has through a real option analysis (ROA). A real option (RO) is the possibility that the management has to modify an investment during the course of its life to cope with the on-going development of the business. Differing from a financial option, it has no legal existence but relates directly to the real assets of the investment. From a capital budgeting perspective, coupling the classical NPV analysis with ROA can enhance the public investment decision process and facilitate decision makers' job. In practice, real options are difficult to recognize and to price properly.

Since the pioneering work of Myers (1977) ROA for private companies' project valuation has been largely studied from the corporate finance perspective (Trigeorgis and Mason 1987, Ingersoll and Ross 1992, Amram and Kulatilaka 1998, Aguerreve 2003, Grenadier and Malenko 2010, to cite just a few among the copious relevant literature) and taken into proper account by analysts and practitioners of the private sector. Anyway, real options seem not yet to have received the attention that they deserve in the decision process of public infrastructure investment projects, either in theory or in practice.

[1] Corresponding author: fabio.pizzutilo@uniba.it

Brand et al. (2000) were among the very first to propose the incorporation of option analysis into the risk management of large public investment planning. Kitabatake (2002) presented an illustrative application study in which real options are employed to evaluate a road construction project. Smit (2003) analysed European airports expansion through a combination of real options theory and game theory. He argued that airports with infrastructures that are less constrained by growth regulations capture more value, because they are in a better position to exercise growth options available in the airport industry. Law, Mackay and Nolan (2004) used the real option analysis to re-examine a case of rail track abandonment in Canada. They concluded that the information incorporated when using real options for a rail-line abandonment decision makes the decision process less controversial. Zhao et al. (2004) presented a multistage stochastic model that incorporates real options for decision making in highway development, operation, expansion, and rehabilitation. Their model accounts for three major sources of uncertainties: traffic demand, land price, and highway deterioration. Van Bentem et al. (2006) proposed an option based model to calculate the value and optimal timing for the introduction of hydrogen as transport fuel for vehicles in large industrial areas. They treat the project as an option to postpone the investment. Kruger (2012) measured the value of the expansion option of an existing two-lane road in Sweden and examined how ownership in a public-private partnership affects the timing of expansion. Rakic, B., Rađenović, T., (2014) employed the binominal option pricing model and the risk-neutral probability approach to price the abandonment options implied in a Build-Operate-Transfer toll road investment. They argued that real options of abandon increase the value of the project. Recently, Power et al. (2015) proposed a model to value options to delay irreversible investments in infrastructure projects. Their model allowed for the stochastic evolution of financial, economic and physical variables and employed the Longstaff – Schwartz least squares Monte Carlo approach to determine the value of an American-style real option for an infrastructure investment and the optimal timing of its exercise. They argued that real-option value for infrastructure investment is substantial.

The pros and cons of implementing a real option analysis for the evaluation of public investment projects are here discussed. We conclude that coupling the classical NPV analysis with ROA enhance the public investment decision process and facilitate decision makers' job. At best of our knowledge this is among the very first studies on the subject, thus making a relevant contribution to the existent literature.

In these pages, it is assumed that the reader is familiar with basic option terminology. Among the countless books on the subject, anyone who is not used to option theory can refer to Hull (2014).

The paper is organised as follows. Next section introduces real option from a theoretical perspective. Section 3 points out and discusses advantages and drawbacks of the implementation of a real option analysis for the evaluation of public transport infrastructure projects.

2. Real options. A theoretical background

The possibility that the management has to modify an investment during the course of its life is called real option. They are options because they give the possibility to exercise flexibility if it is useful (the management is not obliged to modify the project if it is not believed to be worthwhile). They are real because their underlying is a real asset and not a financial one as for common financial options.[3]

The financial literature recognizes four main types of real options: growth (the possibility to make a follow-on investment); delay (any flexibility regarding the timing of the investment); switch (any possibility to make substantial changes to ongoing operations); abandon (it consists of all the possibilities to abandon -totally, partially or temporarily - an ongoing investment).

Growth options are any options that an investment has to expand its operations. They can be viewed as call options on the expansion project, in which the higher costs to achieve such flexibility are the premium of the option, the cost to expand is the exercise price and the maturity is the time in which it is possible to expand. With reference to public infrastructure projects, for example, consider the case of the construction of a new commercial harbour in a developing industrial area. If there is a high degree of uncertainty about the actual attraction of the new infrastructure, it can be wise to analyse the possibility to build rather than, for instance, a four-docks harbour, a two-docks one that is already arranged with the intention to become a four-docks in the future, once, given the actual use of the two-docks harbour, the demand can be assessed more exactly. The cost for the arrangement of the two-docks harbour into a four-docks one (consider, among others, the higher design expenses, the higher cost of building the harbour where there is enough space for a four-docks one, etc.) is the premium that the community has to pay in order not to incur immediately in the higher expenses (and risks) of a four-docks harbour but to have the flexibility to expand the harbour more easily and cheaply if actually needed.[4] It should be obvious that the value of the real option embedded in the two-docks harbour is higher the greater is the uncertainty regarding the actual demand for the harbour and its benefits for the community.

The option to delay consists in any flexibility regarding the timing of the investment to be started. The possibility of deferring an investment provides two main advantages. First of all, the extended time can be usefully employed for in-depth technical, operative, marketing and financial analysis, and so on, aimed at optimizing the planning of the investment and reducing the uncertainty about its costs, revenues and other benefits. Moreover, it gives the chance to choose the best moment to invest (that is the investment can be postponed to when its value is maximized). On the other

[3] For a comprehensive analysis of real option theory and practice, see among others Schwartz and Trigeorgis (2004), Mun (2005), Guthrie (2009).

[4] Notice that if the two-docks road is not arranged to become a four-docks one, the eventual future choice to expand will involve higher costs and a longer time or, in the worst case, will no longer be possible.

hand, if an investment is deferred, there is the possibility that other operators will enter the business, spoiling the expected source of value. Given these considerations, real options to delay are particularly valuable for very-long-horizon investments that cannot (or can only with difficulty) be spoilt by the concurrence (in the private sector think of the exploitation of a mine or an oilfield for which the rights have already been achieved). For these reasons, they are particularly valuable and attractive in public infrastructure investments, which by definition are very-long-term investments that do not face relevant concurrence problems (consider the possibility of deferring the above mentioned harbour project to the moment when facilities essential for its optimal exploitation – like an adequate motorway and railway system - are completed and available). From a financial perspective, real options to delay can be read as call options (in general of the American style) on a project (the underlying asset). The strike price is the amount to be spent to realize the investment (note that there could be uncertainty concerning this value too – think about technological development that could reduce some fixed costs – which adds more value to the option). The premium is the amount that is possibly paid to have the option to wait and see (consider patent rights, concession rights or, to stay in the harbour case, the cost of land expropriation or zoning the area to be used when it is actually beneficial). On the other hand, deferring the project means losing the net benefits that would have been derived from undertaking it immediately. Thus, the option to delay has to be exercised (that is, the investment has to be made) when its value is lower than the net benefits that would otherwise have been achieved.[5] Notice that in the classical DCF framework the investment can be made either now or never. The postponed investment has to be treated as an alternative investment. More efficaciously, ROA analysis advises postponing the investment if the value of the option to delay is higher than the NPV of the project realized immediately, even if the latter is highly positive. Moreover, ROA assumes that an investment cannot always be unattractive. Circumstances can change, so an investment that has a negative NPV if realized today can be attractive for the future.

Switch option refers to any flexibility that the project has to make substantial changes to its inputs and/or outputs. To remain in the harbour project, think of arranging one of the docks so that it can be easily and cheaply converted in a navy one, if the demand for a commercial use of the harbour does not get off the ground. The major costs for such an arrangement are the premium that the community has to pay to achieve such flexibility, which can be useful in countries which have the need to relocate navy operations (for example countries where navy harbours are located very close to congested cities). The financial replication of this kind of real option largely depends on the actual type of switching flexibility that the project has.

Any flexibility for the project to be ceased totally and/or partially and/or temporarily during the course of its life is called option to abandon. Given their similarity and the scope of this paper, to save space and avoid redundancies, in this category we include what should properly be named respectively as the real option to cease (total abandonment), the real option to contract activity (partial abandonment) and the real option to suspend (temporary abandonment). Almost every investment project has the possibility of being halted, contracted or suspended at any moment in time if the business fails. The numerous public infrastructures that have been abandoned or significantly downsized throughout the world bear witness that this kind of option is largely exercised by public agencies too. The value of such a real option largely depends on the value that can be recovered by the eventual total or partial abandonment and from savings in the costs to suffer to cease the activity (totally or partially) or to suspend it and eventually reactivate it (think for instance to the costs to abandon or suspend a nuclear power stations, an asbestos production, a pipelines, etc.). Hence, it could be of great importance in the planning phase of the investment to try to maximize the value of the abandonment real options embedded in the project and not to treat them as a passive event that unluckily can affect the business. For instance, to cope with an eventual seasonality of the demand for the harbour services, the infrastructure can be planned and built so that the costs for a seasonal closing and re-opening of a dock are minimized. The higher costs to be paid to realize in such a manner the harbour are the premium to achieve the flexibility to abandon temporary one dock. The higher the uncertainty about the actual seasonality of the demand for the harbour services the higher the value of this kind of real option. In their easiest forms, real options to abandon can be viewed as put options on the investment. For the ceasing and contracting real options the strike price is the net recovery price. The value of the suspended operations less the suspension costs is the strike price in the case of temporary abandonment. Abandonment real options should be exercised if the value of continuing the business is lower than the strike price.

Real options are often difficult to identify. Moreover, their valuation is more complicated than financial options given that, above others, their underlying is not traded, they can be exercised at different times and the volatility of their returns is a great exercise of estimation. Furthermore, complex investment projects can embed several real options that cannot be valued separately if, as is often the case, they are interdependent and/or conditional (think of a project that has the flexibility both to be halted and to be contracted: if halted, the contracting real options have no further value). Given these complexities, the classical Black and Scholes (1973) formula is rarely deemed to be the best way to approach real option valuation. The flexibility and simplifications allowed by binomial option pricing models (first proposed by Cox, Ross and Rubinstein, 1979), compound option pricing models (Geske, 1979, was among the very first to deal with the valuation of these kinds of options, which can apply to a large series of project flexibilities) and Monte Carlo simulations (Boyle, 1977, was among the very first to apply this class of non-parametric models to the pricing of financial options) have often been considered to be more suitable tools to value real options. Of course, the actual

[5] Those who are accustomed to financial option valuation will immediately note the similarity to an American call option on a stock that pays dividends.

preferred model is a matter of the real option to be valued, its financial and real features and the possible interactions and interdependencies with other flexibilities that the investment project has.
Anyway, the variables on which the value of a real option depends are the same as those of financial options:
a) The strike price (that is, the price at which the option can be exercised). For call options like the growth ones, the lower the strike price, the higher the value of the real option. For put options, like abandonment ones, the lower it is, the lower is the value of the real option.
b) The value of the underlying (that is, the value of the investment project). All other things being equal, it is evident that the higher the value of the project, the higher the value of the real call options written on it (like growth options) and the lower the value of the put real options (like abandonment ones).
c) The volatility of the value of the underlying (that is, the riskiness of the project). The greater is the uncertainty surrounding the project, the higher is the value of the flexibilities that the project has. Thus, the riskier the project is, the higher the value of the embedded real options is, whatever their typology.
d) The maturity (that is, the time until which they can be exercised). It should be obvious that the longer the time until any flexibility of the project can be exploited, the higher its value, regardless of whether the real options embedded in the project are to grow, to delay, to switch or to abandon.
e) The risk-free interest rate. All other conditions being equal, a change in the risk-free interest rate produces an effect of the opposite sign on the value of real put options and of the same sign on the value of real call options. Therefore, it is to be expected that an increase (decrease) in the risk-free rate results in a decrease (increase) of the value of the abandonment real option and in an increase (decrease) of the value of the growth real option.
f) Any cash flow paid by the underlying. If a project distributes the cash flows that it generates, its value reduces by the same amount. Thus, for b) above, the value of a put real option increases and the value of a call real option decreases. All other things being equal, it is better to exercise the option to abandon a project after having collected the cash flows that it can distribute than otherwise. On the other hand, not to grow or to delay an investment means losing the cash flows that the new project would have generated.
Option pricing theory makes another very important point: there are no other variables on which the value of a real option depends.

3. Implementing a real option analysis for the evaluation of public infrastructure investments

Construction of transportation infrastructure usually brings convenience and economic development. However, construction needs cannot be fully satisfied because of the limitation of capital and other resources. Hence, the priority evaluation of transportation infrastructure projects is very necessary (Shi and Zhou 2012). As an important aspect of sustainable transportation, transportation financial analysis has gradually drawn researchers' attention. However, the usual evaluation method is the finacial NPV which ignores some of the aforementioned advantages of ROA. Although some researchers have already begun theoretical studies on transportation evaluation with regard to this aspect, practical and quantitative evaluation methods are still in need.
Although some public infrastructure projects are reported to be realized with the declared intention of having valuable future flexibility, a formal real option analysis is not a usual part of the evaluation process of public transport investments yet.[6] Nevertheless, the advantages that can derive from the use of ROA in public infrastructure investment decisions are manifold.
First of all it has to be considered that the traditional discounted cash flow (DCF) analysis values an investment project with reference to the cash flows that the project is anticipated to produce in the expected scenario. It implicitly assumes that managers are passive in the ongoing operations of the investment once it has been implemented and that they will adhere strictly to the planned strategy, without any possibility to adjust it if needed or valuable. Thus, DCF analysis fails to capture the value of the flexibility, if any, that the management has to adapt or modify the project during its life in response to unexpected internal and external developments, resulting in an undervaluation of the investment.
Another important advantage of employing a real option analysis is that thinking and managing in the light of real options permits the elaboration of a decision tree, a plan in which are drawn the lines for future important actions that allow the exploitation of the flexibilities in the investment. Decision trees enable the provision of rules about if and when to exercise real options and allow the flexibility of the investment to be managed strategically. Moreover, they reduce the conflicts among the executives of the project and improve their ability to react to sudden changes in the business or to important new information since the lines for future strategic actions have already been traced. It also allows more effective control of the variable on which the profitability and the risk of the investment depend and provides the possibility to step in cheaply and in a timely manner to take advantage of the upside volatility of the project or to minimize the downside risk.
Moreover it has also to be taken into consideration that ROA is a complementary analysis to the classical DCF not an alternative one. The actual value of a project is the classical NPV plus the value of the flexibilities. Consider two

[6] Gesner and Jardim (1998) evidenced that for the construction of the Tagus River bridge in Portugal, in 1966, a stronger structure was employed to permit easier enlargement (eventually, in 1993, the bridge was doubled to cope with the traffic increase). Herder et al. (2011) reported that for the construction of Maasvlakte 2, a large-scale expansion of the Port of Rotterdam, the Port Authority chose a phased construction to have the flexibility to abandon the following phase of the project if the market deteriorated.

investments A and B that have the same positive NPV and are identical in all but one point: at any moment during its life, project B can be abandoned at a recovery price P whilst project A cannot. Any rational investor will prefer project B to project A. Thus, project B is worth more than project A. The difference in values is the value of the flexibility that project B has to abandon the operations at any time if they break down. If the uncertainty about the future prospects of the projects is null, there will certainly not be a need to abandon project B. Thus, the value of its flexibility is null and both A and B are preferable. The greater the uncertainty about the future prospects of the projects, the greater the possibility that the management will exercise the exit plan of project B. Real options are worth more the more uncertain the expected scenario is. ROA is thus needed more when the level of uncertainty is high, as it is in many transport investment projects in modern times. NPV fails in considering the value of the flexibility.
Another important advantage can be viewed in the fact that public investments often suffer from inertia in their management. A real option approach instead prompts public executives to manage the project in a proactive way. They are forced to recognize that projects are composed of managerial options and to develop more structured thinking to identify, value, create and manage them adequately.
Last but not least, it has to be considered that a usual drawback of public transport investment is their overbuilding, that is, the fact that they are often built to serve a greater demand than actually exists. An RO approach induces public decision makers and executives of the project to create and preserve flexibility to modify the investment according to the future developments and avoid useless overcapacity.

4. Conclusion

There are some limitations in the use of ROA of which the decision maker has to be aware. The difficulties in correctly evaluating real options are clearly one. Optimistic estimates of variables like the recovery price, volatility, future cash flows and so on or the improper consideration of the interactions between all the real options embedded in the project can lead to excessive evaluations and thus the justification for useless investments. Moreover, the subjectivities implicit in such estimates lead to not negligible conflict of interests between the commonality, the tax payers and the end-users on one side and the private or political interests in the execution (or in the lack of execution) of the work or of the real option on the other. It also has to be taken into consideration that the difficulties inherent in the valuation of the real options can impact negatively on the level of transparency of the public decisional process.
Other limitations come from the fact that adopting a real option investment decision approach requires the skills and capacity to monitor and review the project before and after its implementation. This means investing in human and technological resources. While large public bodies can afford these costs, minor ones cannot. Moreover, especially for small public investments, the costs and the time involved in such an analysis can be excessive, thereby limiting the efficacy of the option valuation process.
The third limitation stems from the public infrastructure investment regulation. As long as it does not explicitly allow for ROA, either in the evaluation phase or in the accounting, managing and financing phases, there could be serious disincentives for its implementation.
The experts focus on the problems of financial analysis and effectiveness estimation of individual investment projects or an assembly of independent projects. Formation and analysis of the investment programs do not have a proper attention. To solve these problems, special methodologies, models, methods, and supporting instrumental facilities must be developed and implemented. Therefore, the transport investment project must be regarded as a complicated large-scale investment project, which would enable one to make use of the procedures and tools developed for financial analysis and effectiveness estimation of the investment projects. Introduction of the proposed methodology into the practice of transport investment project would appreciably improve financial feasibility analysis of infrastrucutral projects, essentially increase validity, quality, and efficiency of the managerial decisions, coordinate the results of planning, and substantially reduce their laboriousness.

ECONOMIC IMPACT OF TRANSPORT INFRASTRUCTURE INVESTMENT

Marko Miljković[1], Jelica Petrović Vujačić[2]
[1,2] University of Belgrade, Faculty of Transport and Traffic Engineering, Vojvode Stepe 305, Belgrade, Serbia

Abstract: Transport infrastructure investment covers spending on new transport construction, as well as on the improvement of the existing network. It provides a number of benefits for the entire economy, including positive impact on availability of goods and services, volume of trade, productivity of the economy, employment and level of business activity, transport costs and possibility of achieving economies of scale, value of assets, balanced regional and local economic development etc. The paper analyses economic impact of transport infrastructure investment, with special focus on positive contribution to economic growth measured by growth rate of gross domestic product in real terms. There can be identified various channels of such an impact. Transport infrastructure investment can lower costs and raise competitiveness of products, which stimulates the production and contributes to economic growth, but also opens the door to greater savings and investments. Investment in transport infrastructure, also affects aggregate demand level by stimulating the construction industry, as well as a series of related branches of manufacturing industry, whose inputs are used in the construction industry. In addition, investment in transport infrastructure provides positive signals to key sectors of the economy. The conducted empirical researches on the impact of transport infrastructure investments, which mostly rely on Cobb–Douglas production function approach, confirm literature findings on positive impact on economic growth, whether the researches were based on multi-country panel data analysis or on single-country time series analysis. The paper also considers the economic impact of transport infrastructure investment from the point of importance of possible crowding-out effect, which indicates that higher public spending, financed primarily from loans, increases aggregate demand and interest rate and thus reduces the level of private investments.

Keywords: transport infrastructure investment, economic impact, economic growth.

1. Introduction

Economic thought has been interested in transport infrastructure investment and its effects on the entire economy, especially on economic growth and development since the time of Adam Smith at the end of 18th century. At the beginning, the issue of justification of state involvement in transport infrastructure financing was mainly addressed by the literature, considering the fact that transport infrastructure possesses some characteristics of public goods. Namely, transport infrastructure is a non-rivalrous good, considering that use of one individual does not reduce availability to others. Furthermore, there are often high costs, or even no possibility of exclusion of users which do not want to pay for use of infrastructure, which causes a free-rider problem. Because of these characteristics, transport infrastructure can be supplied at an optimal level only by public funding, while private sector funding would cause a supply at a suboptimal level (Banister & Berechman, 2000).

Also, the literature from the end of 20th century discussed an importance of crowding-out effect in the case of public engagement on transport infrastructure investment. While Rietveld (1989) and Morrison & Schwartz (1996) indicate that higher public investment in transport infrastructure, financed mainly by borrowing, increase aggregate demand and interest rate and thereby impact on reduction of private sector investment, Aschauer (1991) and researches of World Bank (World Bank, 1996) deny the existence of crowding-out effect in this case and emphasize that development of transport infrastructure significantly decreases operating costs and thereby increase rates of return of private sector investment which actually stipulates investment.

Traditional government funding sources are surely insufficient to meet the increasingly complex and diverse needs of the transportation system. Therefore, a range of innovative financing solutions to support sustainable development have emerged in recent years, including new financial instruments, investment funds and financing approaches (Petrović Vujačić, 2014).

Economic impact of transport infrastructure investment are numerous and they include positive impact on availability of goods and services, volume of trade, productivity of the economy, employment and level of business activity, transport costs and possibility of achieving economies of scale, value of assets, etc. Nowadays, economic literature pays most attention to positive contributions of transport infrastructure investments to economic growth and development, which is actually a main focus of this paper.

At the very beginning of the paper, there are presented transport infrastructure investment and maintenance spending in OECD countries during the last fifteen years, in order to analyse the values, structure and main developments in this field. Preconditions for successful impact on economic growth, as well as channels of such an impact are explained in the third chapter of the paper. Finally, in the fourth chapter there are presented important findings of relevant empirical researches from the last decade.

2. Transport infrastructure investment and maintenance spending

It is important to make a difference between transport infrastructure investment and maintenance spending, considering quite high amounts of maintenance spending nowadays, especially in developed countries with high per capita income

[1] Corresponding author: m.miljkovic@sf.bg.ac.rs

and well developed infrastructure network. According to definition of OECD, transport infrastructure investment covers spending on new transport construction and the improvement of the existing network which increases its performance or capacity, while maintenance spending does not change performance and capacity of infrastructure (OECD, 2013).
Total values of transport infrastructure investment by European countries are presented in Table 1. The countries are selected according to availability of data for the period of last fifteen years and include Albania, Austria, Belgium, Czech Republic, Denmark, Finland, France, Germany, Latvia, Lithuania, Romania, Serbia, Slovakia, Slovenia, Spain, Sweden, Turkey and United Kingdom. The presented data were collected by the International Transport Forum from transport ministries, statistical offices and other public institutions.
The aggregate values of investment in the last fifteen years strongly depend on the size of the country and its development level. Therefore, the highest values were recorded in France, Germany, Spain and United Kingdom, while the lowest values within the sample are associated with Albania, Serbia, Latvia, Lithuania, Slovenia and Slovakia. The first conclusion from presented data indicate positive developments during the period 2005-2009. Aggregate value of investment in this period was in almost each country higher than in the previous five-year period, with non-weighted average growth rate of 92% in nominal terms, i.e. 52% in real terms (with excluded inflation impact). Latvia, Albania, Romania and Czech Republic more than doubled the level of transport infrastructure investments, while Germany experienced a slight decrease in the level of investment. On the other hand, investment has significantly slowed down during the period 2010-2014, with non-weighted average growth rate of only 5% in nominal terms as compared with the previous five-year period, while the growth rate in real terms was even negative and amounted to -10%. Only Nordic countries, as well as Turkey, experiences positive growth rates during this period.

Table 1
Aggregate values and growth rates of transport infrastructure investments by selected European countries in the period 2000-2014

Country	Aggregate value, EUR million, current prices			Growth rate, as compared with previous five-year period			
				In nominal terms, %		In real terms, %	
	2000-2004	2005-2009	2010-2014	2005-2009	2010-2014	2005-2009	2010-2014
Albania	502	1,523	1,089	203	-28	162	-36
Austria	9,635	13,285	11,030	38	-17	25	-25

Further consideration of structure of transport infrastructure investment indicates that the highest share in total transport infrastructure investment refers to road and rail infrastructure investment, which amounts to at least 80%, but often even more than 95%. In most countries, the dominant share refers to road investment, except in Austria and Belgium, which invested more than 60% of total transport infrastructure investment in rail infrastructure. Share of road and rail infrastructure investment in total transport infrastructure investments are presented in more details in Table 2.

Table 2
Share of road and rail infrastructure investment in total transport infrastructure investments by selected European countries in the period 2000-2014

Country	Share of road investment			Share of rail investment		
	2000-2004	2005-2009	2010-2014	2000-2004	2005-2009	2010-2014
Albania	86.0%	97.4%	97.3%	2.4%	0.4%	0.3%
Austria	31.3%	29.3%	16.6%	61.7%	60.7%	81.4%

3. Preconditions and channels of economic impact of transport infrastructure investment

Banister & Berechman (2001) emphasized that transport infrastructure investment need a list of complementary factors in the economy in order to positively impact economic development. These preconditions include the following:

- Presence of positive economic externalities (developed labour market, buoyant local economic conditions, positive expectations etc.),
- Investment factors (availability of funds for the investment, scale, location, timing and network effects of the investment etc.),
- Political factors (supportive legal, organizational and institutional policies and processes and presence of any necessary complementary policy actions such as grants, tax breaks etc.).

As presented in the Figure 1, all these preconditions individually have little or even no impact on development. Even combines on a pair-wise basis they produce limited impact on development and growth.

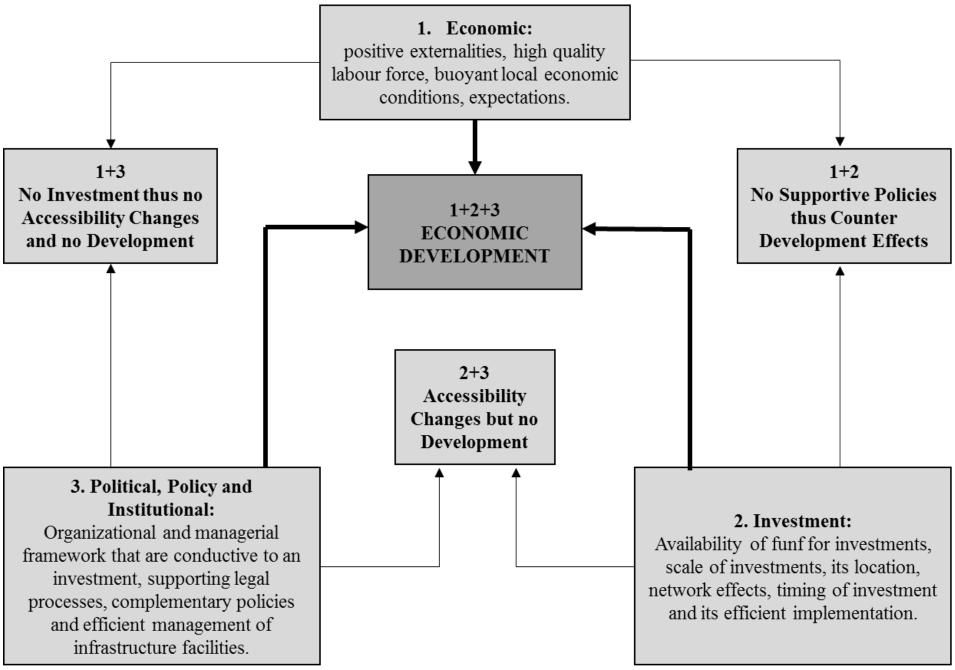

Fig. 1.
Necessary sets of conditions for economic impact of transport infrastructure investment
Source: Banister & Berechman (2001)

Banister & Berechman (2001) also developed a scheme of multi-dimension nature of the links between transport infrastructure investment, its travel effects and primary benefits, allocative externalities and at the very end economic growth. The scheme is presented in the Figure 2.

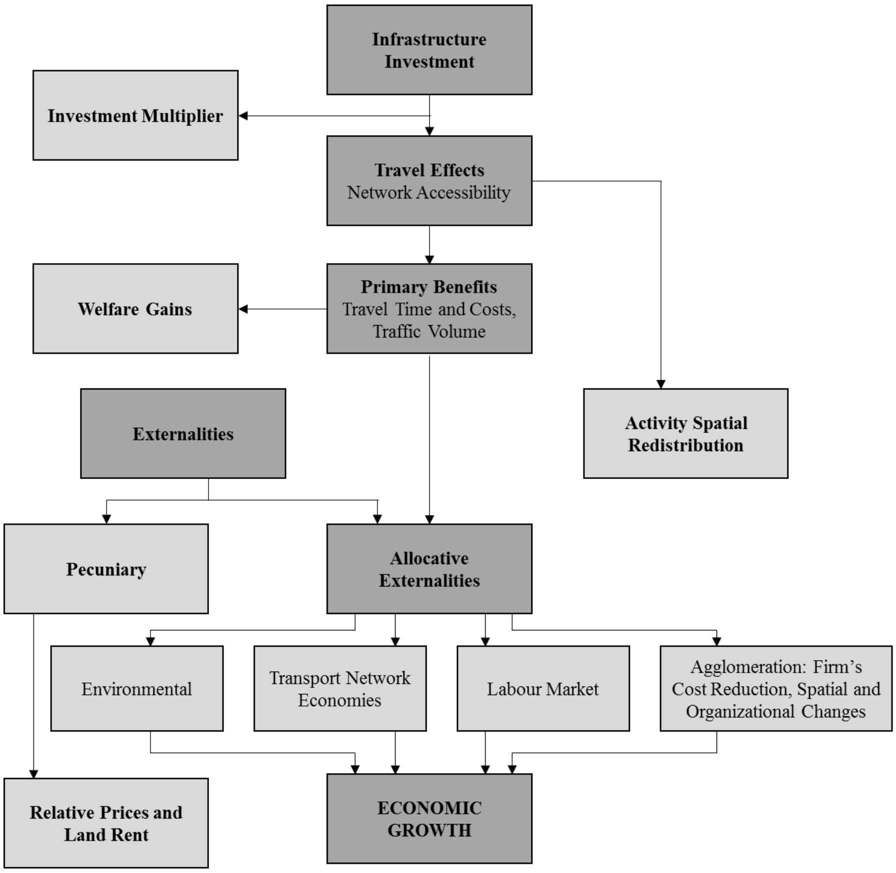

Fig. 2.
Economic growth benefits from transport infrastructure investment
Source: Banister & Berechman (2001)

There can be identified various channels of infrastructure investment impact on economic growth, as follows:

- Operating costs channel - Transport infrastructure investment can lower costs and raise competitiveness of products, which stimulates the production and contributes to economic growth, but also opens the door to greater savings and investments;
- Construction industry channel - Investment in transport infrastructure, also affects aggregate demand level by stimulating the construction industry, as well as a series of related branches of manufacturing industry, whose inputs are used in the construction industry;
- Positive signals channels - Investment in transport infrastructure provides positive signals to key sectors of the economy.

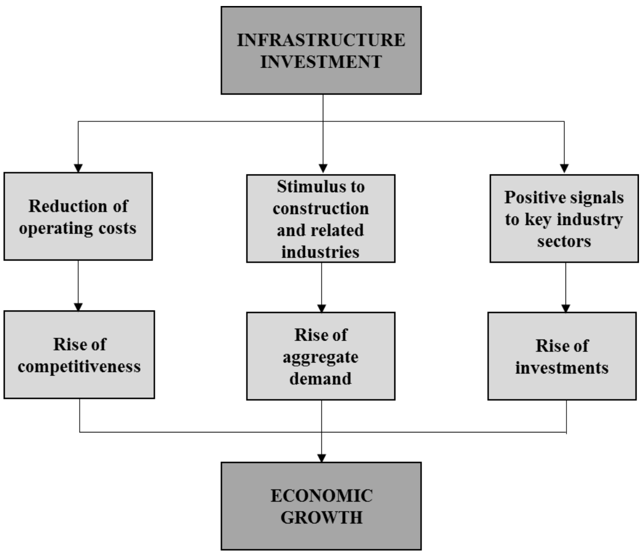

Fig. 3.
Channels of infrastructure investment impact on economic growth

4. Empirical evidence of impact of transport infrastructure investment on economic growth

Most empirical researches on the nature of the links between transport infrastructure investment and economic growth rely on the production function approach. The basis for this approach is the Cobb-Douglas production function $Y=K^{\alpha}L^{\beta}$, where Y represents gross domestic product (GDP), K physical capital, and L labour input. Coefficients α and β represent output elasticity of production factors K and L and indicate sensitivity of GDP to a change in levels of factors K and L used in production. The baseline function is then modified by adding a new production factor I, representing infrastructure: $Y=K^{\alpha}L^{\beta}I^{\gamma}$, where γ coefficient stands for output elasticity of infrastructure. Econometric methods and techniques are applied usually on a log-linearized form of this function: $\ln Y=\alpha K+\beta L+\gamma I$.

Egert et al. (2009) conducted empirical research on the sample of 24 OECD member countries within the period 1960-2005. They identified a positive impact of road infrastructure investment on the level, as well as on the growth rates of GDP per capita in most countries from the sample. On the other hand, in a few countries, there was identified a negative output elasticity of road infrastructure investment, but at the same time a positive output elasticity of motorways infrastructure investment. This may reflect the fact that the road networks in these countries were very well developed and the objectives behind road infrastructure investment reflected more social considerations rather than transport routes and international connections. The same authors demonstrated also a positive impact of rail infrastructure investment on economic growth, with only few exceptions on Iberian Peninsula and Benelux countries, which may be a negative consequence of over-investment in terms of quantity, or eventually high costs associated with poor investment decisions (inadequate locations, expanding already developed networks etc.).

Del Bo & Florio (2008) carried out a research on a sample of 261 European regions defined by NUTS-2 classification within the ten-year period 1995-2005. They defined a production function of the following form: $Y=K^{\alpha}L^{\beta}H^{\delta}I^{\gamma}$, where Y represents gross domestic product adjusted with purchasing power parity, K physical capital, L labour force, and H human capital measured by percentage of labour force employed in science and percentage of highly educated employees. Variable I stands for infrastructure endowment and is consisted of 3 components: telecommunication infrastructure, soft infrastructure and hard infrastructure. Quite higher output elasticity, as well as statistical significance (at 1% level), was identified for telecommunication infrastructure and soft infrastructure measures (multi-modal potential accessibility and time-to market), 0.437 and 0.302 respectively. On the other hand, hard infrastructure indicators, such as railways, motorways and other road, do have a significantly lower elasticity of 0.045, 0.035 and -0.037 respectively at lower statistical significance level of 5% indicating that transport infrastructure is at a steady-state level in European countries. Negative output elasticity of other roads infrastructure investment is in line with findings of Egert et al. (2009).

Cantos et al. (2005) examined impact of investment in road, rail, port and airport infrastructure on economic growth and earnings in Spanish regions within the period 1965-1995. They identified an output elasticity of total transport infrastructure investment of 0.042, meaning that 10% increase of transport infrastructure investment produce 0.42% increase of GDP. Especially high impact is associated with road infrastructure investment (output elasticity 0.088), while quite lower impact can produce airport infrastructure investment (output elasticity 0.0076). The authors found that rail and port infrastructure investment had no statistically significant impact on GDP growth. An important contribution of this research is related to the conclusion that transport infrastructure investment (especially road infrastructure) increase earnings in sectors that produce nationally traded goods (agriculture and manufacturing industry), unlike sectors that produce regionally traded goods (retail and services).

Calderon (2009) researched impact of three key infrastructure sectors, including telecommunication infrastructure, road infrastructure and electric power infrastructure, on GDP per capita growth. He identified positive impact of faster accumulation of telecommunication and road infrastructure stocks on GDP growth and concluded that in African case most contribution comes from more than from better infrastructure.

Aswini at al. (2013) conducted empirical research on infrastructure investment impact on GDP growth in India. The analysis covered a ten-year period from 1999 to 2009. The authors concluded at 10% significance level that 1% increase in infrastructure investment produce 0.46% increase of GDP. Furthermore, all types of infrastructure included in the model (road construction, railways, communications, ports, storage, irrigation, electricity, gas and water infrastructure) are positively linked with GDP growth.

Almeida & Guimaraes (2014) examined whether road and energy infrastructure had any impact on income convergence among Brazilian municipalities in the period 1999-2005 and concluded that the insufficient stock of roads is a main constraint to income convergence and that road infrastructure investment could support pro-poor growth.

Melo et al. (2013) came to important conclusions carrying out a meta-analysis of 33 previously conducted researches in the period 1990-2012. They concluded that transport infrastructure investment has very stronger impact on GDP growth in long-run as compared with short and medium-run. They also identified a quite stronger impact of transport infrastructure investment on growth of agriculture and manufacturing industry, as compared with services. And finally, they found a stronger link between economic growth and transport infrastructure investment in United States than in European countries, considering that US more depends on road transportation.

A summarized conclusions of empirical researches are presented in the Table 5.

Table 5
Empirical findings on impact of transport infrastructure investment on economic growth

Authors	Sample	Time period	Main conclusions
Egert et al. (2009)	24 OECD countries	1960-2005	Positive impact of road (especially motorway) infrastructure investment on GDP growth. In developed countries, negative correlation between other road investment and GDP due to social objectives of these investments.
Del Bo & Florio (2008)	261 NUTS-2 regions of European Union	1995-2005	Positive impact of telecommunication (to a higher extent) infrastructure, as well as of motorway and rail infrastructure (to a lower extent) on GDP growth. Negative correlation between other road investment and GDP (in line with Egert et al. (2009) conclusions).
Cantos et al. (2005)	Spanish regions	1965-1995	Positive impact of road infrastructure (to a higher extent) and airport infrastructure (to a lower extent) on GDP growth. Positive impact of transport infrastructure investment on earnings in agriculture and manufacturing.
Calderon (2009)	39 African countries	1991-2005	Positive impact of faster accumulation of telecommunication and road infrastructure stocks on GDP growth. Most contribution comes from more than from better infrastructure.
Aswini et al. (2013)	India	1999-2009	Positive impact of all types of transport infrastructure on GDP growth.
Almeida & Guimaraes (2014)	Brazilian municipalities	1999-2005	Insufficient stock of roads is a main constraint to income convergence. Road infrastructure investment supports pro-poor growth.
Melo et al. (2013)	Data from 33 previously conducted researches	1990-2012	Transport infrastructure investment has stronger impact on GDP growth in long-run as compared with short and medium-run. Quite stronger impact of transport infrastructure investment on growth of agriculture and manufacturing industry, as compared with other sectors of the economy.

5. Concluding remarks

Economic benefits of transport infrastructure investment are numerous. The paper especially focused on analysing the impact on economic growth. There are identified various channels of infrastructure investment impact on economic growth, including operating cost channel, construction industry channel and positive signals channel. Also there are explained necessary preconditions which have to be met in order to enable a positive impact on economic growth and development, including presence of positive economic externalities, favourable investment factors, as well as political factors. The positive link between economic growth and transport infrastructure development is confirmed by summarizing the findings of recent empirical researches, especially when it comes to motorway, rail and telecommunication infrastructure. Several empirical studies proved negative link between other roads investment (except motorways) and economic growth in developed countries, considering social objectives of such investments.

BENCHMARKING OF COMPANIES DEALING WITH TRANSPORT INFRASTRUCTURE IN TERMS OF THEIR PERFORMANCE

Tatiana Semenova[1], Eva Ondrušková[2], Eva Vítková[3]
[1,2,3] Brno University of Technology, Faculty of Civil Engineering, Department of Structural Economics and Management, Brno, Czech Republic

Abstract: Benchmarking as a method of management has had a new meaning in business. The aim of benchmarking is assessing the efficiency of the company in comparison to other organizations on both the domestic and international market. Lessons learned from other companies can be used for establishing improvement in the targets and for promotion changes in the organisation. This paper describes the scope of these initiatives and discusses the lessons learned and improvement of the opportunities that have been identified in the organizational structure as well as the method of financial management. Data collected for this article has been based on four major construction companies from the Czech Republic and Portugal which focus on realization of transport constructions. Basic parameters of benchmarking have been chosen based on the selected methods of financial analysis representing the performance of the company. Furthermore, the most successful company has been detected based on a comprehensive analysis of calculated results in the value engineering. Recommendations for improving financial situation and effectiveness of other researched companies have been set as a result of the research and analysis of practical activities of the company. In addition the development of construction companies which focuses on realization of transport constructions has been compared to the development of economy of the country for better understanding of company's position on internal market. Moreover issues dealing with application of benchmarking in practice have been discussed in the final part of the article.

Keywords: benchmarking, financial analysis, performance indicators, Czech Republic, Portugal.

1. Introduction

Current economic environment has been characterized by strong competition, increasing uncertainty and discontinuity. Increasing competition on the global market forces enterprises to increase the efficiency of internal processes in order to retain competitiveness. This issue is even more important in engineering industry suffering from the decrease in the volume of public and private tenders. Moreover current global financial situation has had major negative impact on availability of both private and public finance for civil and transport infrastructure investments.

Thus, organizations are required to bring value to their facility delivery programmes. Performance measurement and benchmarking are two tools which can assist companies in improving their status in the international industry. While the former is perhaps the most significant development for solving performance-related problems to ensure business success, the latter is essentially an integral part of planning and the ongoing process of improvement to ensure a focus on the external environment and strengthening the use of factual information in developing plans.

Transport construction is vital for well-functioning of economic activities and represents a key for ensuring social well-being and cohesion of population and thus it is important for measuring and comparing it to the best companies in order to make industry globally competitive.

However, making forecasts at the time of crisis is very difficult. In today's highly competitive world and rapidly changing global economy, every company has to know its economic situation, its business environment as well as competitors in order to promote and maintain its position on the market. Enterprises have to consider, and in many cases adopt or implement, a wide range of innovative management philosophies, approaches, tools and techniques. Benchmarking has proved to be a useful, easily understandable and effective tool for remaining competitive among improvement strategies and techniques such as Total Quality Management, Continuous Quality Improvement and Business Process Reengineering.

2. Literature review

Most of research papers focus on application of benchmarking in different industry sectors, and thus, definitions of the term "benchmarking" are not unified.

Camp (1989) wrote the first definitive book on benchmarking and defined benchmarking as "the continuous process of measuring products, services, and practices against the toughest competitors or those companies recognized as industry leaders". The Construction Industry Institute (CII) has adopted the following definition of benchmarking: "A systematic process of measuring one's performance against results from recognized leaders for the purpose of determining best practices that lead to superior performance when adapted and implemented" (Hudson, 1997).

Traditional view of benchmarking required two separate disciplines focused on performance improvement: measures and methods. Identifying and capturing performance indicators (the measures) is only the first step; developing and implementing performance improvement (the methods) is the second and the most important step for the benchmarking process to be truly effective (Camp, 2006).

Performance benchmarking enables managers to assess their competitive position by product or service comparison. Numerous industries apply performance benchmarking as a standard method in relations with competitors.

[3] Corresponding author: semenovat@study.fce.vutbr.cz

In addition to this, there are numerous classifications, but the most often used is the one which differentiates between two benchmarking types: internal and external benchmarking.
Internal benchmarking implies comparison of some sectors and divisions within the organization. This benchmarking type is generally used in big, multinational companies where each company's department performs specific activity or operation. In these companies an intensive internal research in order to get an insight into business operations, department's strengths, weaknesses and operating methods of each department represents a starting point for the benchmarking project.
External benchmarking is divided into external competitive benchmarking, external industrial or functional benchmarking and external generic benchmarking. External competitive benchmarking is comparison of company's activity to direct competitors. External industrial or functional benchmarking compares company's functions to functions of other companies. External generic benchmarking broadens fields of application of benchmarking process beyond the limits of specific company and industry it belongs to (Marković, Dutina, Kovačević, 2011).
Benchmarking is a continuous learning process. For effective implementation of benchmarking it is necessary to respect the benchmarking cycle. In order to get useful results from benchmarking it is absolutely necessary to keep a systematic approach. Over time, different methodologies have been developed, so different sources describe steps of benchmarking differently. The most important is the approach developed by four organisations which are extensively involved in benchmarking (Boeing, Digital Equipment, Motorola and Xerox). This approach establishes general context for the creation of a process model and uses four phases of benchmarking - planning, data collection, analysis and improvement through adaptation (Wobbe, 2000).

3. Methodology

This research is based on the study and analysis of literature sources, original scientific research papers, studies and available materials on benchmarking. Moreover, these surveys include other sources available on the Internet. It comprises also document research as the financial statements have been used (balance sheet, profit/loss accounts and statement of cash flows) to calculate indicators of the companies studied. The collected data has been taken from the reports and accounts published by the companies creating the research sample.
The aim of the research is to investigate the concept, process and use of financial benchmarking in order to improve business efficiency by comparing the organization to the market leaders and best applying the practices to achieve competitiveness and profitability in business.
This study has used quantitative research methods using standard math tools and descriptive statistics to the respective evaluation of companies creating the sample. The quantitative and qualitative criteria have been operationalized by individual indicators in a further step to be quantified and consequently measured. Actual benchmarking has then been performed at this level of individual indicators. Methodology used specifically enabled to perform fundamental analysis and applying financial analysis of companies across the financial indicators method. Normally, the organizational performance is measured in terms of KPIs.
Since too many KPIs can be unmanageable, management has to select appropriate KPIs. According to Swan and Kyng (2004), the suitable number of KPIs should be 4-10. So in order to draw up a clear picture of a company's performance, the following six most important indicators with different types of ratios have been selected for the research: efficiency, profitability, liquidity and financial and investment leverage. The financial, economic and market data for this study has been collected from the reports and accounts. The information gathered for the performance of the analysis refers to the 2012-2014 period. Four companies with high ratings in the country, two of them from Portugal and two from the Czech Republic have been selected for the research.

3.1. Financial analysis

In practice, methods of financial analysis can be used for assessing the market position in relation to the competitors - it is benchmarking. However, understand the results as a whole is needed for assessing the overall situation of the company (Brigham, Ehrhardt, 2011).

3.1.1. Liquidity ratio

A lot about the stability of the company can be found out with the help of liquidity ratios. Liquidity can be defined as the ability to meet the obligations in time and in full scale. We distinguish three types (degrees) of liquidity that are current ratio, quick ratio and cash ratio. Current ratio and quick ratio have been chosen for the analysis.

$$\text{Current ratio} = \text{Current assets} / \text{Current liabilities} \tag{1}$$

$$\text{Quick ratio} = (\text{Current assets} - \text{Inventories}) / \text{Current liabilities} \tag{2}$$

3.1.2. Activity ratios

Using the activity ratios represent one of the important tools of business management because these ratios provide information on the relative involvement of capital invested in assets.

$$\text{Asset turnover} = \text{Sales} / \text{Total Assets} \tag{3}$$

3.1.3. Debt ratios

The analysis of the company's debt management is made using debt ratios - debt ratio and debt to equity ratio. By determining rate of debt, company can evaluate whether it can have further debt without much risk.

$$\text{Debt ratio} = \text{Liabilities} / \text{Total assets} \tag{4}$$

3.1.4. Profitability ratios

Profitability ratios are one of the most observed ratios of the company, because the basic goal of the company is primarily to maximise its profit. These ratios can measure the earning power of the company. The research focuses on the return on equity and return on assets (Nývltová, Marinič, 2010)

$$\text{Return on equity} = \text{Net Profit}/ \text{Equity} \tag{5}$$

$$\text{Return on assets} = \text{EBIT} / \text{Total assets} \tag{6}$$

4. Background of the companies

This article studies practices of four major construction companies which are focused on realisation of transport constructions and which operate actively on the global market: Metrostav, STRABAG Inc. (Czech Republic), Mota-Engil, and Teixera Duarte (Portugal).

Table 1
Overview of the case study companies

	Metrostav (CZ)	STRABAG Inc.	Mota-Engil (PT)	Teixeira Duarte
Employees (global)	2,889	1,912	14,400	13,261
Revenue	€ 1.078 billion	€ 0.399 billion	€ 2.368 billion	€ 1.629 billion
Net Income	€ 17.74 mil.	€ 3.594 mil.	€ 50.6 mil.	€ 63.9 mil.

Source: 2014 annual reports of the companies

Metrostav (CZ). Today Metrostav operates in all segments of the building industry and its activities account for almost half of domestic underground construction as Metrostav is one of the few companies in the country that employ highly specialised mining methods of construction. Traditionally, transport engineering accounted for the largest share by financial volume (almost one-third of projects), followed by civil engineering, industrial construction and projects manifesting the original focus of the company – subterranean bored structures and metro constructions.
Strabag (CZ). Strabag Inc. as a part of the European concern STRABAG SE is a leading construction company in the Czech Republic. Its portfolio of activities includes all kinds of building achievements in the sectors of transport, land and civil engineering. Transportation engineering realises about 70% of turnover of STRABAG Inc.
Mota-Engil (PT). Mota-Engil is a Portuguese Group, leader in the sectors of civil construction, public works, port operations, waste, water and logistics. The Mota-Engil Group comprises 228 companies within three major business areas – engineering and construction, environment and services and transport concessions. The transport concessions are a business area of strategic importance for the Mota-Engil Group. Resulting from its proven experience in designing, constructing and managing transport infrastructures, Mota-Engil Group, through Ascendi, has been asserting itself more and more on a national and international level.
Teixeira Duarte (PT). Having started its activity in 1921, Teixeira Duarte is now the leading number one of the largest Portuguese Economic Groups. Teixeira Duarte operates in 16 countries in 7 different sectors such as construction, transport construction, concessions and services, real estate, hotel services, distribution, energy and automobile industry. Teixeira Duarte is engaged in civil construction and public works. The company also specializes in maritime and river works and rail infrastructures. Moreover company pays big attention to environment, transport and road development.

5. Analysis and discussion of data obtained

Identifying the most successful company is important for determination of the financial health of every company and comparing it with the average for the country. Past, present and future financial performance of the company is

necessary for assessment provided by financial analysis. The main aim of financial analysis is to identify financial health, weaknesses that could lead to further problems and strengths what the company could improve. Balance Sheet, Profit/Loss account and Cash Flow are the main sources of data for financial analysis.
Financial ratios are very powerful tools for performing quick analysis of financial statements. There are four main categories of ratios: liquidity ratios, profitability ratios, activity ratios and leverage ratios. These are typically analyzed over time and across competitors in the industry. Financial analysis is needed for determination of the company status, its position on the market and if it is close to bankruptcy (Sheremet, Negashev, 2013).
Financial ratios have been identified as a result of the calculation of the basic indicators of activity of the firms. For the comparison, the financial position of companies composed of the result list and summary calculations presented also by country have been used for the correctness of the data (Tab. 2).

Table 2
Values found for the companies in the financial indicators during 2012-2014 study period

Indicator		Year		
		2012	2013	2014
Current Ratio	Mota-Engil SGPS SA	0.94	1.0	1.1
	TEIXEIRA DUARTE	0.9	0.96	1.07
	Metrostav Inc.	1.93	1.75	1.9
	STRABAG Inc.	1.83	1.73	1.64

To identify more successful company, the data obtained by financial analysis was converted into the rating form with award marks from 1 to 4. The best performance and the worst performance are shown in Tab. 3.

Table 3
Values of obtained average ratios determined for the companies during the study period

	Current Ratio	Quick Ratio	Asset Turnover	Debt Ratio	ROE	ROA	Average ratio
Mota-Engil SGPS SA	3	3	3	4	2	3	3
TEIXEIRA DUARTE	4	4	4	3	1	1	2.83
Metrostav Inc.	1	1	2	1	4	4	2.17
STRABAG Inc.	2	2	1	2	3	2	2

Source: personally calculated data

Selective analysis of financial ratios of firms showed that all selected companies were affected by the financial crisis. Despite the fact that the crisis has had varying degrees of influence depending on the situation in the country, all companies retained their effectiveness on the domestic construction industry market. So in the times of crisis, construction organizations had to stand idling for months which meant that their short-term losses were equal to fixed costs or overhead value. The lack of demand for the products of construction companies limits the scope of their production, generates losses and the amount which would mean bankruptcy for the majority of companies. In addition, special attention should be paid to the ability of the Portuguese companies not only to survive but also to develop in difficult conditions. After all, Portugal is well known to be one of the countries which felt the greatest impact of negative consequences of the crisis.

Financial analysis has revealed that the most successful company has been STRABAG Inc. Portuguese companies have been the most exposed ones to financial risks as a result of the worst economic situation in the country. As a consequence of that, practice of management of the STRABAG Inc. company has been studied by benchmarking method and recommendations for improving the financial situation of other companies have been developed with special attention paid to Mota-Engil.

Firstly it should be noted that all companies could expand business to other countries allowing a stable growth in the medium run at the cost of higher investment. Furthermore, the increase in private investment, often associated with higher margins for example, will allow Mota-Engil Africa to sustain high EBITDA margins for a longer period as well as to reduce substantially requirements.

An effective way of improving solvency as well as both absolute and current liquidity is changes in the structure of assets of the organization. Thus, the increase in solvency is possible to achieve by reducing the value of stocks in the total assets which grew during the analyzed period.

For this is reason it is better to make an inventory of stocks in order to identify the illiquid ones and reduce necessity for these reserves and costs of them.

To carry out activities for improving values by reducing receivables and delaying payment of accounts payable represent a relatively low and negative trend in the development of indicators of solvency.

High receivable levels indicate that the company does not have a well-organized procedure for checking the ability of the customer to pay in advance for the work performed. It is necessary to increase attention of the management paid to the organization of payment and settlement of relations. In addition, it is important to follow the terms of the debt for each debtor separately and take timely actions to recover the debts. It is also necessary to reduce the proportion of accounts receivable in total current assets of the company - it can increase the solvency and ability to pay its obligations to the creditors.

6. Conclusion

Railways, roads, airports and ports deliver economic, social and political benefits to international and regional markets. Adequate transport infrastructure and services are needed to make both international and domestic markets work. When infrastructure is absent or degraded, it no longer fulfils its connective functions and the economy suffers.

Transport infrastructure is expensive. Huge investments required for building highways, railways, airports and ports must be well planned. If regularly maintained, transport infrastructure can have a long life span. But this is not possible without financial health of construction companies and maintenance of their investment attractiveness. Public policy has a significant influence on the activities of enterprises.

First of all it should be noted that according to the analysis of firms, businesses are in different conditions depending on the country in which the companies operate. Currently the conditions of transport infrastructure can generally be rated as highly developed in large parts of Europe. Nevertheless, it must be assumed that the national transport infrastructures in Europe differ substantially. This assumption is primarily due to the fact that national transport policies have developed differently despite the risen influence from Brussels. So, it is important to note that both examined countries have carried out active policy for the development of transport infrastructure by Strategic Plan for Transport and Infrastructure which will have foreseen investments of 2.8 billion Euros in Portugal and 5.6 billion Euros in the Czech Republic in the railway sector up to 2020 (UNECE, 2016).

In order to review these assumptions, it is necessary to make the benchmarking of chosen companies. The following questions need to be answered:

- Who is the best? – Notation of the performance of the transport infrastructure,
- How does the best do it? – Determination of the relevant areas requiring action in terms of transport policy,
- What can we learn from the best practice?

Benchmarking is a tool of strategic management whose objective is to determine the position of the company on the market, while the attention is paid to identifying strengths and weaknesses and improving this position which is compared to competing companies (Holloway, Hinton, Mayle, Francis, 1997).

Despite the above mentioned benefits of benchmarking, also the risks which may occur in stages and steps of benchmarking should be identified. These risks may jeopardize successful use of benchmarking. Most likely problems can arise during planning, data collection, analysis and adaptation. For example during planning, it could be improper setting the course in defining the subject of benchmarking, insufficient or too extensive study in defining depth of benchmarking, unclear purpose and scope of the project or inability to influence the objectives. In data collection, lack of persuasiveness in establishing contacts, inability to obtain certain data, obtaining false information as a result of the inappropriate information source selection, incorrect transfer due to lack of staff qualifications, obtaining unnecessary or vice versa inadequate information because of poor choice of data can occur. Moreover creating a plan couldn't be implemented in adaptation the results of benchmarking if the effect of benchmarking is not fulfilled, due to lack of stakeholder involvement, unwillingness of employees to cooperate because they have not been adequately explained the benefits of the change, due to lack of control over implementation of identified actions and inability to link these plans. For this reason enterprises should prevent these risks. They have to define steps leading to their elimination. The above listed measures eliminate the risks that occur most frequently in the benchmarking process.

ECONOMIC IMPACTS OF DEVELOPMENT PROJECTS ON TRANSPORT INFRASTRUCTURE IN URBAN AREAS

Daniela Spirkova[1], Marcel Sevela[2], Julius Golej[3], Miroslav Panik[4]
[1,3,4] Institute of Management, Slovak University of Technology in Bratislava, Bratislava, Slovakia
[2] Faculty of Business and Economics Mendel University in Brno, Brno, Czech Republic

Abstract: Investments into construction of development projects evoke considerable demands for further construction of transport infrastructure which development is limited due to the implementation of constraints of the urban environment. Urban space is negatively affected by traffic jams and poor air quality. This means that transport mainly produces emissions that pollute the air, adversely affect the surroundings through increased noise, consumes land and raw materials. The current EU data show that road transport as the largest single type of service is responsible for the largest share of pollution with the production of about 71% of all CO_2 emissions in the transport sector where emissions from passenger cars account for about two thirds. The construction of both new development projects as well as existing buildings is closely related to issue of parking, Which is a long-term problem, both in Slovakia and the Czech Republic. New projects represent an increased demand for parking places and an additional burden for the affected area. Parking costs represent only forced expenditure which investors have to face and often want to save finances upon them. Serious problem of Bratislava and Prague, as the capitals of both countries is precisely the lack of parking places. Parking places are lacking in central areas, but also in housing areas, which is a consequence of sharply increasing number of cars and the lack of conceptual solutions of problems with urban transport. The attempt is to propose solutions based on the concepts implemented in selected foreign examples that use innovative tools and approaches in the field of intelligent transportation. The aim of the paper is a comparative analysis and critical assessment of the current state of static transport in Bratislava and Prague, Which belong to the most densely populated agglomerations in Slovakia and the Czech Republic.

Keywords: development projects, transport infrastructure, urban development, transport economics.

1. Introduction

European cities are important centers of housing, economy, culture and from over 80% of EU GDP. There are more job opportunities than in rural settlements. On the European continent, despite the expected decline in the population, the number of people living in cities by 2050 will increase from 73 to 80%. Urban areas are responsible for a high proportion of total CO_2 emissions from transport, about 23%. Urbanization, greater integration and global cooperation supports economic growth and helps foreign trade, investments and the proliferation of ever-accelerating technological progress. On the other hand, the city is constantly evolving as a result of new development projects, which take over quality agricultural land and increase demands on static traffic.

Most planners and city politicians agree that urban sprawl endangers the sustainability of urban development. There is a clear conflict between the benefits of the few who get better life conditions in the suburbs and the problems of the many whose quality of life is negatively affected by the externalities (environmental consequences of land take and growing traffic) of sprawl. The extremely low price of agricultural land (in most cases good agricultural land) compared to already urbanized land (e.g. brownfield sites) or former industrial sites, is also an important factor underlying urban sprawl. In many development projects, the cost of agricultural land acquisition is relatively low. Thus, it enables greater profits to be made compared to those from already urban land or former industrial waste land, even in cases where no remediation is needed (non-polluted sites) (Oueslati et al, 2015).

An exception are not even the capitals of Slovakia and the Czech Republic, Bratislava and Prague. In connection with spreading of cities and the increasing number of cars, transport problems and problems with parking capacities are growing. The causes are rooted in the past in the context of intensive construction of residential areas from time before 1989, when the vehicle ownership per capita was not as high as it is now and such rapid growth was not foreseen in the future (Fig. 1).

Current problem of transport in these capitals is that they are centre of interest to development companies for the construction of such residential and commercial real estates. Currently (August 2016) in Bratislava are registered 79 new development projects and 115 in Prague, most of them is located near the centers of these capitals. This results in ever increasing number of registered vehicles, and thus the demand for parking spaces.

Private car traffic brings also a range of costs and externalities, such as air quality and noise which both cause reduction of the value of the property in close proximity to busy roads and streets, which also reduces the quality of life for local residents and workers. They can then prefer moving into more remote and less burdened parts of the city. On the other hand, because of inadequate transport infrastructure, they will use primarily vehicular traffic. It is important to realize that transport is not an isolated phenomenon, but an integral expression of land use. Its intensity is also a subject exposed by the structure of the city.

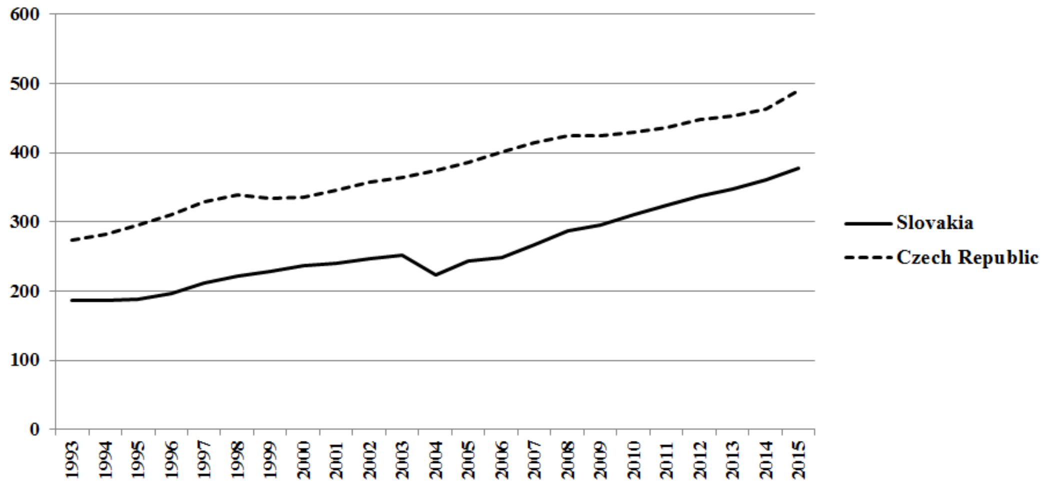

Fig.1.
Motorisation rate (the number of passenger cars per 1 000 inhabitant) 1993 - 2015
Source: Own calculations based on data from the central vehicle register of the Ministry of Interior of the Czech Republic and vehicle registration of the Ministry of Interior of the Slovak Republic

This means that an increasingly large degree of motorization brings in both capitals increasingly greater space requirements. That causes the space became the most valuable object. One of the most serious current problems that closely related to urban space in Bratislava and Prague is the traffic situation, in particular the issue of static traffic. However, space for static traffic cannot be longer solved by organizational measures in communications network and open spaces, as these opportunities are mainly in the city center and already used up. Also current static traffic facilities can not meet the actual needs of the resident population. The problems also becomes with the communications capacities, particularly nodes connecting service and collection roads and approaches to mass storage amenities. Conflicts between vehicular traffic and preferred bicycle and pedestrian movement are also happening more often. Their solution is very difficult, as the overall poor urban concept does not allow to space separation of transport service of automobile transport from walk and bicycle transport even in a recreational location nor in the position of transport service. Last but not least, the static traffic complicates the situation of fire fighters during fire fighting including possible evacuation of people with a high-lift machinery, and most problematic situation is a dense concentration of residential buildings with lack of parking spaces. As an transparent example we can use Petržalka, which is the largest urban area in Bratislava (Spirkova et al., 2014) where the most working population across Bratislava is concentrated.
Car-sharing is an innovative approach to growing traffic problems in major metropolitan areas. Car-sharing is a service that operates on the basis of using a car without owning it, pay insurance and care for its operation and maintenance. For car-sharing could be to some extent considered a renting a company car to its employees. The less often the car is used, the lower the cost of the actual driving (variable costs), while the higher cost of the independent expenses (fixed). The advantages of car sharing are based mainly on financial savings. When driving less than 15 000 km per year, participation in car-sharing is cheaper than owning a car. It is due to elimination of fixed costs - purchase of car, repairs, insurance, accident insurance, car wash and parking fees in the city. User pays only for the time he uses the vehicle. Another positive fact is saving the environment. Although car-sharing user has the same opportunity to use the car as his own, see the real cost per kilometer better and often chooses other ways of transport - go on foot, ride a bicycle or public transport. This limits the unnecessary traffic over short distances. According to a study conducted by the Swiss Office of Energy, it shows that car-sharing users reduce their energy consumption in transport by 50%. Significant benefits of car-sharing can be seen from different views of society and the city:

- Encourages greater use of public transport,
- Increases urban security and reduce traffic jams,
- Improves the availability of the car for everyone, thereby improving the mobility of poorer people,
- Reducing the consumption of fossil fuels,
- It is a tool for more economical utilization of the fleet,
- Supports the local economy,
- Promotes neighborly relations and community,
- Reduces total mileage,
- Reduces emissions and thus saves the environment,
- Replaces old vehicles with new more efficient vehicles,
- Provides a new element of urban mobility.

The sharpest increase in car-sharing users takes place in Europe and the world in the last 10 years. The number of people using car-sharing has increased from less than 20,000 in 1995 to more than 120,000 in 2000. At present, most

systems of this kind are active in Switzerland, Austria and Scandinavia. People can be involved in the system of car-sharing (under different names and in different versions) already in nearly 500 cities in the world. It is also interesting that the addition of urban transport to this system does not require any subsidies from public budgets. All necessary fees will be covered by user (Kutacek, 2003).
One example is the Belgian city of Ghent, where car-sharing is one step for the ambitious urban development strategy called "climate neutral Ghent2050".This strategy is defined by its vision - to be climate-neutral city by 2050 - which focuses on all aspects of the functioning of the city, not only for transport.
As part of that strategy was drawn "plan of solving climate change for the years 2008-2020" (it is an action plan with 105 activities) and "plan to fight air pollution. "It suggests (in addition to car-sharing) a number of specific steps, such as: tools to encourage cycling as an emissions-free transport, 'greener' public transport, low emission zones, traffic management systems and so on. (Bruhova-Foltynova, Jordova, 2012).
Another example is the Spanish city of Donostia-San Sebastián which by promoting sustainable mobility took a number of activities and campaigns, including system car-sharing and car-pooling, etc.

2. Methodology and Materials

In the paper were used the statistical data and analyzes done by Eurostat, the Czech Statistical Office, Statistical Office of the Slovak Republic, Automotive Industry Association and Czech Republic Automotive Industry Association of the Slovak Republic. Based on data from the central vehicle register of the Ministry of Interior of the Czech Republic and vehicle registration of the Ministry of Interior of the Slovak Republic we calculated the motorization rate. This indicator is defined as the number of passenger cars per 1 000 inhabitants. A passenger car is a road motor vehicle, other than a motorcycle, intended for the carriage of passengers and designed to seat no more than nine persons (including the driver); the term "passenger car" therefore covers micro-cars (need no permit to be driven), taxis and hired passenger cars, provided that they have fewer than 10 seats; this category may also include pick-ups. Further were analyzed the selected documents and regulations of capitals of the Slovak Republic (General regional transport plan of capital Bratislava and Methodology of traffic capacitive impact assessment of investment projects) and the Czech Republic (Prague construction regulations and Vision for mobility and public space - Prague 2025), which are the starting points for tackling the problems of the static traffic. Prague construction regulations regulate the system for calculating the capacity of parking for new construction. The document "Vision for Mobility and Public Space - Prague 2025" includes solutions of reduction of the demand for automobile transport in the wider center. This is a promotion and implementation of alternative transport such as car-sharing, carpooling, and so on.

3. Results and Discussion

The problem in a comprehensive transport solutions in Bratislava is the lack of sufficient database of traffic data and the city/0} does not have detailed current conditions of its urban road network. City of Bratislava lacks regular traffic surveys and the results which would show the disproportions for current situation and predict its evolution (Methodology of capacitive traffic impact assessment of investment projects, 2014). In accordance with the approved Methodology of traffic capacitive impact assessment of investment projects in 2014, it is important that any investment project (or group) in defined range should be subjected with traffic engineering analysis to preparatory documentation in space and time in order to benefit and demonstrate the carrying capacity of the territory of the new road infrastructure. One of the starting points of this methodology with regard to development activities Bratislava was the definition of an investment project - "building investments whose primary requirements for static traffic excess 300 new parking places." The results obtained using the above methodology should enable the developer to obtain information primarily on the extent and quality of the increased load of dynamic and static traffic in the area of interest in terms of their upcoming projects and propose solutions and measures which will eliminate negative impacts on the territory.
The general regional transport plan of capital Bratislava shows (December 2015) that the City of Bratislava is a city with monocentric structure and highly concentrated built-up area of 8 clearly identifiable urban units, which are located in 4 urbanization axis. Acording to Bertaud (2009) “The Classical Monocentric model: strong high density center with high concentration of jobs and armentities, radial movements of people from periphery toward center”.
Capacity for parking in Prague for new construction determine Prague building regulations (PBR), which reflect the new paradigm of so-called compact city, which opposes the principles of the Athens Charter. Prague has in comparison with the Czech Republic its own specific building legislation. The fact that the City of Prague can adjust the requirements for land use and construction by itself from the rest of the Czech Republic, with the importance and specific nature of the construction in the city. The current version of the (PBR) enters into force on August 1st 2016. It establishes minimum, but also the maximum number of parking places and addresses storing bicycles. PBR ideologically reflect new urban trends (Wien, Zurych, Berlin, Copenhagen) and revive traditional planning tools emphasizing block development, town-creating elements, the quality of public spaces, and economically sustainable living and ground green parter. Their implementation has been the subject of professional and institutional disputes. Generally, the PBR is considered as more liberal. PBR provides solutions for a system of calculation parking capacity. Conversion works by determining the percentage of the basic number of parking spaces for each zone in the area by land plan in the Annex of given regulation. The aim is to make the illegal parking worthless. Even so, some opinions consider the requirements for parking as excessive and forcing builders to construct unnecessary parking with negative

impact on the price of the apartments. In Vienna, a city typologically similar to Prague, was created the project of house (Bike-City), which is adapted to the purpose of its inhabitants who prefer bicycle transport (the housing project "Bike-City“ focuses on the needs of bicyclists, but the true innovation came about by convincing the Vienna government to exempt the development from obligatory parking lot legislation. Accordingly, money that would have been put into constructing parking space has been invested in facilities that directly improve the resident's standard of living. The project has received a lot of attention and has already resulted in plans for another bike-city project in Vienna).
For individual purposes of use is in the appendix 2 of (PBR) established indicator of the basic number of parking spaces, which is defined by gross floor area of the purpose of use of 1 m^2 per parking space. For the family house (the use for housing) is necessary to establish one parking space per 85 m^2 of gross floor area (GFA) for purpose of living. It is up to the gross floor area (see § 2 letter g + comment on p. 48 of publication) of a family house, to GFA for the purposes of calculating of the necessary parking spaces are not included areas of garages, basements, technical and auxiliary premises and technical infrastructure facilities. At the same time it introduces a correction of max. 2 spaces per apartment. So if the calculation result in more parking spaces than 2 spaces per apartment, for a base number of parking space is used the number of housing units x 2 parking spaces.
In the centre of Prague already are thousands of parking spaces which nobody uses. If the construction regulations for the central part of the city do not have set a limit for the number of parking spaces, then it should be an upper limit, not lower.
Parking places are distinguished as binding (for the users of buildings) and visitor parking. The resulting number of places is limited on both sides (minimum and maximum) and is calculated separately for housing and other purposes of use of buildings. Besides the capacity requirements, determined are also requirements as the form and character of (method of location) parking lots, their landscaping, etc. Paradoxically, now more parking problems show Prague postwar neighborhoods than the inner city. Limiting the number of parking spaces is fairly effective regulator - generally traffic is efficiently regulated by the capacity limits on the principle of traffic induction and reduction that are valid also for transport at quiet period of day. Lack of parking is a mental barrier for the decision to go by car. Copenhagen for 30 years reduces in the city center every year 2% of parking places in the streets. Zurych and Bern set a ceiling for parking capacity in the city center according to limit from 1993 and approval of the construction of additional parking places in conditioned by cancellation of a parking space on the street.
Quite surprisingly public in Prague absorb new paradigm of public space and parking itself ceases to be seen as a key aspect of quality of life.
The key problem of Prague transport is transport that is consequence of chaotic suburbanization of the Nineties. From the so-called satellites arrive to the city center thousands of cars that have no place to park, where construction of Park & Ride parking spaces is limited by the lack of suitable land on the outskirts. Generally, new urban trends (e.g. Danish architect Jan Gehl) emphasize more human scale and quality of public areas and divert it from adapting town planning transport infrastructure. It can be assumed that some of the new technological and socio-economic trends (autonomous transport, car-sharing), help to implement this approach faster. A key condition of such an approach is sufficient quality of public transport, public spaces as well as a shift in the value scales of municipal representation and residents.
Paid parking zones are distinguished by colored stripe on the table under additional traffic signs indicating parking (see Fig. 2):

- **Blue Zone**: parking allowed to residents and subscribers - citizens and entrepreneurs residing in the district, based on the purchased parking card (parking card do not guarantee a free parking place to its holder); In legal terms, the blue parking zones are reserved parking places which means that towing illegally parked vehicle is possible even when it is not causing an traffic obstruction,
- **Orange zone**: short-term parking (up to 2 hours) - with payment using parking meter;,
- **Green Zone**: mid-term parking (up to 6 hours) with payment using parking meter,
- **Reserved parking**: For disabled people is parking characterized by lawful claim; for other subjects usually by special permit of road use; with commercial entities with significant charge.

The system is functional since autumn 2014 with four types of zones. Existing **green areas** for mid-term parking **are replaced with mixed purple zones**, **newly to be introduced green zones for selected types of vehicles.**
Mixed zone (purple) during the day (tentatively set for a period from 8 a.m. until 8 p.m.). There can park in addition to residents also other drivers, parking is paid.
Visitor Zone (orange): paid parking with limited time up to two hours, designed for medical centers and offices.
Residential zone (blue).
Ecological zone (green) for ecological cars and trucks in the system of car-sharing.

New parking zones in Prague
Source: www.praha.cz

4. Conclusion

The fact is that both cities are centers of interest to development companies for the construction of such residential and commercial real estates which results in increasing rate of motorization. Furthermore, it is non-existent support system of public transport, demand, lack of parking places and pressure from developers. Each function generates a certain number of parking places.
The problem of parking in Prague is generally not related with some kind of planar lack of parking spaces. In Prague's neighborhoods (relatively autonomous neighborhoods) is realized since 2007 (in the narrow historic center since 1996) the introduction of so-called blue zones, which in fact allows parking only for residents. The pricing policy of parking permits in each district differ fundamentally, however, it depends on the rule that for residents (household), the price for parking one car is negligible, but for parking the next second, third car is very expensive. The number of districts, which regulate parking, gradually increases from the center to the periphery of the city, because of the introduction of the regulation, part of drivers move to cross-border city district.
Basic problems with parking in Bratislava can be summarized into four areas:

1. Illegal but also legal, but standing with adverse impact on traffic safety, throughput of local communications for emergency vehicles as well as pedestrians and cyclists. Vehicles parked on the sidewalk, on the grass, at the crossroads, on bike paths, squares and pedestrian zones. Public space then looks like the car park where pedestrians "intertwine" between cars,
2. Paying recklessness exceeds 50%. This significantly influences the transport behavior of residents and visitors - car becomes quick and cheap way transport when traveling to Bratislava,
3. Resident parking does not have a common form and the rules in the city. Ownership of more than one vehicle is not specially charged and vehicles are parked on a public space. Lack of regulation that blocks the efficient introduction of the concept of sharing (car sharing, car pooling), greater modal split in favor of public transport and encouraging cycling.,
4. Missing comparison between the offers of transport methods, i.e. navigation / mobile application / website informing the public about travel alternatives (implemented in established and immutable routes and methods of transport), for example navigation for cyclists (map of safe cycle tracks with speed information) and the necessary infrastructure (e.g. a secure storage for bicycles).

Due to request of Old Town (central and historical part of the Bratislava) were commissioned a static transport analysis and paid parking project in the area of this city district. The expected solution is to create a simple and transparent system, where nobody will have the right to reserved parking, all parking spaces will be available to all drivers. Regulatory tool of static traffic in the Old Town should be the price of parking, and residents just like everywhere in the world will have an advantage over visitors and the introduction of short-term parking - limited up to two hours. City of Prague was used as an example for the drafting of solutions to the problems of static traffic due to many years of successful experience in this field.

PROVABLE LOSS IN PUBLIC LINE TRANSPORT AND TRACK-BASED PASSENGER TRANSPORT

Jiří Čejka[1], Martin Telecký[2]
[1] *Institute of Technology and Business in České Budějovice, Department of Informatics and Natural Sciences, Czech Republic*
[2] *University of South Bohemia in České Budějovice, Faculty of Economics, Department of Accounting and Finance, Czech Republic*

Abstract: The transport policy of the government in ensuring the transportation performs a critical function, be it the public line transport or the track-based passenger transport. The government here stipulates the basic international legislation and agreements. The transport companies must agree the terms and conditions which are included in the public service contract with the specific client (municipality, region, state). The terms and conditions are related to the determination of the amount of a provable loss, adequate profit and consequent paying to the relevant transport companies from the public budgets of the different tiers of government. The calculation of a provable loss and other indicators is regulated, as to its development, by Regulation No. 241/2005 Sb. and Regulation No. 493/2004 Sb. What is more, it does not have to always meet the requirement of capturing the objective reality.

Keywords: public line transport, public track-based passenger transport, public urban transport, provable loss, adequate profit, economically substantiated costs.

1. Introduction

Ensuring of the traffic services is included in the primary services that the inhabitants and tourists are provided with by the state, regions and private carriers for a certain price. Besides the public line transport, also the public track-based passenger transport must be financed from the public budgets in individual regions of the Czech Republic. An important indicator for the potential cash injection for the transport companies in the public line transport or the public track-based passenger transport is a provable loss. The attention paid to this indicator may be, hence, deemed necessary. This paper is aimed to analyse Regulation No. 241/2005 Sb. on the provable loss in the public track-based passenger transport and on the definition of the parallel public passenger transport, Regulation No. 493/2004 Sb., regulating the provable loss in the public line transport and specifying the method of the exercise of the professional government supervision in the road transport over funding the traffic services, and Regulation No. 296/2010 Sb. on the procedures for establishing the financial model and setting the maximum amount of the compensation. Based on the analysis of the above regulations, it is necessary to draw up the information on the adequate profit and the classification of the substantiated costs and sales. These regulations will be compared and their differences and deficiencies will be pointed out.

2. Financing of public passenger transport

2.1. Provable loss in the public line transport

In case of the public line transport, the "provable loss" term is defined (pursuant to Regulation No. 493/2004 Sb.) as the difference between the sum of the economically substantiated costs and the modified adequate profit and the earned receipts and revenue.

2.2. Provable loss in the public track-based passenger transport

In case of the public track-based passenger transport, the provable loss is stipulated as the "*difference between the amount of economically substantiated costs increased by the adequate profit and the total revenue from the operation of the public track-based passenger transport using the regional and nationwide transport trains".*
To calculate the provable loss, the carrier has to allocate the economically substantiated costs to the stretches of tracks separately for the trains serving the regional transport and the nationwide transport and to divide them into the territorial districts.
Based on the basic report of the costs and revenues from the transport activity in the public track-based passenger transport, the following is included in the revenues:

- Receipts from the fare,
- Receipts from the luggage transportation,
- Receipts from the surcharges and fines for failure to meet the transportation code,
- Receipts from other services related to the passenger transport,
- Loss paid from the pupils´ fare.

[1] Corresponding author: cejka.jirka@volny.cz

In the public track-based passenger transport, the total revenues will be ascertained upon all types of the income transport documents maintained in the carrier´s accounting system. The receipts from the fare will be divided for the regional transport trains and the nationwide transport trains and then according to individual territorial districts of the region. The loss paid from the pupils´ fare will be calculated as the difference of the fare without the discount for the pupils´ fare and the fare with the discount for the pupils´ fare. The loss paid from the pupils´ fare (prices excl. VAT) is calculated and submitted to the Ministry of Transportation by the carrier himself to be paid the provable loss. The more exact terms and conditions are set forth in the public service contract.
The provable loss is covered from public budgets (of municipalities and regions); more exact terms and conditions for payment of the loss are provided in the public service contract concluded between the client and the carrier. Under this contract, the provable loss may be paid out as advance payments for every quarter provided that the preliminary report of costs and receipts from the transportation activity in the public line transport and the track-based passenger transport is made. These financial means designed to cover the provable loss cannot be used for any other business purposes.

2.3. Adequate profit in public line transport

Another important indicator is the adequate profit in the public line transport and the track-based passenger transport.
Regulation No. 493/2004 Sb. defines the "adequate profit" term. *"The amount calculated as the sum of the amount which after taxation and a minimum allocation to the mandatory funds does not exceed 1/8 of the price of buses used, as a rule, for the public line transport by meeting the public service obligation, and the amount which does not exceed the share of the price of investment related to the operation of the public line transportation corresponding to the service life as per the special law provided that the transportation authority (client) has given consent to inclusion of these investments into the calculation of the provable loss."*
$[(\frac{number\ of\ buses\ x\ price\ of\ a\ bus}{8} - depreciation\ of\ buses)/coefficient]$ – earmarked subsidy from the state budget and the client´s budget for the purchase of buses,
where:
The coefficient is calculated as follows: $\frac{100-\%\ income\ tax}{100}$. The coefficient is used for the needs of including the corporate income tax.
Under the contract, the carriers are allowed to pay out the adequate profit, which is designed for the renewal of vehicles in the public line transport and the urban public transport (buses) only. As well as the provable loss, the adequate profit cannot be spent on any other business purposes. It is understood as an option of obtaining the financial means (resources) for the rolling stock renewal.

2.4. Adequate profit in public track-based passenger transport

Pursuant to Regulation No. 241/2005 Sb. the adequate profit in the public track-based passenger transport must not exceed 5 % of the economically substantiated costs.

3. Classification of economically substantiated costs

For calculating the provable loss and the adequate profit, it is necessary to classify the economically substantiated costs. The economically substantiated costs pursuant to Regulation No. 493/2004 Sb. on the provable loss and Regulation No. 241/2005 Sb. are classified as follows:

- **Fuel** – consumption of fuel, consumption of diesel, oil, gasoline, lubricants for the mileage in the bus line transport for the whole accounting entity
- **Traction energy, traction diesel on the rolling stock, traction energy on trolleybuses**
- **Rubber rims** – new tyres, inner tubes, valves, etc.
- **Other direct material** – spare parts, electric parts, cleaning and washing detergents, anti-freezing mixtures, uniforms, protective aids, common repairs (it is a direct material directly consumed for the buses, rolling stock)
- **Direct wages** – wages of drivers, inspectors, guards/conductors, cleaning staff, cash desk personnel, technical and economic staff, etc.
- **Depreciation of buses** – depreciation of the buses, tangible fixed assets which are directly associated with the bus line transport, depreciation of the capital goods related to the information system of the pre-sale of tickets; the accounting entity will determine the procedures for the fixed assets depreciation and will set the depreciation rates by itself (as per the performance, in terms of time, etc.).
- **Depreciation of the rolling stock –** only the accounting depreciation, see the Depreciation of buses.
- **Means of transport leasing** – lease instalments for the means of transport, equipment related to the operation of the public line transportation, cost of down payment
- **Repairs and maintenance of buses** – external repairs quantified upon individual invoices, their own repairs
- **Road tax** – buses providing the internal national transport are exempt from the road tax

- **Third party liability insurance** – it is the statutory insurance and the collision insurance related to the bus line transport and the public track-based passenger transport
- **Fare** – travel costs pursuant to the Transport Compensations Act
- **Payments to the funds** – social security insurance, contribution to the State employment policy and the premium paid for the general health insurance
- **Overhead costs** – costs directly related to the bus transport operation and the regular line transport operation; the accounting entity must determine the method of the overhead cost dissolution in the contract (as per the mileage, number of drivers and vehicles, or based on the operating costs); the method of the overhead cost dissolution is established upon the travelled train-kilometers in the public track-based passenger transport
- **Charges for the use of the rails, if the carrier is not an owner of such rails. In this case, the carrier will make an agreement with the Railway Infrastructure Administration (RIA, the Czech abbreviation: SZDC)**

Prior to making the contract, all cost items directly related to providing traffic services must be discussed.

4. Regulation No. 296/2010 Sb. on the procedures for establishing the financial model and determining the maximum amount of compensation

The Regulation No. 296/2010 on the procedures for establishing the financial model and determining the maximum amount of compensation supersedes the term "provable loss and the adequate profit" by the term "amount of compensation."

Under the new regulation, the carrier is required to submit to the client all information on the situation of its assets related to providing the traffic services, the performance and all activities. The carrier is thus more intensively controlled and the more demanding requirements are applied than in case of the previous regulations.

The maximum amount of compensation will be calculated in the same way as the adequate profit, however, the requirement of the maximum permissible rate of return per the capital must be met.

Pursuant to Regulation No. 296/2010 Sb., each carrier is required to report all of its operating assets before making the contract. This necessity was not directly required in Regulation No. 493/2004 Sb. The reason for reporting operating assets is a new requirement for not exceeding the maximum permissible rate of return per the capital, being 7.5 % annually from the operating assets. The maximum permissible rate of return per the capital is calculated as a share of net income and the value of operating assets under the public service contract. Only the value of operating assets in the amortised cost at the end of the immediately preceding accounting period will be included in the operating assets.

The transportation companies must use the assets which are always procured and recorded as their property. To calculate the adequate profit, it is necessary to determine the exact amount of depreciation and the average prices of buses providing the traffic services. In case of the public track-based passenger transport, it must not exceed 5 % of the economically substantiated costs.

If the assets are leased, the carrier may include only the first extraordinary instalment to the leasing company in the operating assets and reduce its value evenly throughout the leasing period. In case of the leaseback, the assets must not be included in the operating assets. The accounting entity will post the leaseback in the Other revenue item. The leasing company then becomes the owner of a vehicle. The carrier will then only pay the rent to the company. The rent may show only indirectly in the costs per the output unit (km).

Pursuant to Regulation No. 296/2010 Sb. on the procedures for establishing the financial model and determining the maximum amount of compensation, the sales in the public line transport and the track-based passenger transport are divided as follows:

- Sales from the fare (sales obtained from passengers – fare)
- Other sales from transportation (sales from the luggage transportation, other surcharges for failure to meet the transportation code)
- Other revenue (revenue from the sale of the fixed assets is not included; pursuant to the agreement in the "contract", we can include the revenue from the sale of assets in case of the leaseback transaction which can accrue throughout the leasing period).

Regulation No. 296/2010 Sb. divides the revenues (sales) into three groups. The reason is better explanatory power and correct posting of some sales or revenues in the required group of revenues (sales).

Pursuant to Regulation No. 296/2010 Sb. the initial financial model must be established prior to making the contract and all prerequisites and the expected development must be known so that the net income is not a negative value.

If the costs in the report on the actual costs and revenue in the public line transport and the public track-based passenger transport are lower than in the initial financial model or if the revenue is higher, the accounting entity will return the different amount of compensation to the client or will transfer the difference into the next period as agreed in the contract. If the actual costs are, on the other hand, higher than in the initial financial model, only a half of the value from the different deviation will be paid. With respect to financing of the traffic services, it is not the incentive behavior. The carrier is bound by the contract where these facts are usually addressed. A specific addendum to the contract is, moreover, concluded to unambiguously specify the financial amount to be paid to the carrier by the client.

The contract may require the payment of the full amount compensation.

5. Conclusion

Many carriers who have made the public service contracts follow the still valid Regulation No. 493/2004 Sb. and Regulation No. 241/2005 Sb. After the contract terminates, however, a new contract will have to be made. This contract will already contain the new rules and conditions of payment of a maximum amount of compensation pursuant to Regulation 296/2010 Sb. The principle of paying the maximum amount of compensation is similar to that of the provable loss and the adequate profit, however, the older terms were replaced with the new ones, and the new rules and the new reports with newly divided costs and sales were created to determine the maximum amount of compensation. The Regulation No. 296/2010 Sb. requires more detail information on the carrier providing the traffic services to avoid unnecessary overestimating of the amount of compensation. Regulation No. 493/2004 Sb. and Regulation No. 241/2005 Sb. do not require these detail requirements; they, however, must be determined in the contract between the carrier and the client. Originally, the requirements were negotiated between the carrier and the relevant transport authority. The payment of the provable loss and the adequate profit (maximum amount of compensation) is mostly negotiated in the contracts and may deviate from the relevant regulation. The conditions and the method of determining the adequate profit are individually set forth in every region in the public service contract. If 5 % of the adequate profit is taken into account in the public track-based passenger transport, it is, basically, a very reasonable percentage of the economically substantiated costs. In many contracts made with the carriers, approximately 2 % of the economically substantiated costs are reckoned with.

Regulation No. 296/2010 Sb. requires that every carrier submits to the client the situation of its assets, without the operating assets, which the carrier directly uses to ensure the traffic services. In my opinion, this condition is satisfactory as the maximum amount of compensation is established in this way. Upon the amortised cost the client receives the information on the age of the rolling stock and, finally, provides higher compensation for the renewal of the older rolling stock with partially new vehicles.

For the purposes of the cost breakdown in the track-based transport, the procedure for determining the amount of the provable loss is insufficient. The reason is especially the use of the heterogeneous group of the powered and non-powered vehicles on the same lines, the different capacity of trains and other factors. These facts have a significant influence on the operating costs of individual lines.

The task was to compare two basic regulations in the public transport which determine the amount of the provable loss and the adequate profit. Regulation No. 493/2004 Sb. and Regulation No. 241/2005 Sb. were superseded with Regulation No. 296/2010 Sb., which already meets the European standards and requires more detail information on the accounting entity providing the traffic services. The advantage of Regulation No. 493/2004 Sb. is not the requirement for not exceeding the maximum permissible rate of return per the capital, but the carrier obtains just a part of compensation under the terms and conditions of the contract. The accounting entity must present to the client the initial financial models including the initial costs and sales (revenue) and the report of operating assets and prepare the reports of actual costs and sales (revenue) at the end of the accounting period and resolve the deviations, if any. This will remove the risk of overestimating the cost items and increasing the net profit which is closely related to the amount of compensation. Most transport companies still have the valid public service contract pursuant to Regulation No. 493/2004 Sb. and Regulation No. 241/2005 Sb. For the external users it would be good to specify in more detail some cost and revenue items in order to make the explanatory power of the reports more efficient. The Regulation No. 296/2010 Sb. lays down the basic requirements upon which the maximum amount of compensation is calculated by means of establishing the initial and actual financial models. For calculating the net profit, it is necessary to know the amount of operating assets included in the report of operating assets. The Regulation should, however, justify in more detail why some items are not included in the total value of operating assets.

THE COMPARISON OF PUBLIC ROAD AND RAILWAY TRANSPORT COSTS

Václav Cempírek[1], Petr Nachtigall[2], Petr Novák[3], Matěj Pluhař[4]
[1,2,3,4] The University of Pardubice, Jan Perner Transport Faculty, Pardubice, Czech Republic

Abstract: This article compares the costs of public road and railway regional passenger transport in the district of Pardubice. The article focuses on the differences in unit costs between two means of transport, the objective point of view of the road and railway transport costs in the Pardubice region. The topic of the solution is the classification of the differences in costs for road and railway passenger transport because road transport does not include costs for road infrastructure.

Keywords: costs, railway transport, road transport, fees.

1. Introduction

In terms of costs, we can observe significant financial differences and completely unlike approach to cost issues between road and railway transport. In railway transport, we have to distinguish whether the commissioner acts in the interest of the state transport services (i.e. the state through the Ministry of Transport of the Czech Republic) or to secure regional transport service.

Road bus transport in the Czech Republic is commissioned solely for the needs of regional transport services; so-called long distance (or other) lines operate accepting the business risks and their costs are hence covered by the transport carrier. In terms of actual costs processing, we have to differentiate several calculations, which are described later in the article. In another part we investigate and calculate actual costs for a chosen example, especially with respect to fees paid for use of railway infrastructure; the calculation, procedure, and fees are more or less different in every European country.

2. Defining the costs of the Pardubice Region

Defining the costs of the Pardubice Region (PR) is based on the fact, that PR grants subsidies from the Regional Office´s budget for both bus and railway public regional transport. This cost defining is based on actual costs paid by PR to individual transport companies under contracts concluded according to the Act No. 194/2010 Coll., On Public Services in Passenger Transport and amending other acts; between PR and individual transport carriers.

It must be pointed out that these actual costs are not those that are borne by the transport company itself, but those borne by the Pardubice Region. This study investigates these costs of the transport company because the amount of compensation and hence costs of PR depends on these costs as a part of income, revenues and subsidies determined on the basis of transport carrier´s "financial model".

The range of planned services in road transport was set as high as 16,110,377 bus-km for the year 2015 with overall compensation for all transport companies at CZK 299,542,449 and an average subsidy of CZK 18.60 per bus-km.

On the other hand, the range of planned serviced in regional rail transport was set to 4,776,692 train-km for the same year with overall subsidy valuing CZK 478,264,460 and hence an average compensation of CZK 100,12 per train-km.

The subsidy is paid from the PR's budget in costs of transport services. On the basis of the Czech Government Resolution No. 1132 of August 31, 2009, and the Czech Government Resolution No. 1350 dated October 28, 2009, the State participation in funding railway transport for long-distance transport was approved by a concluded Memorandum about the commitment by the State to finance regional rail transport.

Five variants were selected for the processing procedure and as well as the basis for alternative calculations and comparison of the cost of a public road and railway regional transport.

The actual processing of costs of securing the transport services was carried out in four variants and its results are shown in a table following the description.

- **Variant No. 0** (Current state) is a current state variant that is used to determine the cost of both types of public regional transport. This alternative does not represent the result to this study but it is shown for the complexity of the solution,
- **Variant No. 1** (Direct costs calculation) is based on actual cost of the transport carrier (total financial cost) processed on every route (on every line) and therefore also on collated data from individual routes or lines for the full range of provided transport services in train- and bus-km. On the basis of thus identified transport company cost it is possible to compare the cost of public road and railway transport by cleansing the cost of railway carrier (variant No. 2) or by increasing the cost of road carrier (variant No. 3) and by this to achieve comparable base for both public transport types,
- **Variant No. 2** (Comparable cost – railway transport adjusted) is based on cleansing the costs of both transport modules so that are comparable. The costs are stated in three categories: comparable, incomparable and

[4] Corresponding author: matej.pluhar@student.upce.cz

adjusted. For the purposes of cost comparison, the adjusted costs of the railway carrier are used (without infrastructure cost, without the cost of levy for renewable electricity sources and the costs of building fund).

- **Variant No. 3** (Comparable cost – road transport increased) focuses on problem of different range of costs by increasing the cost of the road carrier by infrastructure cost and cost of other services that need to be covered by railway carrier on its own account but not by the road carrier (such as maintenance, repair and investments into the road system, IRS, the Regional Office staff, etc.),
- **Variant No. 4** – this alternative, according to the methodology set up by Transport Bulletin 11/2013, issued by the Ministry of Transport of the Czech Republic quantifies **external costs.** (The ministry od Transport, 2016).

Table 1
Comparison of variants

Variant	Transport type	Per 1 km	Per 1 seat-km	Per 1 customer	Per 1 passenger-km
		[CZK]	[CZK]	[CZK]	[CZK]
0	Train	100,12	0,67	44,49	2,80
	Bus	18,60	0,41	26,16	2,63
1	Train	111,68	15,52	x	x
	Bus	120,84	31,33	x	x
2	Train	88,26	0,59	39,22	2,47
	Bus	18,60	0,41	26,16	2,63
3	Train	100,12	0,67	44,49	2,80
	Bus	25,14	0,56	35,28	3,54
4	Train	125,42	0,84	55,73	3,51
	Bus	36,12	0,80	50,73	5,09

However, the **other European countries** should be also checked, how they process their transport costs. The calculation of fees for use of railway infrastructure, when compared to other countries, takes into the account similar conditions of railway categories in Pardubice Region, which are set up as following:

- **category of nationwide** (corridor) electrified lines, for example, Česká Třebová – Pardubice,
- **category of regional lines**, for example, Pardubice – Hradec Králové or Pardubice – Havlíčkův Brod,
- **category of secondary lines**, such as f. e. Choceň – Litomyšl or Přelouč – Prachovice.

Fees for use of railway infrastructure in some EU countries
It was decided for a model calculation because the actual comparable data from individual countries cannot be obtained due to their confidentiality.
For a **model calculation of fee for use of railway infrastructure, a trainset** consisting of a motor unit of 844 series (RegioShark) was chosen, which also consists of two connected carriages with the capacity of 120 seats and weights 84.4 tons (and has 6 axles). The train journey is 50 km in one direction. The prices do not include any other costs like depreciation, wages, energy, etc., are in CZK without VAT and are displayed in Table 2 below.

Table 2
Comparison of individual countries

Country / Line category:	Czech Republic	Slovakia	Poland	Austria	Germany
European line (corridor), electrified:	579.00	1 669.00	2 479.00	2 879.00	6 141.00
Nationwide line, electrified:	475.00	1 557.00	1 813.00	2 139.00	4 358.00
Regional line (secondary), non-electrified:	357.00	1 543.00	1 252.00	1 609.00	4 000.00

Fees for use of railway infrastructure (economic cost item) in the case of public transport in the Czech Republic are **still at some 25 - 35 % in comparison with Slovakia and remain the lowest in whole Europe**.
Such fee settings **may be associated with subsidizing these costs on railway infrastructure from the state budget**. It may be inferred that more funds the governments in other countries save on using the railway infrastructure, the more

they must provide from the state budget for subsidized fares (as reimbursement to counties) in public transport directly to particular carriers.
As an example of another model of charges for using transport infrastructure, **let us take Austria**, where, for the purpose of determining the amount of fees for use of railway infrastructure, the lines are divided into five categories:

- Mountain line through the Brenner Pass (most expensive) = 3.6514 EUR / km,
- Additional rail network (terminating branch lines) = 1.0856 EUR / km[2*],
- Other international lines = 2.0248 EUR / km[3*],
- Other mainline railway network = 1.4778 EUR / km[4*],
- Western main haul (second most expensive) = 2.9923 EUR / km ,

The highest fees for use of railway infrastructure can be, as expected, found in Germany. There, it is considered to be a model of a hidden railway infrastructure financing by the state. Regarding the high public transport fares, those are paid by individual federal states and the government hence receives some funds from the federal states back. Due to the fact that fees for use of railway infrastructure do not distinguish the train´s weight (it is paid per so-called route-km), this is used to secretly finance the freight transport as well. The surcharge for freight trains is calculated for trains with a total weight of more than 3,000 tons in total of 0.96 EUR / CZK 26.50 per kilometer. The only difference is then a surcharge of 2% to the overall price in case the freight train does not consist of 90% of railcars equipped with noiseless ("silent") brakes. (Zajíček, 2010), (Soušek, Říha, 2014).

3. Theoretical approach for setting the comparability of costs in individual transport modes:

Now let´s compare bus and rail transport. To be able to compare the financial costs of the public bus and rail transport, it is necessary to adjust the starting cost base to comparable cost items.
Only such financial costs can be compared objectively, which individual carriers generate based on clear or same facts or activities (for example Eq. 1).
Total financial costs C_{tot} are described as a sum, given by the following formula (Eq.1):

$$C_{tot} = C_p + C_e + C_{mc} + C_{dv} + C_{om} + C_{infr} + C_o \quad (1)$$

Consisting of: Personnel costs (C_p); Financial costs of energy (C_e); Financial costs of maintenance and cleaning (C_{mc}); Depreciation of transport vehicles (C_{dv}); Financial costs of terminal operation and maintenance (C_{om}); Fee for use of the infrastructure (C_{infr}); Overheads (C_o).

Comparable financial costs C_c

$$C_c = C_p + C_e + C_{mc} + C_{dv} \quad (2)$$

Comparable financial costs are a total of those financial items that are reported by all carriers as necessary expenditures to ensure transport requirements. These include personnel costs, energy costs, costs of maintenance and cleaning, depreciation of transport vehicles and financial costs of terminal operation and maintenance described in both transport modules.

Incomparable cost items C_{ic}

$$C_{ic} = C_{no} + C_{infr} \quad (3)$$

Regional rail transport is, in comparison with bus line transport, loaded with two other fees that increase its operating costs:
Fee for use of the infrastructure (C_{infr});
Costs of operation and maintenance of terminals for bus transportation (for example bus stations and stops) (C_{bs}) will probably be different and lower than similar costs (such as railway station buildings, buildings at stops and station operating staff) (C_{ts}) for railway transport. To balance the difference between both types of costs, we will include only the Cbs costs into the financial costs of the railway transport C_{ts}.
For this reason, to determine comparable cost base, these incomparable costs are deducted at railway transport.

"Adjusted" total operating costs C_{adj}

$$C_{adj} = C_{ic} + C_{res} \quad (4)$$

[2*] Comparable to the line Choceň – Litomyšl or Přelouč – Práchovice.
[3*] Comparable to the line Pardubice – Hradec Králové or Pardubice – Havlíčkův Brod
[4*] Comparable to the corridor lines.

The term “adjusted” total operating costs for this study´s purposes means decreasing railway transport cost items by such items that does not appear in road transport (such as fee for use of the railway infrastructure and levy for renewable electricity sources Cres) or are charged but in significantly lower values (cost of terminal operations). In this case, for the railway transport calculation, we use the cost of terminal operations, but at the same level as for road transport. Such “adjusted” total operating costs in the railway transport are often likened to VLAD costs.
At present, the cost calculation for both types of transport modes is performed without adjusting the differences between these modes, and thus carries elements of mutual incompatibilities.
In terms of railway transport, apart from some other variables, one significant variable also enters into the whole process: lockouts and closures. And precisely this variable often extends the journey time and makes the passengers to change to alternative types of transport (generally buses). And for that reason, it is crucial to eliminate simultaneous closures within one route of long-distance trains (in the Czech Republic such trains are labeled with letter “R” accompanied by a number, for example, R10). (Kamenický; Čermáková; Soušek; Němec, 2011), (Zajíček, 2010), (Soušek; Dvořák, 2015)
In terms of rail transport, however, one particularly crucial variable enters the process, namely line closures and replacement of services. This in itself often prolongs travelling time and forces passengers to change to an alternative means of transport (usually bus). For that reason it is necessary to eliminate simultaneous closures within one long-haul rail route (in the Czech Republic, this is indicated by a capital letter “R” and a number; e.
The distribution of closures occurring at different closure points can then be broken down as follows:

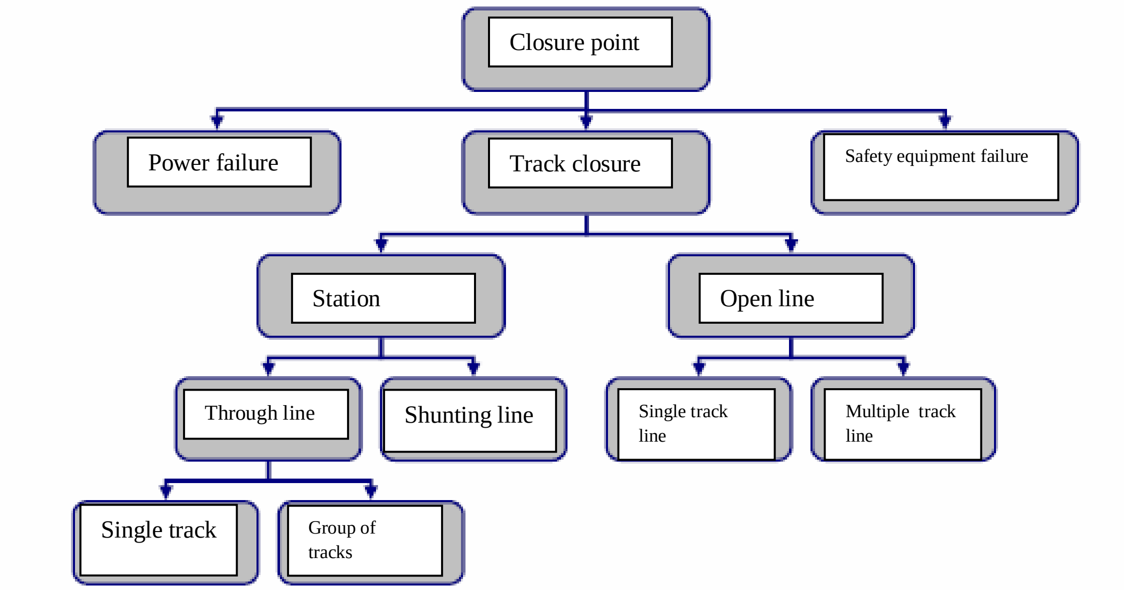

Fig. 1.
Breakdown of closures according to the point of closure

The figure shows that the term “closure” can be applied generally and that its use is varied. However, a power outage will have a different impact on the regularity of rail services than a closure of both tracks on a double track line. When considering the closure point, it must also be taken into consideration whether it is a through line or a shunting track or whether the track in question is occupied or located at a platform at a railway station. As well, the causes are also different. It may be a result of maintenance, repair, refurbishment or upgrading. These latter are often the longest, and usually the most expensive. Maintenance closures deal with the maintenance of a railway line for such purposes as removing vegetation along the track or they may occur during the course of a track inspection when it is necessary to stop regular operations. These closures usually last a few hours or perhaps days, but considering that they are part of a network of transportation, even minor issues have, or may have, an impact on the network infrastructure.
Closures for repairs may last longer. They may last some weeks, and often actually involve part of the railway substructure or superstructure. Examples include the repair of bridges or tunnels on the line, the repair of overhead catenaries or repairs related to the track (reballasting, etc.). Their impact may be considerable, as that section will generally be closed for a longer period of time and in terms of longer term planning (annual plan of closures) it may not be included at all; i.e., the need to close a line for repair may not be known until a relatively short time before it happens.
Closures for refurbishment are closely associated with the idea of “closures for repair”, but usually last longer and are more planned. Refurbishment may mean such operations as the complete replacement of the rails in connection with the construction of an overhead catenary. Its impact is evident given the scale and especially these types of closures must be reflected in the concept of long-term planning of closures in context, as defined in this work. Upgrading closures refer to a complete restoration or extensive reconstruction of a section of track. This includes for example, the extensive upgrade of a railway line through the construction of another parallel track in conjunction with an increase in line speed and the electrification and construction of a rail transit corridor (such as that which took place in 2015 in Úvaly). From

the point of view of the current status, several basic premises generally apply in the Railway Infrastructure **Administration (SŽDC) when planning closures**; particularly:

- Avoiding overlapping closures in order to prevent a train from twice being,
    - ✓ replaced by a bus service during its journey,
    - ✓ diverted, or both diverted and then replaced by a bus service in another part of the route,
- Providing all necessary measures for the timely commencement, suspension and termination of closure work,
- Fully utilising the closure time period,
- Permitting any changes in closures that have already been authorised to take place,
- Restricting closures which require alternative transport during a time of:
    - ✓ Monitored or anticipated transport peaks or at a time of,
    - ✓ Increased transport operation.

Costs of using rail transport routes are reduced proportionately by the untravelled (closed) section, usually in the order of some percents. However, costs increase for the provision of alternative transportation, which for closures of more than about 50 km are higher than the costs of using the transport route. This then creates another fairly substantial financial burden while, according to the operators, passenger numbers fall; hence the organisation of large-scale closures (such as the closure of the Zábřeh – Jesenik line in the Olomouc region in summer of 2016) are very costly and difficult to organise, as shown in the diagram on the previous page.

4. Conclusion

Total financial costs of bus and rail public transport are most strongly influenced by the rates of depreciation of transport vehicles (around 86 %).

A big part is played by the fact that a bus and a railway rolling vehicle have severalfold different buying price as well as a period of service life (factory preset). When using rolling stock at the end of its technical life or even beyond the depreciation line, this provides the railway transport with undull advantage. When using the road and rolling stock with similar purchase years, this, on the other hand, represents a disadvantage for the railway transport due to its higher buying price, which often depends on different technical and safety requirements for road and rail transport vehicles.

In terms of the financial costs of road and railway transport, a very frequent marker and an argument are the value of "total financial costs per km".

Even though it completely ignores the different weight of **transport vehicles used in bus and rail transportation**. Despite the undeniable fact that the weight of rolling stock is usually related to greater transport capacity, its part is also played by legal conditions, which the railway carrier cannot control. The most significant are the safety requirements on the vehicle´s frame structure (according to the Act no. 266/1994 Coll., On Railways and the Regulation no. 173/1995 Coll., which issues the Rules of Railway Operations). Due to this a typical bus Karosa weights around 10 tons when diesel railcar of 810 line weights double. Yet their operational and technical parameters (such as engine, transmission, capacity, etc.) are comparable. It seems that the only objective measure is to relate the economic and technical data to gross tonne-kilometer (grtkm), which would, however, not too objectively favor the railway transport in the end.

Due to the fact, that the main objective of public passenger transport is to satisfy transport needs of the population in a defined territory, the decisive parameter of each vehicle is its transportation capacity. As objective hence could be seen a conversion of operational-technical and economic values per seat of the offered transportation capacity.

For non-electrified tracks, the commissioner, and the railway carriers must have an interest in preferring self-contained motor railcars or motor units of lightweight construction to trainsets consisting of classic passenger railcars pulled by a diesel locomotive.

A road and railway public passenger transport commissioner will always, before preparing and agreeing to new Timetable or before issuing a license to a new carrier, face the decision whether to prefer financial costs or passenger comfort. In the first case, more convenient would be to put into the service “older” vehicles being aware of a possible negative reaction by the public. A very critical moment for the railway transport is the **fleet renewal**. Due to the network characteristics of the railway transportation and long service life of rolling stock, it is important to agree on the highest consistency between the individual commissioners of passenger transport in the public interest. This mainly applies to regional transport. It would be desirable to exclude cases when individual Regional Offices require different types of rolling stock and their requirement is given its weight by contributing to the purchase from their Regional operational programs.

Experiences from Germany on the organization of public passenger transport – a transportation within given region is planned and commissioned by individual federal states, which then act as so-called regional rail transport commissioners. Depending on national legislation, these commissioners become members of organizational structures of transport associations, special-purpose associations, local corporations or respective departments of regional administration. How exactly the regional transport is organized, what types of trains and on which lines will operate, with which transportation capacity, whether they will be manned by an accompanying train staff, all of these parameters are not decided by transport companies such as Deutsche Bahn or their competitors, but by individual commissioners, hence the state governments.

IMPACT OF NEW APPROACHES ON THE DEVELOPMENT OF ECONOMIC EVALUATION METHODOLOGY FOR TRANSPORT INFRASTRUCTURE PROJECTS IN THE CZECH REPUBLIC

Vít Hromádka[1], Eva Vítková[2], Petr Vařbuchta[3], Hana Kovářová[4], Lukáš Labudek[5], Michaela Holá[6]

[1,2,3,4,5,6] *Brno University of Technology, Faculty of Civil Engineering, Department of Structural Economics and Management, Brno, Czech Republic*

Abstract: Projects in the field of transport infrastructure form a very important part of public investments in the Czech Republic. For this reason it is essential that only those projects that meet the requirements for achieving economic efficiency and acceptable risk levels should be implemented. Currently, the assessment of economic efficiency and risk management in the Czech Republic are dealt with separately for each fundamental means of transport, i.e. road, rail and water. There is an individual methodology for each of these areas. Each of these methods has worked with characteristics of the specific transport sector in its own evolution. With the newly coming legislation, particularly from the European Commission, there has been a need of transformation of used methodologies specifically into a form that complies with European legislation. The subject of this paper is a detailed analysis of the new requirements for economic evaluation of projects in the areas of road, rail and water infrastructure and comparing them with capabilities of existing methodologies in fulfilment of these requirements. The outcome of the paper has been a list of recommendations leading to the projection of the acquired information into existing approaches to the economic evaluation of projects and the creation of a new comprehensive methodology. The outputs of the paper have been very important arguments for the subsequent discussion about the final form of a new comprehensive evaluation methodology for transport infrastructure projects in the Czech Republic.

Keywords: economic efficiency, transport infrastructure projects, methodology, Czech Republic.

1. Introduction

Transport infrastructure projects represent key strategic projects in any country. In most cases these projects are important not only in terms of the expected impacts on the development of mobility and economy of the state in general, but also from a financial perspective. These projects are very demanding from financial, time and organizational point of view. So it is necessary to carry out only projects sufficiently beneficial for the society. There is usually a national methodology for evaluation of the efficiency of these projects. In the Czech Republic they are currently three methodologies related separately to the road and highway infrastructure, rail infrastructure and water infrastructure which are valid. These methodologies are, however, presently not fully consistent with European Commission requirements stated in the "Guide to Cost Benefit Analysis of Investment Projects" document. For this reason, one of the goals of the Ministry of Transport of the Czech Republic is to create a uniform methodology for evaluating the economic efficiency of projects across all transport infrastructures.

The paper is particularly focused on identifying the fundamental differences between the currently valid approaches and methodology of the European Commission, on the assessment of the impacts of these differences on economic evaluation of projects and on formulation of recommendations for carrying out a new comprehensive methodology for evaluation of infrastructure projects in the Czech Republic.

2. Present state references

Investment projects in transport infrastructure are very important both for the population of the country and general economic growth of the national economy. New or modernized transport infrastructure brings new business opportunities to individual regions; it accelerates and simplifies the transportation of productive factors and results of the production itself. Besides the impact on businesses entities, it is necessary to emphasize also the significant impacts on the population providing diverse, faster and safer transportation options. According to the fact that in most cases the projects are very costly from the investment point of view and moreover financed from public sources, it is important to evaluate not only the factual side of the projects, but also their economic aspects.

One of the basic objectives of the allocation of public resources is respecting the 3E principle (Economy, Effectiveness and Efficiency) in their whole life cycle. Economy refers to efforts to minimize especially financial resources. Efficiency indicates the use of such resources, which enable to achieve maximum volume and quality of products. In the course of economic evaluation of investment projects in the area of transport infrastructure, it is essential to respect the minimal amount of impacts of a certain project on the society. Economic impacts are usually grouped into (a) direct economic benefits, i.e. economic costs and benefits directly related to the project, where travel-cost savings form typically the most important (user) benefit category for infrastructure projects, and (b) indirect economic benefits, the (wider) economic effects not directly related to the project but resulting from the direct impacts, e.g. productivity gains of firms and distributional effects (Geurs & van Wee, 2004). Among socio-economic impacts of transport projects are also included: environmental impacts e.g. pollution or noise (Thanos, Wardman & Bristow, 2011), (Browne & Ryan,

[1] Corresponding author: hromadka.v@fce.vutbr.cz

2011), benefits to the natural habitat (Oxman, Lavis, Lewin & Fretheim, 2009), visual intrusion, health impacts (Thomopoulos & Grant-Muller, 2013), settlement cohesion, accessibility, land use planning, agglomeration, labour displacement and habitat fragmentation and equity (Mancebo Quintana & Martin Ramos, 2010).

Cost Benefit Analysis (CBA) is an appropriate method for assessing the economic efficiency of public projects generating particularly non-financial benefits. Use of CBA is emphasized by various authors, e.g. (Mackie, Worsley, & Eliasson, 2014), (Hyard, 2012), (Jones, Moura & Domingos, 2014), (Damart& Roy, 2009) and (Jajac, Marović & Hanák, 2014). A more detailed analysis of the benefits of investment projects in road infrastructure has been already published in the article by Korytárová & Papežíková, (2015).

In the Czech Republic the methodological materials to assess the economic efficiency of projects in the field of transport infrastructure based on CBA principle have already existed. Methodology called “The implementing instructions for evaluating the economic effectiveness of projects of road and motorway construction” by the Road and Motorway Directorate of the Czech Republic (RSD CR, 2014) is used for the projects of road and highway infrastructure, methodology called “The implementing instructions for evaluating the economic effectiveness of projects of railway infrastructure” by the Ministry of Transport of the Czech Republic (MOT CR, 2013) is used for railway infrastructure projects and “The implementing instructions for evaluating of the economic effectiveness of projects on water ways” methodology by Ministry of Transport of the Czech Republic (MOT CR, 2005) is used in the case of important transport projects in water infrastructure.

As mentioned above, these methodological materials are based on the CBA principles, but in some parts do not meet the requirements demanded for CBA analysis processing, defined by the “Guide to Cost Benefit Analysis of Investment projects” by European Commission (Sartori, 2014). The subject of this paper is to identify selected differences and to specify in detail the impacts of potential changes in the methodologies on the economic evaluation of the projects of transport (especially road and highway) infrastructure.

3. Methodology

The basic methodological approach used in the research is the analysis of differences between approaches to economic evaluation of transport infrastructure projects in the Czech Republic currently used according to the valid documentation and the approaches recommended based on the appropriate documentation of the European Commission. As the results are suggested recommendations for possible changes to already existing implementation documentation and depiction of impacts of potential changes on the evaluation results. This depiction has been carried out using a further methodological tool: a case study. The key differences between already existing state of economic evaluation of transport infrastructure projects in the Czech Republic and modification of the relevant documents suggested by the European Commission have been identified as the first step of the case study. Subsequently the impacts of potential changes to the evaluation of economic efficiency of the project have been quantified on example of the real traffic infrastructure construction in the Czech Republic.

Within the case study, the principles of Cost-Benefit Analysis (CBA) based on the calculation of the Net Present Value of economic flows in the project and sensitivity analysis based on the assessment of the resistance of the project against changes in the key input variables have been subsequently applied.

The paper is focused mainly on the economic evaluation of projects of road and highway infrastructure according to the fact that most changes are expected in the area of economic evaluation of this type of projects.

4. Results and discussion

Economic evaluation of road and highway infrastructure projects in the Czech Republic have currently been dealt with using "The Implementing Instructions for Evaluating the Economic Effectiveness of Projects of Road and Motorway Construction" by the Road and Motorway Directorate of the Czech Republic (RSD CR, 2014). Due to the requirements put on the economic analysis resulting from the European Commission document "Guide to Cost-Benefit Analysis of Investment Projects" (Sartori, 2014), the interim methodology reflecting certain requirements from the above mentioned document of the European Commission, supplementing existing national methodology, has been prepared. This methodology will be valid until a new common methodology for road, rail and water transport will have been approved.

It can be stated based on the analysis of relevant documents carried out that fundamental difference between the existing and the desired methodologies can be found in the following areas:

- Evaluated period,
- Discount rate,
- Investment costs,
- Performing qualitative and quantitative risk analysis,
- Assessed values in the frame of the sensitivity analysis,
- Residual value of the project,
- Conversion factor.

Evaluated period

According to existing documentation, projects are evaluated for the period including the investment phase and thirty years of operation. According to the requirements arising from documents by the European Commission, the considered evaluated period should be thirty years in total including both investment and operating phase of the project.

Discount rate

Compared to the existing regulation, the financial discount rate is reduced from 5% to 4% and economic discount rate from 5.5% to 5%.

Investment costs

In the current economic evaluation of investment projects, only the costs of the construction work carried out are considered within this category according to the new regulation, investment costs include costs related to the purchase of land as well as.

Residual value of the project

In the existing documentation, a residual value of the project assessment is based on the financial value of the acquired property, when the final residual value of each types of purchased property depends on its purchase price and durability beyond the evaluation period. According to the new requirements, the residual value should be determined on the basis of expected cash flows from the investment after the end of the evaluated period to reach average lifetime of the assets acquired by the project (determined by weighted arithmetic average of lifetimes of individual types of property where the weights are the investment costs).

Assessed values in the frame of the sensitivity analysis

According to the current practice, sensitivity analysis of projects of road and highway infrastructure is carried out for a change in construction costs and for a change in the overall user benefits. According to the new regulations, sensitivity analysis should be more detailed and among the assessed values should be, besides investment costs, also partial benefits (time value, cost of accidents) and the expected development of transport intensity or number of years of construction.

Performing qualitative and quantitative risk analysis

According to the current practice, only sensitivity analysis including the determination of "overlap" values of assessed variables is carried out in the frame of the risk analysis. Newly, a detailed qualitative risk analysis covering their determination and definition, determining their probability and degree of impact and description of potential measures to reduce or eliminate the risks, should be carried out. A quantitative analysis of key risk factors using mathematical simulations with Monte-Carlo method should be also implemented.

Conversion factor

Conversion is used in economic analysis. This is a transfer from the financial analysis to the economic analysis. The economic analysis evaluates how the project contributes to changing the level of prosperity, and therefore it is important to use shadow prices that represent the social opportunity costs of goods and services. Conversion factor has not been used up to now for evaluation of projects of road and highway infrastructure, however, the inputs into economic analysis have been considered without VAT.

4.1. Case study

The impact of some of the above mentioned changes on the overall evaluation of the project has been demonstrated by a case study. The case study has been carried out on the project of the new construction of “Southern Conjunction” - a section of four-lane capacity road of citywide importance which represents a new capacitive connection between D11 motorway and the centre of Hradec Kralové city in the Czech Republic. The basic design category of “Southern Conjunction” is MS4d 19/70. Communication has two opposite direction lanes separated in the middle by 3.0 meters wide centre lane. The design speed of “Southern Conjunction” is 70 km/h., from which horizontal and vertical lines are derived. Total length of the main route is 2.96 km and the estimated investment costs are 1,609,963 thousand CZK (59,628 thousand EURO) without VAT. Data for carrying out the case study were taken from the study evaluating the efficiency of the project (AF-CityPlan, 2015). General situation of the project is displayed in Fig. 1.

Fig. 1.
Project I/11 – I/37 Southern Conjunction Hradec Králové – general situation
Source: own work using mapy.cz server

The basic input data for the economic assessment in actual and new approaches is shown in Table 1.

Table 1
Input data for the economic assessment

Input variables	**Actual approach**	**New approach**
Duration of investment phase (years)	3	3
Duration of operational phase (years)	30	27
Total duration of evaluated period (years)	33	30
Residual value assessment	residual value of property according to the lifetime	discounted cash-flows till reaching the average lifetime of the property
Investment costs (1,000 EURO without VAT)	59,628	59,628
Discount rate	5.5%	5%

Source: own work according to the project study (AF-CityPlan, 2015)

It is evident from Table 1 that in comparison of the calculation of economic efficiency according to the actual and new approaches, the changes in determining the length of the evaluation period, residual prices and a change in the discount rate have been taken into account. However, the change in the determination of investment costs, regarding the current uncertainties arising from determining the economic value of purchased land has not been considered.

The final values of economic indicators calculated both using actual and new approaches are shown in Table 2.

Table 2
Values of economic indicators

Indicator	**Actual approach**	**New approach**
Net Present Value (NPV)	1,851 mil. EURO	10,497 mil. EURO
Internal Rate of Return (IRR)	5,72%	6,09%
Benefit Cost Ration (BCR)	1.034	1.182

Source: own work according to the project study (AF-CityPlan, 2015)

Materials to make the calculations were taken from the project study (AF-CityPlan, 2015).
The results of the case study show that in the case of evaluated project, the considered combination of changes has had a positive impact on the economic evaluation and the economic results of the project are within the new approach more favourable for the project despite shortening of the length of the evaluation period. Different results can be, however, expected especially in the case of projects with a longer investment phase. In the case of large projects (some projects in the Czech Republic have expected length of the construction process up to 17 years) it is possible to expect more significant impact of the shortening of the evaluated period, even so it can be to some extend compensated (but at the same time distorted) by a new method for determining the residual value.

In the frame of the case study, the sensitivity analysis processing according to the current practice and the new approach have been compared. According to current practice, the sensitivity analysis has been carried out for two input variables - construction costs and overall benefits. In the case study, these input variables have been supplemented by partial benefits within the new approach. The results of the supplemented sensitivity analysis for the evaluated project are shown in Figure 2.

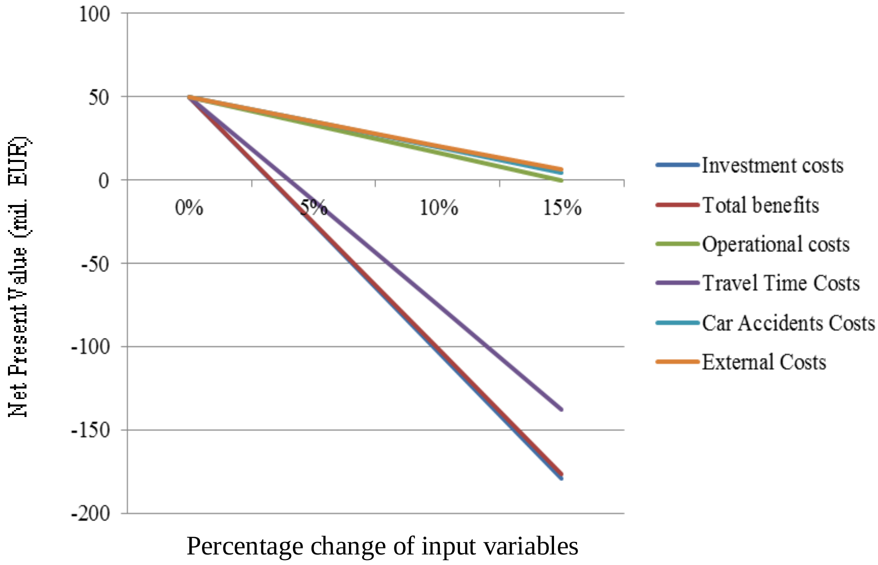

Fig. 2.
Sensitivity analysis – dependence of project NPV on percentage change in input variables
Source: own work according to the project study (AF-CityPlan, 2015)

Figure 2 shows the relationship between the percentage change of the input variables (benefits and costs) and Net Present Value of the project. For illustrative purposes the percentage change is defined in such way that it decreases the final Net Present Value (in the case of the benefits, the change in negative, in the case of the costs, the change is positive). Material for the calculation of the sensitivity analysis has been taken from the project study (AF-CityPlan, 2015).

4.2. Discussion

The subject of this paper is the analysis of the way of the current economic evaluation of the projects of road and highway infrastructure in comparison with changes in the economic evaluation resulting from the need of implementation of the principles stated by the new European Commission documents. As a part of the introduction to this chapter, following significant areas of changes in the economic evaluation have been identified:

- Evaluated period,
- Discount rate,
- Investment costs,
- Performing qualitative and quantitative risk analysis,
- Assessed values in the frame of the sensitivity analysis,
- Residual value of the project,
- Conversion factor.

Duration and structure of the evaluated period, discount rate and the residual value of the investment are relatively clear areas with easy implementation from a methodological point of view. First part of the case study presented in this paper brings an example of the impact of changes in these variables on the calculated efficiency of the evaluated project. In the case study, the impact of changes is rather positive; the project appears to be more efficient than in the case of usage of the already existing approach. However, this conclusion cannot be generalized, since the duration of construction and therefore duration of the evaluated part of the operating phase with the constant length of the evaluation period of 30 years including both investment and operational phases will play a significant role.

Investment costs should include expenses related to the purchase of property according to new approach. In terms of methodology, it is a correct decision. However, the problem lies in determining of the economic (shadow) costs associated with this acquisition. The final purchase price is often several times higher than the estimated price or a price determined according to the price map, and is often significantly influenced by the exaggerated requirements of the owners. In this respect, it is possible to formulate recommendations for the creation of a new methodology, which consists in creation of a procedure for determining the economic (shadow) prices of purchased pieces of property

showing the actual detriment for the society by their use in the road infrastructure, e.g. at the level of values listed in the price maps or at prices determined by an expert according to the corresponding legislation.
In the risk analysis of investment projects in the road and highway infrastructure, only a sensitivity analysis evaluating the impact of changes in investment costs and changes in total benefits on the evaluation criteria has appeared so far. Within the sensitivity analysis, a more detailed sensitivity analysis covering the assessment of impacts of the effects of changes to partial benefits or changes to the intensity of traffic may be recommended in accordance with the relevant documentation. Sensitivity analysis supplemented by more detailed assessment of impacts of partial benefits is the subject to the second part of the case study presented in this paper. Following the results of the sensitivity analysis, paying more attention to those inputs for which a high degree of sensitivity has been found (in the case study they are mainly the costs of travel time) can be recommended.
Following the sensitivity analysis, further steps can be recommended. Such key step can be the determining of critical variables (their description should be clearly defined in the methodology) further tested within the recommended mathematical simulation using Monte-Carlo method. Part of the risk analysis should also be a qualitative risk analysis comprising their identification including description, determining of their significance (probability of occurrence and intensity of the negative impact on the project) and the description of the measures for their reduction or elimination.
The last monitored area has been the conversion factor issue. Conversion factors should not be calculated for each project separately, they should be included in the national methodology. For a specific project they should be calculated only if the national parameters are not available. It is therefore possible to recommend the formulation of conversion factors within the frame of the arising general national methodology. Taking conversion factor into account will be particularly important in determining the investment costs (shadow prices of purchased property and the cost of the construction itself).

5. Conclusion

The subject of this paper was a detailed analysis of new requirements for economic evaluation of projects in the areas of road, rail and water infrastructure, and to compare them with capability of existing methodologies to fulfil these requirements. The outcome of the paper is a list of recommendations leading to the projection of the acquired information into existing approaches to economic evaluation of projects and formation of a new comprehensive methodology. The paper is particularly focused on the evaluation of economic efficiency of projects in the road and highway infrastructure. In the introductory part of the paper, an analysis of the current state in order to identify the available literature sources covering the above-mentioned issue has been carried out. Subsequently the methodology of processing the research has been briefly introduced. The essential part of the paper is represented by the fourth chapter, where the key changes in the evaluation of economic efficiency of projects in the road and highway infrastructure caused by new requirements by the European Commission have been identified and described. In the case study, the effects of these changes on the resulting economic evaluation of projects and their interpretation have been tested. Mainly the changes to the structure and length of the evaluation period, the discount rate, calculating of the residual value of the project and changes to the risk assessment using sensitivity analysis have been tested. The recommendations arising from the conclusions of the analysis and case study for the purpose of creating of the new general methodology for the evaluation of transport infrastructure projects in the Czech Republic have been subsequently formulated in the discussion.

IMPACT OF LIBERALIZATION OF FOREIGN TRADE ON THE SERBIAN ROAD FREIGHT TRANSPORT SECTOR

Olivera Medar[1], Jelica Petrović Vujačić[2], Marko Miljković[3]
[1,2,3] University of Belgrade, Faculty of Transport and Traffic Engineering, Vojvode Stepe 305, Belgrade, Serbia

Abstract: The process of trade liberalization in Serbia since the year 2000 went in several directions. The most important of these are in the areas in which Serbia has the largest volume of trade that is countries of the European Union (EU), countries of the Western Balkans region and the Russian Federation. On January 1st 2014 Serbia came into the sixth and final year of trade liberalization with the EU on the basis of the Stabilization and Association Agreement (SAA). In December 2006, the countries of the Western Balkans signed the Central European Free Trade Agreement (CEFTA), which substituted a network of bilateral free trade agreements. The countries remaining in CEFTA are: Albania, Bosnia and Herzegovina, FYR Macedonia, Montenegro, Serbia, UNMIK-Kosovo and Moldova which make up for a common market of close to 23 million consumers. The paper analyzes the influence of foreign trade liberalization on the Serbian road freight transport sector with special focus on haulers. International road freight transport input (vehicle purchase) and output (tones carried or tone-km performed) follow closely the demand cycle of the economy (GDP) in general and trade (exports) in particular. Dropping demand during financial crises in 2008 caused a contraction of haulage (million tons). In economic as well as road transport related literature the term of liberalization or deregulation is often used to describe the process of facilitating or improving conditions of operations for economic entities in road transport, that is, haulers. Transport, in particular international road freight transport, has always been regulated for justified reasons such as the need for safety, security, technical harmonization. The paper gives special attention to the effects of specific types of permits and quotas on transport flows and flows of goods.

Keywords: foreign trade liberalization, road freight transport sector, Serbia.

1. Introduction

Since the middle of the 20th century, when the General Agreement on Tariffs and Trade (GATT) was created, the world trading system has benefited from various rounds of multilateral trade liberalization, as well as from unilateral and regional liberalization. The economic literature suggests that there is no country in recent decades which has achieved economic success, in terms of substantial increases in living standards for its people, without being open to the rest of the world (IMF, 2001). OECD (2011) emphasizes that further opening of trade can stimulate economic growth, job creation, as well as higher real wages for workers.

The process of significant trade opening in Serbia started at the beginning of the 21st century and went in several directions. The most important of these are in the areas in which Serbia has the largest volume of trade that is countries of the European Union (EU), countries of the Western Balkans region and the Russian Federation. On January 1st 2014 Serbia came into the sixth and final year of trade liberalization with the EU on the basis of the Stabilization and Association Agreement (SAA). In December 2006, the countries of the Western Balkans signed the Central European Free Trade Agreement (CEFTA), which substituted a network of bilateral free trade agreements. The countries remaining in CEFTA are: Albania, Bosnia and Herzegovina, FYR Macedonia, Montenegro, Serbia, UNMIK-Kosovo and Moldova which make up for a common market of close to 23 million consumers. Additionally, Serbia liberalized its trade with the Russian Federation, Belarus, Kazakhstan, EFTA countries, Turkey, as well as with USA under General System of Preferences, which makes a duty-free market for exports of more than one billion people.

On the other hand, market access has been reduced by a series of obstacles arising from the existing permit quotas for bilateral, transit and cross-trade transport operations. The transport permits make it very difficult, if not impossible, to operate in certain markets, they complicate the organization of transport processes, reduce work efficiency and create additional costs for the hauliers and users alike. The permit quotas include CEMT permits issued to the Serbia within the multilateral system of quotas, and bilateral permits exchanged between the Republic of Serbia and other states. The number of permits available to Serbian hauliers, which are distributed by the competent authority, does not correspond to their needs. The insufficient quotas are the result of many things, including a very restrictive approach the other states have taken to protect national hauliers or the environment; a focus of interest in another field; poor negotiations or even the total lack of engagement by national authorities in this respect. More often than not the status and needs of the market change too rapidly for the national authorities to react (Medar & Manojlović, 2011).

2. Foreign trade dynamics of Serbia: contribution of trade liberalization

Serbian economy is characterized by continuously high values of the deficit in external trade in goods. In 2015 the deficit amounted to EUR 4.3 billion and it declined as compared with previous years. The structure of Serbian external trade by products is also unfavourable. Products at lower levels of processing, primarily raw materials and semi-finished goods, possess the dominant share in the structure of Serbian exports. On the other hand, capital goods and energy, which generate quite higher value, have a significant share in the structure of imports, in addition to non-durable consumer goods. In Table 1, there are presented values and volume of exports, imports and foreign trade balance of Serbia during the last ten years.

The most important exporting markets for Serbia are European Union member countries, primarily Germany, Italy and Austria, which made almost two thirds of value of Serbian exports in 2015. The second largest foreign trade partner are CEFTA member countries, which Serbia continuously achieves high amounts of trade surplus with. The detailed structure of exports by countries, Serbia has free trade agreements with, is presented in the Figure 1.

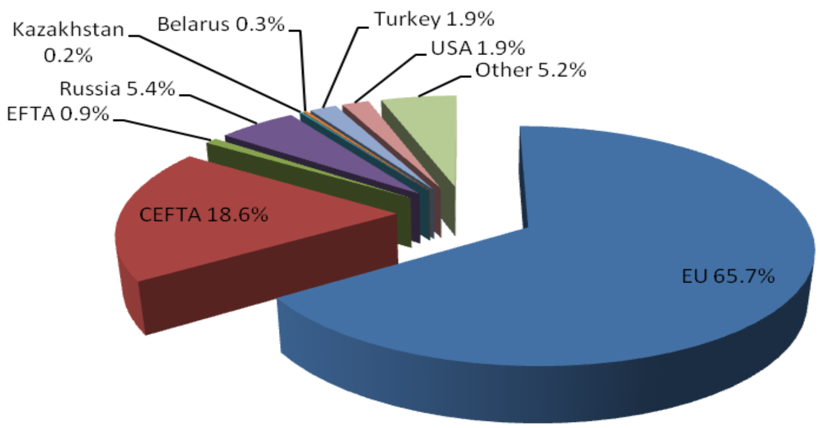

Fig. 1.
Structure of Serbian exports by exporting markets in 2015
Source: Trade Map Statistics Database

Liberalization of trade contributed significantly to growth of exported values, what is presented in Table 2. The best indicator of such a contribution is the value of exports growth in the year of trade liberalization. For example, in the year when free trade agreements came into force, the value of exports to Turkey (in 2011), Belarus and Kazakhstan (in 2010) more than doubled. Significantly high growth rates of exports value achieved in the first year of trade liberalization with Switzerland (28.4% in 2011) and CEFTA countries (35.4% in 2007). The only one exception is related to European Union, considering the first and strongest wave of global economic crises which occurred in 2009 and which significantly affected aggregate demand level in EU member countries. However, the averaged data on exported values before and after Stabilization and Association Agreement do indicate the positive contribution of trade liberalization with EU. There are also presented average values of exports, as well as average growth rates of exports in the period before trade liberalization (after 2006), as well as after trade liberalization (till 2015). Significantly higher growth rates of exports were recorded after the trade openings, up to ten times higher growth rates.

Table 2
Effects of trade liberalization on Serbian exports in the period 2006-2015

Group of countries	Year of trade liberalization	Exports value growth in the year of liberalization	Average value of exports, EUR mil.		Average growth rate of exports	
			Before liberalization	After liberalization	Before liberalization	After liberalization
European Union	2009	-21.4%	3,826.2	6,521.8	11.8%	12.6%
CEFTA countries	2007	35.4%	n.a.	1,925.3	n.a.	6.8%
Switzerland - EFTA	2011	28.4%	50.1	72.9	10.6%	12.4%
Russia	2001	n.a.	n.a.	507.4	n.a.	14.9%
Turkey	2010	104.8%	34.2	151.0	5.2%	43.6%
Kazakhstan	2011	105.6%	6.2	11.9	6.7%	49.6%
Belarus	2010	115.9%	11.6	45.4	8.4%	24.5%

3. Impact of trade liberalization on Serbian road freight transport sector

Road freight transport is a dominant mode of international transport in Serbia. Comparing data published by Statistical Office of the Republic of Serbia (SORS) for external trade, exports and imports, in the SORS Statistical Database to the data for road transport from SORS Statistical Releases “Entry, exit and transit of freight road vehicles” for the period 2004-2015 the international transport of goods by road (transit excluded) was almost twice as large as transport by other modes of transport, measured in transported tonnes (Fig. 2). Serbian hauliers are the most active, representing over one half of total performance (in tonnes) (Fig. 3). More than 30% of foreign hauliers are from Bosnia and Herzegovina, followed by hauliers from Montenegro (~15%), FRY Macedonia (~10%), Croatia (~7%), and Slovenia (~6%) – the hauliers from ex-Yugoslavia republics dominate between foreign hauliers. The Bosnian hauliers aside, those from the states that are involved in a large-scale external trade (Italy and Germany for instance) do not have an adequate share in Serbia’s international road transport market. This market is not attractive to them due to too many obstacles during transport operations.

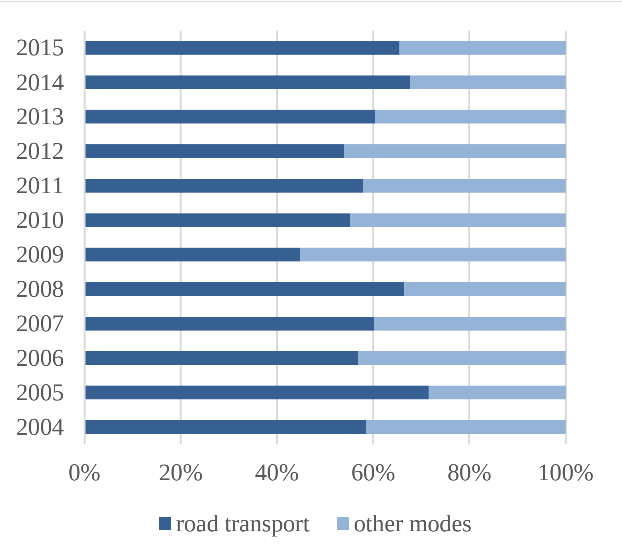

Fig. 2.
Road transport share in total exports (based on tonnes) [%]

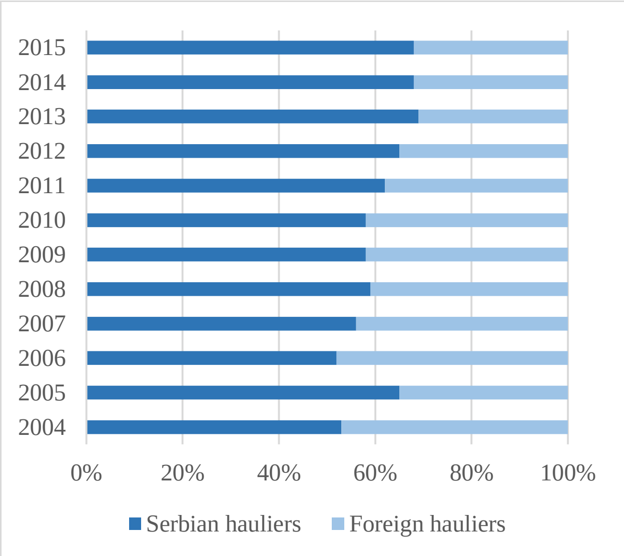

Fig. 3.
Share in international road freight transport by the haulier’s nationality (exports, based on tonnes) [%]
Source: Calculation of authors based on SORS Statistical Releases SV31

In Serbia, in 2000, at the time when political changes have started, there were around 350 hauliers[2] performing the international road transport operations. For the purposes of this paper, Serbian hauliers involved in international road transport of goods include the hauliers that have met the legal conditions for admission to the occupation of road haulage operator, and perform the activity continually over the year. These include the hauliers that participate in the annual distribution of foreign and multilateral permits (Annual Permit Distribution Plan). There is an irrelevant number of other hauliers, whose involvement in international road transport is sporadic, and mostly for their own account, or in a limited market only. From the end of 2000 until 2003 the number of has grown for about 50%, around 450 hauliers, at the biggest growth rate till today. In the following years this growing trend continued with a lower rate and at the end of 2008 the number of hauliers was more than doubled (Fig. 4), amounted around 770 hauliers. Then, the number dropped during the period of the global economic crisis, and after 2012 the recovery trend can be seen, with 902 hauliers at the end of 2015 having on average 10.5 vehicles and 12 drivers (Fig. 5). The number of hauliers is not too big due to legal provisions in force: international road transport can be operated only by domestic company (legal person), and a large number of entrepreneurs are deprived of performing the activity of international road transport. This situation will be changed in 2017 when new provisions enter in force.

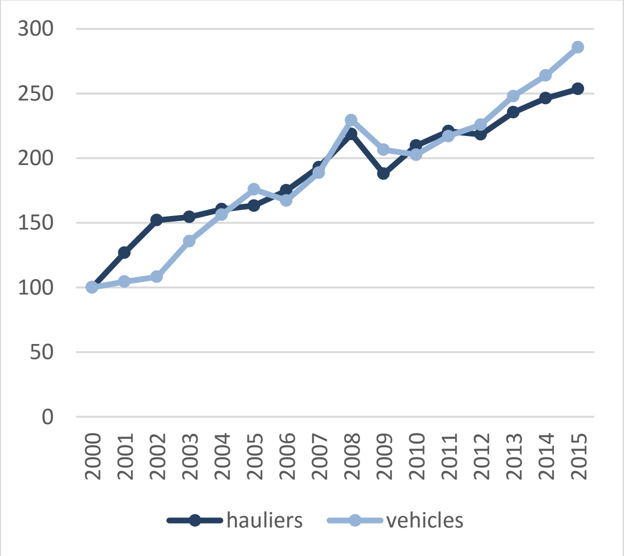

Fig. 4.
Number of hauliers and drawing vehicles (lorries and road tractors), Indexes 2000-2015 (2000=100)
Source: Calculation of authors based on MCTI Annual Permit Distribution Plan

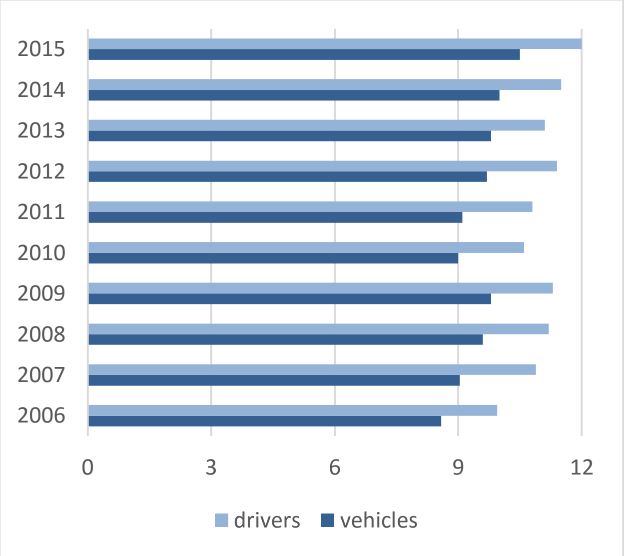

Fig. 5.
Average vehicle fleet size and average number of employed drivers, 2006–2015
Source: Calculation of authors based on MCTI Annual Permit Distribution Plan

During the same period, 2000-2015, the number of drawing vehicles (lorries and road tractors) was raised a little bit faster, with almost 10,000 vehicles at the end of 2015 which is the number nearly tripled comparing to 2000. Similar trends to number of haulier have been noted for number of vehicles (Fig.4). Apart from the increase of vehicles in numbers, the fleet structure have been changed significantly in favour of environmentally friendly vehicles (Fig. 6). This purchasing strategy is confirmed also with data on average fleet size which remain around 9 vehicles over long period (Fig. 5). Purchasing of vehicles meeting emission, noise and safety standards were motivated above all by the possibility of overcoming severe market access barriers for Serbian hauliers (quotas of bilateral and ECMT permits). The 2007 research (*Medar and Manojlović*, 2011) showed that the permits motivated 69.2% hauliers to buy better vehicles because they have been aware that any addition to the existing quotas was only possible by reshaping fleet structure in favour of environmentally friendly vehicles. In the years 2007 and 2008 Serbian hauliers purchased almost 1,000 new vehicles manufactured the same year (Fig. 7). The average age of road tractors in 2008 was at the lowest level – 5.8 years.

[2] For the purposes of this paper, Serbian hauliers involved in international road transport of goods include the hauliers that have met the conditions for admission to the occupation of road haulage operator, as defined by the national legislation and perform the activity continually over the year; these include the hauliers that participate in the annual distribution of foreign and multilateral permits (Annual Permit Distribution Plan), which grant them access to the international road haulage market. There is an irrelevant number of other hauliers, whose involvement in international road transport is sporadic, and mostly for their own account, or in a limited market only.

3. Quota of permits for international road haulage – the main obstacle for sector development

Serbian hauliers access international road transport market on the basis of bilateral agreements (in most cases under the quota system of bilateral permits) and on the basis of ECMT multilateral quota system of permits. Practically the existence of quotas means limited access to markets, and in some cases exclusion. As a consequence, transport operations are more difficult to organize, efficiency is reduced (primarily through increased number of empty runs), and hauliers have additional costs. Sometimes this is the reason for improper use of permits. This results in a reduced competitiveness of national hauliers, increased environmental pollution and affects foreign trade. The outcome of the study performed in 2007, where major problems in the sector have been defined and the critical ones underlined, shows that insufficient quotas exchanged between Serbia and some other countries and the allocation of permits to hauliers are highly ranked issues (*Medar & Manojlović*, 2011).
When we discuss issues related to foreign trade, one of the solutions of this problem is liberalization of bilateral transport operation. Liberalization of transport which is significant in terms of share in total operations performed is agreed just with 12 countries (Table 3). Liberalization of bilateral transport operation as result of negotiations is, besides facilitating foreign trade as primary objective, motivated by objectives as protection of national hauliers or the environment. Thus, only with seven countries Serbia reached agreement for full liberalization of bilateral transport operations while with two countries partial liberalization was agreed. Most of these countries are neighboring countries, with typically significant value of foreign trade. However, there are countries which are not neighbors or even those with whom there is no significant volume of trade, but both sides have interest to facilitate international transport operations. In recent years, liberalization of bilateral transport operations is standpoint of the Republic of Serbia in

almost all negotiations on road freight transport. Despite this attitude, five countries which are among the top 10 in terms of volume of exports and imports have not yet accepted proposals to liberalize bilateral transport operations, namely Russia, Romania, Italy, Ukraine and Germany. Number of permits for Russia and Italy are critical for many years despite continuous insistence for increase. The main reason is very low share of their hauliers in performed transport operations.

Table 3
Agreed liberalisation of some transport operations between Serbia and other coutries

Country	Liberalized transport operations	Date of effect
Bosnia and Hercegovina	bilateral and transit	1.1.2009.
Bulgaria	bilateral and transit	1.6.2015.
Croatia	transit	1.8.2012.
	bilateral	1.1.2014.

Switzerland	all	1.1.2008.

Source: Knežević, 2016

Contingent of permits where the total number of permits exchanged is not sufficient to meet the requirements of hauliers are declared critical. Practically, at the beginning of the year the contingent is critical if more than 80% of permits was used during the previous period or, for example, in September remaining number of permits is less than 20%. Sometimes, even with countries where contingents are not critical or additional number of permits can be exchanged on request, the speed of changes in the market is much faster than the speed of authority's reaction and it happens that non-critical permits became critical during the year. The permits for couple of countries are critical for years as for Austria, France, Italy and Russia, and for some of the countries contingent became critical in last years (Table 4).

Table 4
Some of the countries with critical contingents

Country	2003	2004	2005	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015

Source: Authors based on Annual Distribution Plan of Permits

The relationship between the Republic of Serbia and the Russian Federation is a good example of poor coordination of authorities in charge of trade and transport. During 2000 an agreement was signed between the Federal Republic of Yugoslavia and the Russian Federation on trade of goods with a lower tariff rate (1%) with no provisions for adequate transport liberalization. Initially, the list of products that were covered by the trade agreement was not large, commodity exchange has not increased dramatically, and the Russian market wasn't particularly interesting for hauliers from Serbia. Over the years the list of products covered by the agreement has been expanded and trade quantity in tones transported by road has been more than doubled in 2006. The Russian market has become more attractive and the number of exchanged permits insufficient in relation to demand. The quota of 1,000 permits was sufficient and used at the level of about 30% by 2003. In 2004 usage was increased to 70%, while in the years after the usage grew at almost 100%. Exports and imports in tones transported by road in 2015 has grown 10 times as compared with 2001 and number of permits from 1,000 has been enlarged to 7,500. Insufficient number of bilateral permits resulted in usage of

ECMT multilateral permits for bilateral transport operations between Russia and Serbia, and in significant share of hauliers from third countries.

4. Conclusion

Trade liberalization demands more than tariff reduction and the transformation of non-tariff barriers into tariff rates. When tariff rates are reduced and competition is stifled in some other way or policies, procedures and rules are not applied transparently or systematically or some providers are given preferential treatment the effects of trade liberalization may be lacking. The effects may be negative if a country lacks the necessary adequate institutions, laws and policies.

Non-tariff barriers impede the business operations of hauliers in Serbia and diminish the full effects of foreign trade liberalization. Furthermore, given that Serbian accession to the WTO is in progress a large number of non-tariff barriers, quantitative restrictions and certifications are yet to be in-lined and harmonized with WTO standards.

SESSION 15: TRANSPORT INFRASTRUCTURE AND INTELLIGENT TRANSPORT SYSTEMS

ABOUT THE PROCESS OF DESIGNING RAILWAY INFRASTRUCTURE

Martin Scheidt[1]
[1] *TU Vienna, Institute of Transportation, Research Center of Railway Engineering, Traffic Economics and Ropeways, Vienna, Austria*

Abstract: Nowadays the process of designing railway infrastructure is mostly seen as a sequential process. The sequential approach would appear to be obsolete, since it is lacking a consideration of customer needs. Therefore, it must be widened and parts of processes must be considered as what they are: sub-processes in a bigger picture. Since the sub-processes are dependent on each other they can be depicted as a cycle. This article presents the cycle of designing railway infrastructure. It has its focus on the German speaking area and aims to give an overview to the tasks and the relationships between sub-processes. It concludes seven sub-processes and eight relationships. It starts with the customer needs for transport which have only been considered indirectly and are generally not one of the primary concerns for designing railway infrastructure. After that a political process determines how to correspond with these customer needs. It includes several inputs like funding, general laws for railway, and the geographic constraints. From the complex political process originates a design target, which is translated into an operational concept. These operational concepts differ in Europe with different focuses on the primary target and an example is discussed as a guide for further development. The operational concepts are then further processed with common evaluation tools to create the bases of design for the infrastructure. There are feedback loops from the evaluation tools to reconsider certain constraints from former sub-processes. After the evaluation tools conclude that an infrastructure is feasible, the infrastructure will be constructed. Later, a specific timetable is constructed on the basis of the infrastructure, which will then be used by customers to full-fill their needs.

Keywords: design, railway, infrastructure.

1. Introduction

The design of the railway infrastructure must take into account different requirements of technical, economical or environmental perspectives. In order to offer services on a railway infrastructure, the design of the track topology is essential. From the track topology, the other infrastructure can then be derived. The track topology therefore offers itself as the base for the design of railway infrastructure.
So far, the process of designing track topology was presented sequentially and processed accordingly (see figure 1, compare Walter, 2016, p. 56). At a closer look, however, shows that all the sub-processes (including first and last stage) are interrelated and therefore should not be considered separated from each other. It therefore makes sense to consider the design of track infrastructure and thus a track topology, as a continuous cyclic process. The cycle may extend over several decades. Since the design of the railway infrastructure is a strategic planning, the operational planning is not considered in the following description.

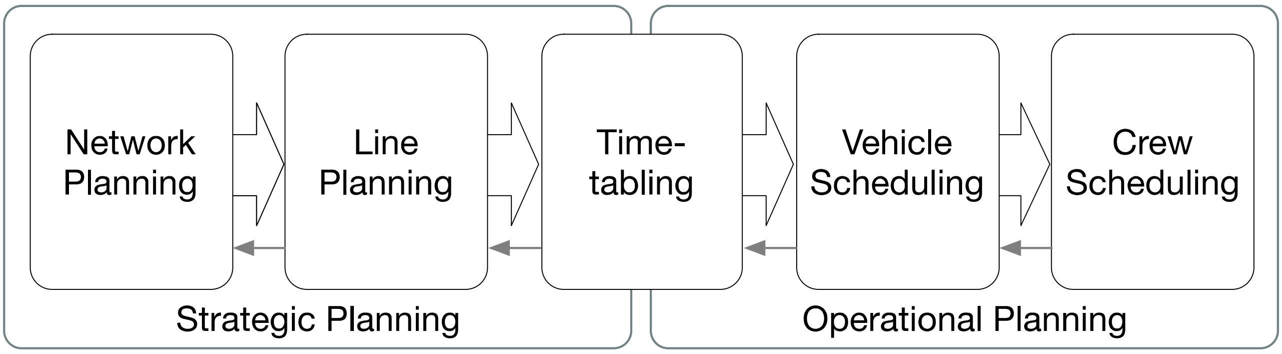

Fig. 1.
Sequential progression of infrastructure planning compare Walter (2016, p. 56)

2. Cycle of Track Topology Design

The individual sub-processes of the cycle can run parallel to each other. Figure 2 illustrates a perception of this cycle. Following paragraphs will discuss the different stages (marked with a circle, i.e. Ⓐ) and their transitions (marked with a diamond, i.e. <0>) in the cycle.

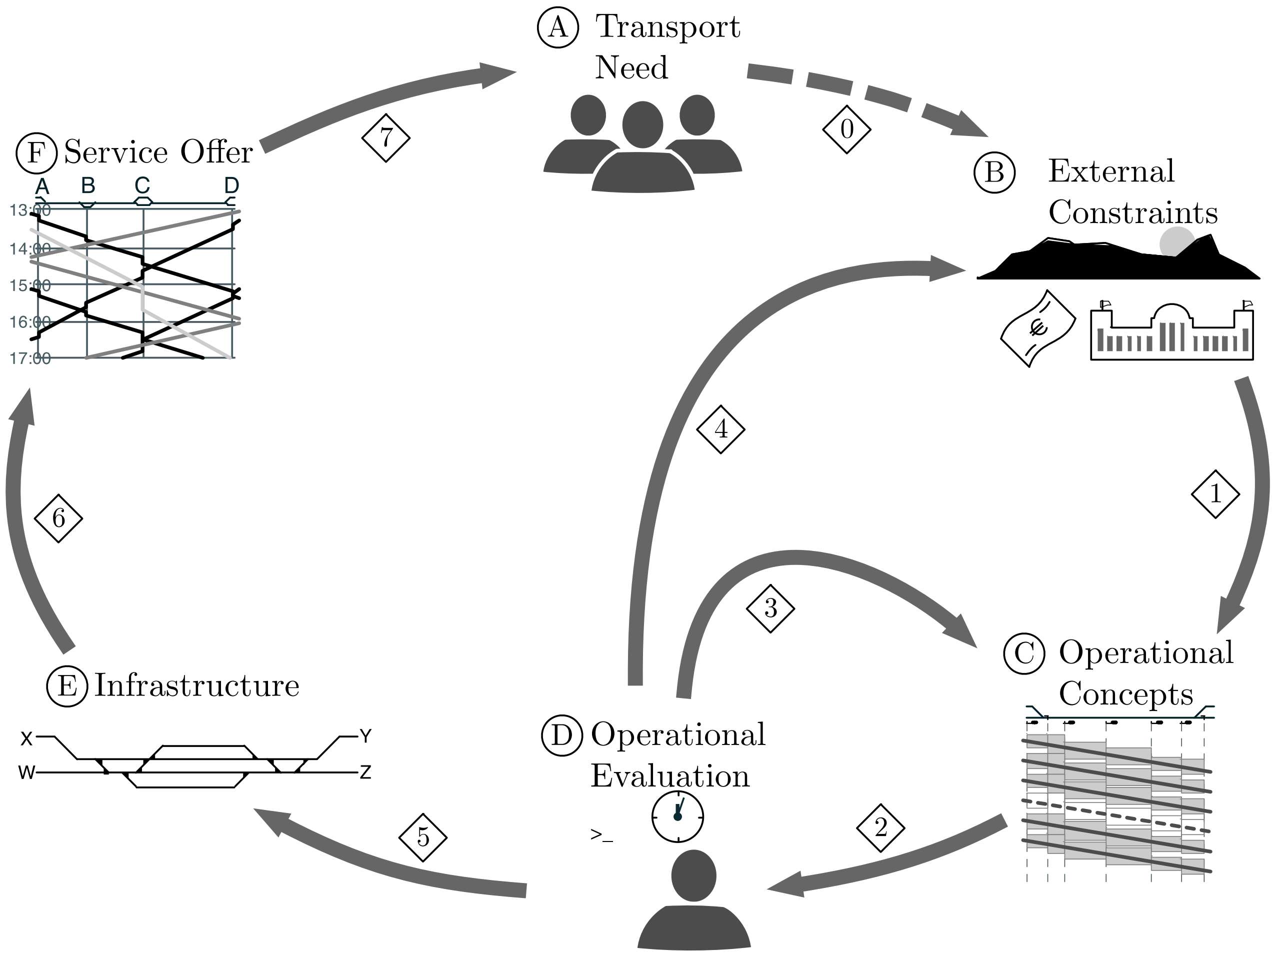

Fig. 2.
Cyclic progression of track topology design

Ⓐ
Means of transport are built for people. People use means of transport to ship goods or travel as a passenger. Use of transport is triggered by the user needs.
The needs come from the spatially relevant basic functions of existence: home, work, care, education and recreation (compare Partzsch, 1970). To satisfy the needs, passenger traffic arises as a mediator between the locations of the individual basic functions of existence. Freight traffic arises from the spatial structure of the economic fabric which provide goods or services to consumers. Needs cannot be satisfied arbitrarily and are in feedback with the transport offer. Therefore, in general, the *transport needs* of users are bundled in corridors and balance against the impact of traffic for the public interest. With this balancing the transport need can be limited in time and space. Spatially through the provision of service and in time by peak, off-peak periods and night's rest.
<0>
A transport demand is derived from the transport need. The derivation is formed by modelling the transport needs in dividing the basic functions of existence in areas which is called a traffic model. There are different models with different gradations to detail and input variables. For instance a traffic model is the Model EVA described in Lohse and Schnabel (1997, p. 250 ff.).
The input parameters and the result of a model need interpretation and training in the handling. Since the interpretation cannot be completely objective, it needs scientific and political work to derive instructions. The instructions from science and politics must not be mutually consistent.
Often the instructions are characterized by the historically developed problem solving strategy in a specific geographic region. Those instructions will be based on the external constraints.
Ⓑ
Under *external constraints* are geography (topology, demography, economic structure, etc.), financing and legal/political directives summarised. All external constraints can be influenced.
The geographical constraints can be influenced by means of engineering works (such as tunnels or bridges), but this is only possible if they are funded. Politics can be influenced by the political will of a region, which in turn affects the legal and financial constraints. Nowadays the political will is mainly influenced by concerns of the financing.
Financing takes place primarily by the public sector in the form of transfer payments. Schwarz (2003) describes how the funding of infrastructure is organised on several levels within a framework of financing arrangements in Germany.

Part of the framework is subsidising transport services as offers on the infrastructure. Offers are created by transport service agencies and are awarded through tendering processes.

Non-financial policy guidelines are implemented through regulation, legislation and related institutions. Riesen (2007) describes how far and how successful regulation are carried out to implement social and economic policy objectives. Motherby (2009) shows how extensive legal regulations can be. All government activities are accountable to laws that are drafted and shaped by the legislative. Institutions such as the German “Bundesnetzagentur” subsequently enforce politically motivated regulation of the transport market within their means.

<1>

From this complex political process specifications arise that are brought to the infrastructure managers. However, at least in Germany, the state infrastructure policy has a major contradiction between restructuring of the state-owned company (i.e. DB AG) and handling a federal-state conflict in infrastructure financing (compare Riesen, 2007, p. 134 ff.). This conflict leads to partly inconsistent or contradictory specifications.

A sensible way to address this is the possibility to define a *service intention* for lines and networks (compare Mahadevan, 2007). Service intention describes holding pattern, operating intervals and times for network sections. E.g. an integral periodic timetable can be adapted by additional trains for higher traffic demand during peak hours. The infrastructure can then be put into dimension based upon such a service intention. In most cases the specifications are not as detailed as a service intention. Usually the specifications are based on desired development stages, which are subsequently determined as a target network.

Ⓒ

The specifications may vary depending on the railway line and location in the network. Often the requirements for capability and behaviour for a railway line are in accordance with the UIC Code 406 (see UIC, 2004). Nevertheless, the sole consideration of capability and behaviour is neglecting the aspects of user-oriented services. Therefore, requirements of service and *operational concepts* are combined.

Operational concepts may vary according to speed, stopping patterns, type of train as well as by primary and secondary networks (compare Weigand and Heppe, 2013, p. 444 ff.). A possible operational concept for a railway line could consist of a superimposed periodic traffic with different holding patterns for passengers and additional freight trains for example. In contrast to a service intention an operational concept is more detailed concerning the data for vehicles and infrastructure.

The larger the area considered, the more complex the operational concept. This way the complexity of a concept of operations for a single region is different than for an entire country. To reduce the amount of data to what is necessary, the area and the level of detail is adjusted. In Radtke (2014, p. 56 ff.) distinction is made in three levels of detail:

- Macroscopic,
- Mesoscopic,
- Microscopic.

By the combination of the considered area, operational concept and level of detail, the inputs are formed (<2>). These inputs are used in the form of a timetable and a desired infrastructure in a railway operation research analysis.

Ⓓ

Operational evaluations are performed to make predictions on the feasibility of a specific concept. For that various tools are available (see Pachl, 2002, p. 137 ff.).

To utilize these tools in a reasonable way, an educated guess is required. The educated guess is an assumption based on knowledge and experience and therefore likely to be correct. However, it results in a lack of transparency of the process and the results. The complex and extensive data storage and many variable factors of each tool make it mandatory that an user contributes experience and knowledge in the handling. Furthermore, the tools have a little intuitive user interface (UI) and use UI concepts from the late nineties.

When performing an operational evaluation with the tools, the creative process of planning is often in the background, data management and data purity are usually more essential. Only a good data pool makes the operational evaluation feasible. In addition, a complex operational evaluation requires high personnel and time effort (compare Martin and Schmidt, 2010). To make the operational evaluation more comprehensible, it requires simple and understandable ways to explain all decisions and document them. Due to the number of variables alone that possibility is severely limited. In total, a better transparency of procedures and results would be desirable.

The result of the operational evaluation is a prediction/estimate about the performance of a concept. If the evaluation meets the original specifications of Ⓑ, the basis for the track topology (<5>) is created. If the evaluation does not meet the specifications, either the specifications or the concept must be adapted.

<3>

Changing in the input variables from the operational concept within the specifications of Ⓒ occurs frequently. The cause of the change is the iterative nature of the operational evaluation (compare Weigand and Heppe, 2013, p. 490). The input variables are altered to approximate a target value in the iterations. The target value is based on existing variables. The educated guess is most commonly used so that the alteration is as close as possible to the goal.

The change is generally a slight modification of the timetable. Otherwise, it may be conducted by infrastructure-side changes (e.g. signal or switch locations or altered track numbers and connections).

<4>
It could be that it is not possible to change the input variables of the operational concept within the specifications. Then the project must either be discontinued or the specifications are to be adapted to make it possible. The adaption then has to be done within the margins of external constraints Ⓑ. One obvious way is to change the mode of financing. Nevertheless, there is also an option to examine the legal framework of operation and therein make other arrangements effective (e.g. BOStrab[2] instead of EBO[3]).
Some operation research analyses are used to evaluate feasibility and recommendations as to the public sector. An example is the feasibility study about the "Deutschlandtakt" (see BMVI - Bundesrepubik Deutschland, 2015).
Ⓔ
When the operational research analysis is completed, specifications (<5>) are formed and the *infrastructure* is constructed by building, adapting or overhauling. The new construction or the adaptation of infrastructure is carried out by a project promoter and the construction firm. However, the ideal condition of the infrastructure after the implementation is only of limited duration. Over its lifetime, the railway infrastructure comes to wear and measures might be taking to ensure traffic safety. This is also a possibility for change in traffic demand. Therefore, a continuous adjustment of the offer (<6>) is necessary.
Ⓕ
In preparation of the *service offer* methods of timetable construction are used (compare Pachl, 2002, p. 175 ff.). The input variables are obtained from the infrastructure, for that an institution (i.e. transport association) or a transport company is able to create an offer. Different timetables are generated depending on the traffic volume in the operational concept Ⓒ. Some timetables are created beyond the scope of the operating concept. Those are e.g. seasonal timetables with additional offers or timetables in phases of maintenance or renewal work.
Due to the timetables a range of transportation links are fabricated. Those links are utilized by users to satisfy their needs of transport (<7>).

3. Conclusion and Critique

The sequential consideration of the design of railway infrastructure appears outdated. It is therefore necessary to extend and represent the dependencies of the sub-processes in a cycle. The transport needs of the user is considered only indirectly and is not commonly in the foreground. The specifications for the design come from complex political processes, which are transferred into service and operational concepts. These concepts are reviewed and assessed to turn them into a basis for the infrastructure and consequently into a timetable.
The cyclic progression of track topology design shows how its individual sub-processes interact. The consideration of the cycle, facilitates the structuring of methods for targeted design of track topology. Since the means of transport are generally established for users, the question arises whether the process should be oriented closer to the traffic demand Ⓐ of the users.
Users can generally only react to the timetable Ⓕ. Without knowing the transport needs, one can make any assumptions for the timetable in the operational concept Ⓒ without consequences. Only after the restructuring of F a timetable it may become evident that the users had other transport needs. There is an urgent need for a stronger focus on traffic demand modeling (<0>).
At the same time, there is a lack of discussion about how far to give in to traffic demand. Even if and where a limit on the fulfillment of the transport need exists. The question of how to find the balance between resource use and free development of mobility needs arises.
The discussion is mainly a social one and primarily driven through politics. Riesen (2007) shows, however, that this task is carried out only to a minor extent. Also missing are binding target definitions within the framework of service intentions (<1>).
In order to implement the service intention purposeful, the design process must move into the foreground with the tools of operational evaluation Ⓓ. Currently, these tools are not comprehensible without an educated guess, and are therefore centered on the feasibility. It is important to make the know-how communicable and comprehensible on a larger scale.

ACTIVE AND DYNAMIC RELIABILITY MEASURES BASED ON AUTONOMIC BEHAVIOUR OF ITS

Florin Codrut Nemtanu[1], Marius Minea[2], Ilona Madalina Costea[3], Ciprian Angel Cormos[4], Valentin Iordache[5]

[1,2,3,4,5] *Telematics and Electronics for Transport Dept., Transport Faculty, Politehnica University of Bucharest, Bucharest, Romania*

Abstract: The intelligent transport systems are applications of electronics, communications, sensors and IT in transport and this is the main cause for its high complexity. The complexity has advantages as the increased number of functions provided but has also disadvantages as the decreased reliability is. During the design phase of Intelligent Transport Systems is important to understand this complexity and the effect on the reliability of the system and to implement methods and measures to increase the reliability. The authors proposed in this paper an architecture of ITS based on autonomic behaviour (self-healing, self-optimising and generally speaking, self-* properties) as well as an algorithm to implement active measures to increase the reliability of the system. The algorithm is based on a reliability function defined in terms of ensuring the active reliability in dynamic and complex systems.

Keywords: autonomic ITS, active reliability, ITS reliability, reliability of complex system, reliability measures.

1. Introduction

The Intelligent Transport Systems are now more complex and diverse than the transport processes and they need a special attention in terms of insurance of safety. Safety in transport systems is very important because in these systems the probability of incident appearance is high, compared with other social activities, and the impact is measured in lives and huge amount of money. The role of ITS in increasing the safety is very important (Regan, Oxley, Godley, & Tingvall, 2001) and the new approach is to integrate ITS in transport system as a natural component. For this reason, is important to analyse the impact of ITS, as a component of transport systems, on the safety of transport system. The main condition of insurance a good level of transport safety is that the intelligent transport system has to be able to do its functions, with other words the ITS has to be reliable. A reliable system is a system which is able to be trusted and ITS needs this approach in terms of its intervention in traffic and other safety related aspects of transport.

The reliability of ITS has to be approached at the beginning, during the design of the intelligent transport systems and a reliability model is mandatory to be created and used as a reference for all components of ITS (Kabashkin, 2007).

The reliability of surface transport network is analysed in (ITF, 2010) and the approach could be extended to this research in terms of defining indicators to measure the reliability as well as the most important reliability variables which are included in active measures.

Another important and vibrant approach is the autonomic system. This concept was defined by IBM in (Jacob, Lanyon-Hogg, Nadgir, & Yassin, 2004) and was extended to other domains as transport systems and ITS are (McCluskey, et al., 2016) (Schlingensiepen, Nemtanu, Mehmood, & McCluskey, 2016). The autonomic systems could be designed and implemented in the field of transport systems and the approach of autonomic behaviour could be also used in the development of new ITS for various reasons (in this paper the main motivation is to find a solution to increase the reliability of ITS based on implementation of autonomic functionalities and active measures). The autonomic framework is important at the design stage to integrate these functionalities into the architecture of the system (Schlingesiepen, Mehmood, Nemtanu, & Niculescu, 2013). The challenge in terms of reliability is determined by the new technologies, in ITS the impact of cloud computing will transfer the reliability to other entity and the process will be adapted and the command will be replaced with a request for service.

The reliability of an ITS service is determined by the all components hardware and software and the algorithm implemented could be fundamental for reliability of the system as well the service (Kaparias, Bell, & Belzner, 2008).

The reliability of one component will affect the reliability of intelligent transport system and the reliability of ITS will affect the reliability of transport system as well as the safety of transport system (Oskarbski & Jamroz, 2015) and the main scope is to increase the safety through the reliability of the system. The quality of service (QoS) is another important concept which are able to define the service as well as the system and the reliability of the system is one variable of the QoS (Mocofan, Ghita, Tomas Lopez, & Nemtanu, 2016).

The main idea of this research is to analyse the reliability of complex system, as intelligent transport systems are, and to find the best solution in rising this reliability having as main objective a high level of safety of transport systems.

The paper is started with the analysis of reliability and the main components of it as well as the definition of the reliability functions which will be decomposed into elements. The main factors of reliability are defined in terms of correlating this factors with the general behaviour of the systems. The factors are defined through the variables/objects which are considered as inputs and the reliability function is considered as main output of the system.

Active and dynamic measures to increase the reliability of the system are based on the collection of data from the system, sometimes the monitoring system is able to collect information about the reliability of the components (Costea, Nemtanu, Dumitrescu, Banu, & Banu, 2014) and the system has to receive the commands to modify the value of the variable/object in terms of increasing the reliability of the system.

[1] Corresponding author: florin.nemtanu@upb.ro

2. Description of methods

The reliability of intelligent transport systems is the ability of the system or systems' components to perform its required functions under stated conditions for a specified time. That means, the system has to be designed and installed based on some principles and measures which are able to provide a stable and accurate level of reliability. At this step a definition of the reliability functions is needed and as well as a decomposition of this function.
The reliability of the system is the result of the reliabilities of every component of the system. A reliability function is defined to define and understand the reliability of the system. The ideal value of the reliability function is 1, that means the system is ideal and the system will be able always to perform the functions.

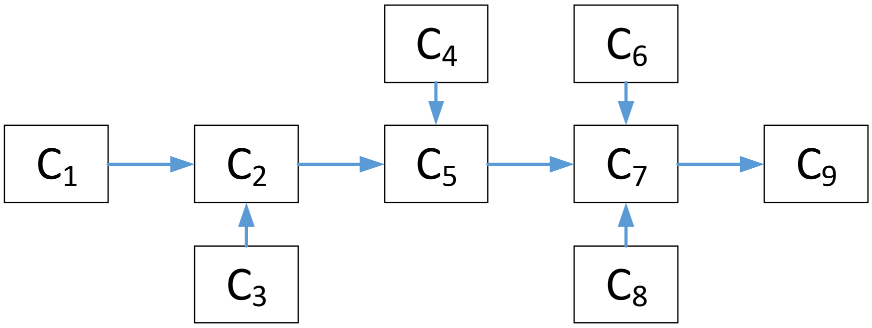

Fig. 1.
ITS structure - global reliability function

In Fig. 1, the system is decomposed into components (C_1 to C_9) and some components are redundant in terms of increasing the reliability function of the system. Every component has a number of variables which are the inputs of the model (the reliability model of the system) and the reliability function is the output of the model.

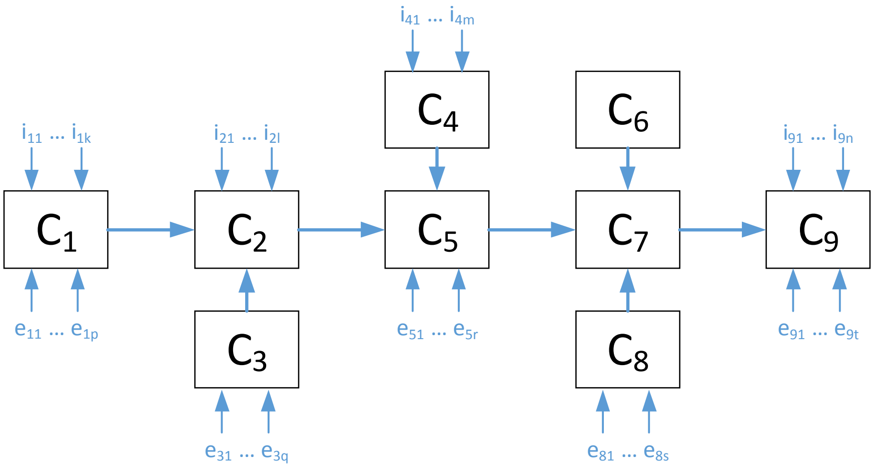

Fig. 2.
ITS components and reliability's variables/objects

Every components of the systems could have two types of input objects or input variables: internal object $\boldsymbol{i_{jk}}$ which is a variable connected to the component itself (design, materials, subcomponents, construction etc.) and an external object $\boldsymbol{e_{fg}}$ which is dependent by the operational environment of the component. These objects are influencing the reliability of the intelligent transport systems and the main objective of this research is to find the best way to increase the reliability of the system through the manipulation of these variables in a dynamic and active manner. All objects $\boldsymbol{i_{jk}}$ of all components are building together a matrix which is the matrix of the internal influenced objects of the system (***I***). All *objects* which have the same characteristics are included in a *class*. The matrix is defined by components (rows) and classes (columns).
The matrix ***I*** is defined as:

$$I = \begin{pmatrix} i_{11} & i_{12} & \dots\ i_{1k} \\ \vdots & \vdots & \vdots \\ i_{j1} & i_{j2} & \dots\ i_{jk} \end{pmatrix} \tag{1}$$

, every row contains the internal objects of reliability for one component of the system and the assumption is that the system has j components; every column contains k classes of internal and external variables of reliability.
And the matrix ***E*** is defined as:

$$E = \begin{pmatrix} e_{11} & e_{12} & \dots\ e_{1k} \\ \vdots & \vdots & \vdots \\ e_{j1} & e_{j2} & \dots\ e_{jk} \end{pmatrix} \tag{2}$$

The reliability of the system will be characterised by the matrix which is the sum of ***I*** and ***E*** (the main assumption is to have the same dimensions of the matrix, *j* and *k*).

The matrix R, reliability matrix, is defined as the sum between ***I*** and ***E*** and has the following expression:

$$R = \begin{pmatrix} i_{11} & i_{12} & \dots\ i_{1k} \\ \vdots & \vdots & \vdots \\ i_{j1} & i_{j2} & \dots\ i_{jk} \end{pmatrix} + \begin{pmatrix} e_{11} & e_{12} & \dots\ e_{1k} \\ \vdots & \vdots & \vdots \\ e_{j1} & e_{j2} & \dots\ e_{jk} \end{pmatrix} = \begin{pmatrix} i_{11}+e_{11} & i_{12}+e_{12} & \dots\ i_{1k}+e_{1k} \\ \vdots & \vdots & \vdots \\ i_{j1}+e_{j1} & i_{j2}+e_{j2} & \dots\ i_{jk}+e_{jk} \end{pmatrix} \tag{3}$$

The matrix R, in expression (3), has *j* rows (one for every component of the system) and *k* columns (one for every classes of objects) and the element *jk* ($i_{jk} + e_{jk}$) is the variable which is specific for the component *j* and the category *k*. The main reason of defining objects as main inputs is to convert, after the elaboration of the methodology, these inputs into software elements which will be able to increase the reliability of the component, at micro level, and the reliability of the system, at macro level.
The matrix R is the reliability matrix of the system and it is a picture of all internal and external variables (objects) and the elements i and e are calculated by the system using data from the design of the components as well as real time data collected from the component. The system will calculate a real time R matrix and will keep the matrix updated (the failure of one component will be registered by the system as well as the cause of the failure – object/class). The process of building and updating the matrix is described in the following figure, using UML diagrams.

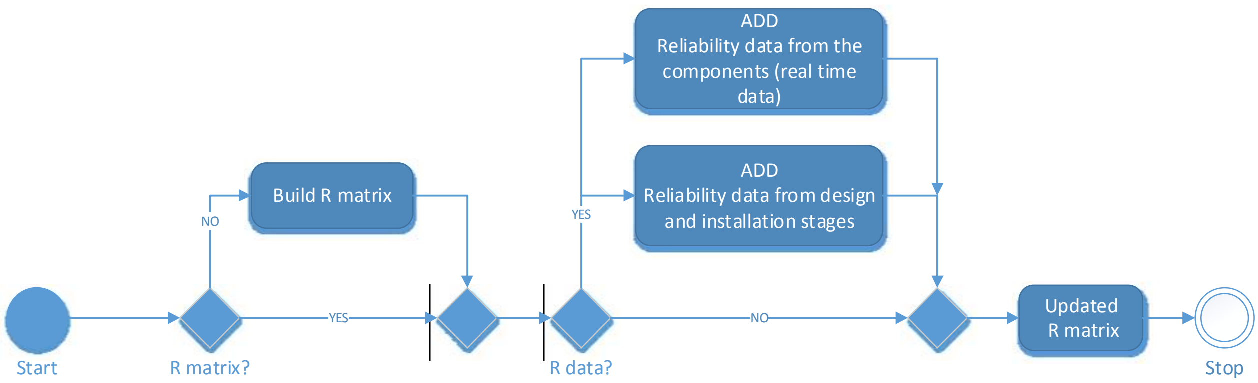

Fig. 3.
The process of building updated R matrix of the system – activity diagram

The process will start with building the matrix R and after that the data will be add to this matrix having as main result an updated R matrix. This R matrix will be used as main input for the active and dynamic measures to increase the reliability of the system. The real time data from various components of the system will be collected form a network of sensors and data loggers which are able to send real time information about the state of functionality for every component.
The paper is focused on the collection of real time data with relevance for reliability of the system and the process which is able to use this data for applying some active and dynamic measures.

3. Works

The solution proposed is based on the collection of real time data about the reliability of every component of the system, the update of the R matrix, the comparison with an ideal R matrix (or target R matrix), the applied measures to increase value of the objects in R matrix. All steps of this process will be done based on the autonomic approach (without any human intervention and based on machine learning techniques).
The model for testing the method is created in LabVIEW and 4 components of the system will be considered as well as 4 classes. The 4 components of the system, selected for this case are: the server, the display wall, bundle of cables and the HMI consoles. The 4 classes selected for this experiment are: temperature (t), humidity (h), vibration (v) and mechanical stress (m).

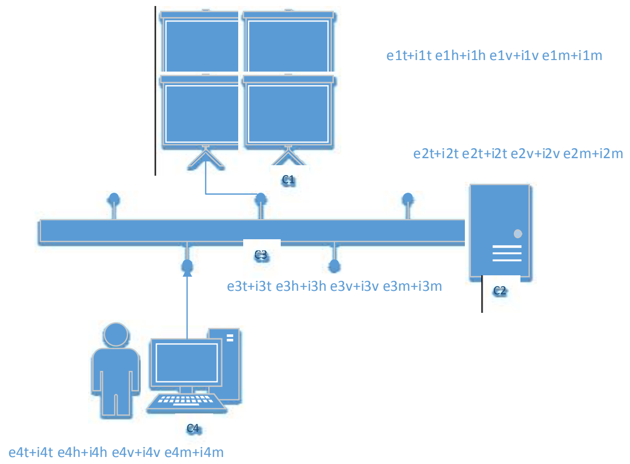

Fig. 4.
The model of the system

Based on the Fig.2 the model of the system (Traffic Management Centre) is presented in Fig.4 and the internal and external reliability objects are presented for all 4 components of the system. The R matrix of the system showed in Fig. 4 has the following expression:

$$R = \begin{pmatrix} e_{1t}+i_{1t} & e_{1h}+i_{1h} & e_{1v}+i_{1v} & e_{1m}+i_{1m} \\ e_{2t}+i_{2t} & e_{2h}+i_{2h} & e_{2v}+i_{2v} & e_{2m}+i_{2m} \\ e_{3t}+i_{3t} & e_{3h}+i_{3h} & e_{3v}+i_{3v} & e_{3m}+i_{3m} \\ e_{4t}+i_{4t} & e_{4h}+i_{4h} & e_{4v}+i_{4v} & e_{4m}+i_{4m} \end{pmatrix} \tag{4}$$

The implementation of the measures is done based on the following algorithm in terms of maintain or increase the reliability of the intelligent transport system. The algorithm is defined to increase the reliability based on collected and initial data.

4. Results

The active and dynamic reliability measures based on autonomic behaviour is realised based on a LabVIEW programme which is able to collect information from sensors (based on the data acquisition boards) and from data logger (based on importing function). In the example, the authors are implementing both sources of data for initial form of R matrix: sensors and data loggers.
The process of implementing the active and dynamic measures to increase the reliability of ITS is described in the following diagram:

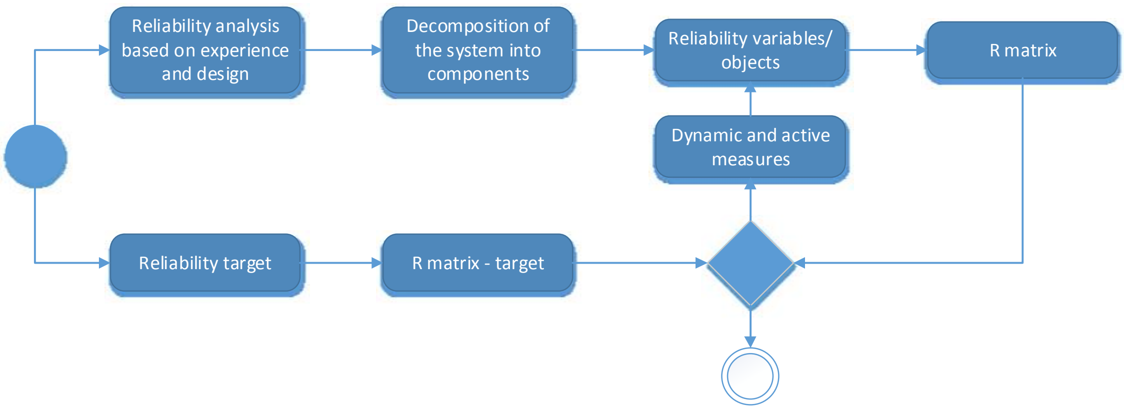

Fig. 5.
The process of increasing the reliability using R matrix

The implementation in LabVIEW has both exchange of data from data logger and sensors to the system. Based on collected data, the virtual instrument (vi file) will update the R matrix, it will compare the R matrix with the target matrix and it will send the variables to actuators to increase the reliability of the system.

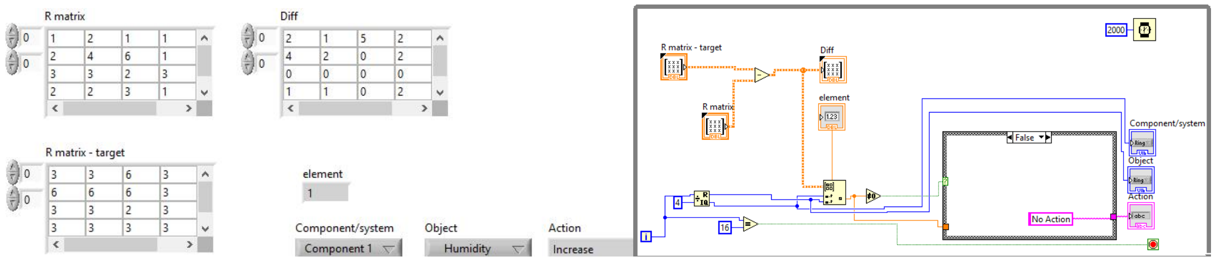

Fig. 6.
The Front Panel and Block Diagram of main VI

In Fig. 6 the R matrix is generated locally and the next step is to generated R matrix based on sensors and log files. In the same virtual instrument, the difference between R matrix and R matrix target (which is the matrix objective) is calculated and the result is displayed in Diff matrix. If the element (the number of the component as row and the object/variable as column) of Diff matrix is 0 the programme will do nothing, else, the programme will try to increase the value of the object and will send a command to an actuator or command element (for instance the command of AC to decrease the temperature).

5. Conclusions and recommendations

The main scope of this paper is to analyse the reliability of the intelligent transport systems and to find the best measures to increase the level of reliability through active and dynamic ways.
The analyse of the reliability is done through a matrix which is the main tool and will be the container of initial information as well as the real time data collected form the components of the system. The matrix will be integrated in the process of increasing the reliability of ITS. The main issue of the matrix is to populate it with internal and external objects/variable (i_{jk} and e_{jk}) and the definition of these objects.
The matrix as a tool was choose to pave the way for future mathematical processing and to facilitate the implementation of the algorithm in various software environment.
The implementation of the method in LabVIEW has the following advantages:

- The collection of data from various sensors based on the DAQ boards which are native integrated in LabVIEW,
- Import and export of files, in different format, is very facile,
- The possibility of implementation of mathematical calculus (Matlab integration facilitate),
- The existence of GUI objects,
- The possibility of actuating hardware components.

The autonomic behaviour is based on Artificial Intelligence, machine learning and other computer science technologies and it has as main result the increasing of reliability (and the efficiency of the measures of the system's reliability).
The increasing of the reliability is fundamental, not only for intelligent transport system, but also for transport system in terms of increasing the efficiency of ITS implementation. Sometimes the reliability of the ITS is strong connected with the functionality of transport system where the ITS are installed.
During the research activity the authors elaborated the following recommendations, based on the objective of this paper:

- The stability of the system after the implementation of the solution to increase the reliability of the system;
- The initial values of the R matrix are fundamental in the first stage of the implementation of the solution and the effect is decreasing at the next stages,
- The software environment is used as an integration platform and has to be able to collect data from components and to be ready for the implementation of the algorithm,
- The internal and external objects have to be defined based on the experience and best practice and have to be calibrated based on the real time data collected form sensors and data loggers,
- For components implemented in a cloud environment the command to increase the value of the object in terms of reliability will be replaced with a request for service (the system will send a request to cloud service provider to increase the reliability of the component).

ROAD SAFETY IN TUNNELS: THE ECOROADS PROJECT

Marios Miltiadou[1], Liljana Cela[2], Mate Gjorgjievski[3]
[1,2,3] *South East Europe Transport Observatory (SEETO), Serbia*

Abstract: Safety in tunnels is usually focused on risk management in case of incidents more general than road accidents (fire, collisions or car breakdown, etc.) and the safety measures and response to these incidents according to the 2004/54/EC Directive. The Road Infrastructure Safety Management Directive (2008/96/EC), which does not apply in tunnels, could be beneficial for risk prevention in tunnels, focusing on infrastructural elements seen from the road safety point of view. The "Effective and Coordinated Road Infrastructure Safety Operations" (**ECOROADS**) is an on-going project, which is financed by the EU Horizon 2020 Programme. Its general objective is to overcome the barrier emerging from the formal interpretation of the Road Safety and Tunnels Safety Directives that do not allow Road Safety Audits and Inspections (**RSA/RSI**) to be performed in uniform way along both open roads and tunnels. In this aspect, the project experiments on an integrated approach for road infrastructure and tunnel safety management, on the basis of the existing legislative framework, the available experience of road and tunnel experts and best practices. This common approach is tested at five sites in Central and Southeast Europe, where joint safety operations are performed by a mixed team of (tunnel and road) experts. This paper presents the ECOROADS approach, the results of the field tests that have been performed by August 2016 and the evaluation of the experience gained towards the improvement of this approach and the formulation of recommendations for incorporating road safety operations into tunnel safety procedures.

Keywords: road safety, tunnel safety, South East Europe, ECOROADS project.

1. Introduction – The ECOROADS project

RSA during project design or RSI after opening to traffic, according to the prescriptions of the Road Infrastructure Safety Management (**RISM**) Directive 2008/96/EC (European Commission, 2008), could be beneficial for risk prevention in tunnels. However, the RISM Directive does not apply in road tunnels, which are covered by the Tunnels Directive 2004/54/EC (European Commission, 2004) that mainly focuses on safety issues and risk management in case of hazardous incidents. The strict application of the two Directives leads to a non-uniform approach to the infrastructure safety management outside and inside tunnels and the ECOROADS objective is to experiment on merging the road and tunnels safety procedures in one integrated approach for joint road safety operations.
The project comprises workshops with stakeholders (European tunnel and road managers), exchange of best practices and experiences between tunnel experts and road safety professionals, joint pilot safety operations (field tests) at five European road sections that feature both open roads and tunnels, and - based on the results of these field tests – the formulation of recommendations for the application of the RSA/RSI concept in tunnels.
Based on the outcomes of the 1st project Workshop with stakeholders and a seminar for exchange of best practices between road and tunnel experts (September and November 2015, respectively), the relevant Directives, the available literature and the results of national and international research projects, the Common Procedures for the field tests were elaborated (ECOROADS Consortium, 2016a).
Then, from the experience gained from the first two field tests, the experts' feedback and the evaluation made during the 2nd project Workshop with stakeholders held in June 2016, the common procedures are fine-tuned during the second set of field tests organized within the period August – October 2016, paving the way for the formulation of the project recommendations for joint road and tunnel safety operations.

2. Common procedures for joint road safety operations in roads and tunnels

The ECOROADS Common Procedures concern the organization, performance, reporting and evaluation process, including the roles and responsibilities of visiting teams, the tools and methods to be used, the road/ tunnel safety elements to be assessed, etc. (Miltiadou M. et al, 2016).

2.1. The ECOROADS test sites

The ECOROADS test sites have been selected among several candidatures, following a multi-criteria ranking procedure, taking into account different parameters related to the infrastructure and the project particularities, i.e. the relevance to the project, the readiness of the hosting Road Authority/ Infrastructure Managers (**IMs**) and completeness of the candidature (information and data), and budgetary issues (accessibility to site, mobilization of experts, etc.).
All sites are located along sections of the Trans-European Transport Network (**TEN-T**) and its extension in the Western Balkans and are presented below, according to the project scheduling:

- **1st set of field tests:**
  - **Kennedytunnel, Antwerp - Belgium:** RSI at a 690m long tunnel under Schelde River, which consists of two unidirectional tubes with three lanes each for car traffic (also 1 tube for train traffic and 1 for pedestrians and cyclists). *Procedure concluded (March – May 2016)*

[1] Corresponding author: mmiltiadou@seetoint.org

- **Krrabe tunnel, Tirana – Elbasan highway - Albania:** RSI at a twin tube tunnel (2.23-2.5km) with two lanes each. Open road section on the one side of the tunnel is a motorway (RSI), while motorway construction works are unfinished on the other side (RSA). *Procedure concluded (April – May 2016)*

- **2nd set of field tests:**
  - **BAB A71/ Rennsteig Tunnel - Germany:** 19.6km motorway (two traffic lanes per direction) with four consecutive tunnels with total length of 12.6km included. Proposed site for RSI: 10.3km (including the longest tunnel, 7.9km). *Procedure commenced – Site visit performed in August 2016*
  - **Belgrade bypass Strazevica tunnel, Serbia:** RSI at single tube tunnel (745m long) with one lane per direction (bidirectional traffic), along the Belgrade bypass, which is foreseen to be constructed in full motorway profile. *Procedure commenced – Site visit scheduled for September 2016*
  - **Demir Kapija tunnel, Corridor X – Former Yugoslav Republic of Macedonia:** RSI at a single tube tunnel (554m long) with one lane per direction. Open road section on the one side of the tunnel is a motorway (RSI), while construction works are unfinished on the other (RSA). *Procedure commenced – Site visit scheduled for October 2016*

The joint operations at all sites should be performed bi-directionally on adjacent (to the tunnel) open roads, transition areas and tunnel interior, presented in **Figure 1**.

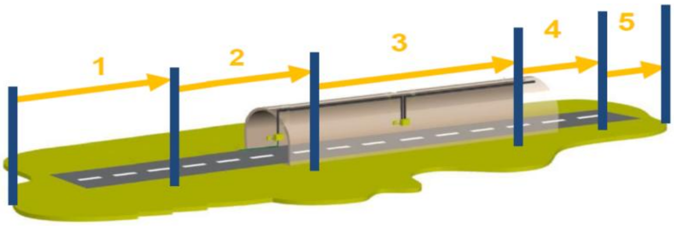

Fig. 1.
Segmentation of infrastructure for the ECOROADS field tests
Source: ECOROADS Consortium, 2016a

The length of the open road in each field test is defined, taking into account the influence of the tunnel before the transition area of the tunnel and it is defined based on the local conditions and particularities, after receiving information from the IMs and local experts, and taking into account the distance of warning of road users about the existence/ approach to the tunnel (vertical signage and road marking) and the presence of adjacent interchanges, entry/ exit ramps, weaving maneuvers, etc.
The transition area between an open road and a tunnel for the scope of ECOROADS project, is defined at least as the sum of a) the distance calculated as the distance covered in 10 seconds by a vehicle travelling at the speed limit before the tunnel portal and b) the stopping distance after the tunnel portal, for a vehicle travelling at speed limit, if not identical with design speed. This minimum rule obviously applies on the opposite direction and also - maybe slightly modified due to reduced speed within the tunnel - at the exit of the tunnel and on the same direction. The stopping distance may be calculated according to the World Road Association (PIARC, 2003), using the initial vehicle speed and other important factors, such as the driver reaction time, the longitudinal friction coefficient or the vehicle deceleration rate. Obviously, the tunnel interior section for this exercise is defined as the remaining part of the infrastructure between the transition areas on both sides of a tunnel (ECOROADS Consortium, 2016a).

2.2. Organization, planning and involved parties

Each RSA/RSI is performed by a Core Team, which is an international team of experts that jointly and independently (from the IMs) perform an RSA/RSI at a designated field test and report on their findings. This team consists of at least three and preferably four (2 road + 2 tunnel) experts, with one of road safety experts as Team Coordinator. The Core Team is part of a wider RSA/RSI Group, composed additionally by a “Facilitator”, representative(s) of the host organization/ IMs, “External” observers, an “Internal” observer, and other external experts and stakeholders.

Specifically, the participants and their roles are:

- **“Facilitator”:** a local/ national expert and member of the ECOROADS consortium that ensures a direct link with the IMs for organizational and operational purposes.
- **Infrastructure (Road/ Tunnel) Managers or State/ Regional Road Authority:** co-organizes and facilitates the RSA/RSI, provides the necessary information and data and responds to the RSA/RSI Report.

- **“External” Observers:** stakeholders with different competences, representing different authorities that can provide information to the Core Team (particularities of a test site, seasonal conditions, peak months, raining or hard winter days, etc.).
- **Other “External Experts” and Stakeholders:** experts/ stakeholders from local and national interested parties (incl. road user groups and associations), which provide complementary information.
- **ECOROADS “Internal” Observer:** a member of the ECOROADS consortium, who participates in a field test, reports to the consortium and ensures the effective monitoring and the proper and homogeneous application of the Common Procedures.

Two meetings of the RSA/RSI Group are organized at each field test:

- a **Briefing Meeting**, for presenting to the participants the scope and procedures of ECOROADS field tests, for presenting details of the project under RSA/RSI to the Core Team, for providing clarifications on issues that emerged from the available data and information, and for gathering information and opinions from external experts and stakeholders; and
- a **Completion Meeting**, for the presentation of their preliminary findings by the Core Team and for the coordination of further activities (reporting, feedbacks, deadlines).

The reporting, feedback and monitoring process comprise:

- the RSA/RSI Report of the Core Team: report with the identified road safety deficiencies, delivered to the IM and the other members of the RSA/RSI Group, with description of the proposed measures and experts’ recommendations/ advice for solutions to alleviate problems and to reduce risks and accidents’ numbers or severity in the short-, medium and long-term.
- the feedbacks from all members of the RSA/RSI Group, on specific templates designed per participant's role.
- a Report of the “Internal” Observer on the conformity of the procedures followed with the Common Procedures.
- feedback from the IM on the RSA/RSI Report.
- the Final Report, taking into account the response of the IM.

The workflow of the aforementioned activities is summarised in **Figure 2** for the first set of the field tests. The same cycle is foreseen - after fine-tuning the procedures - during the second set of the field tests.

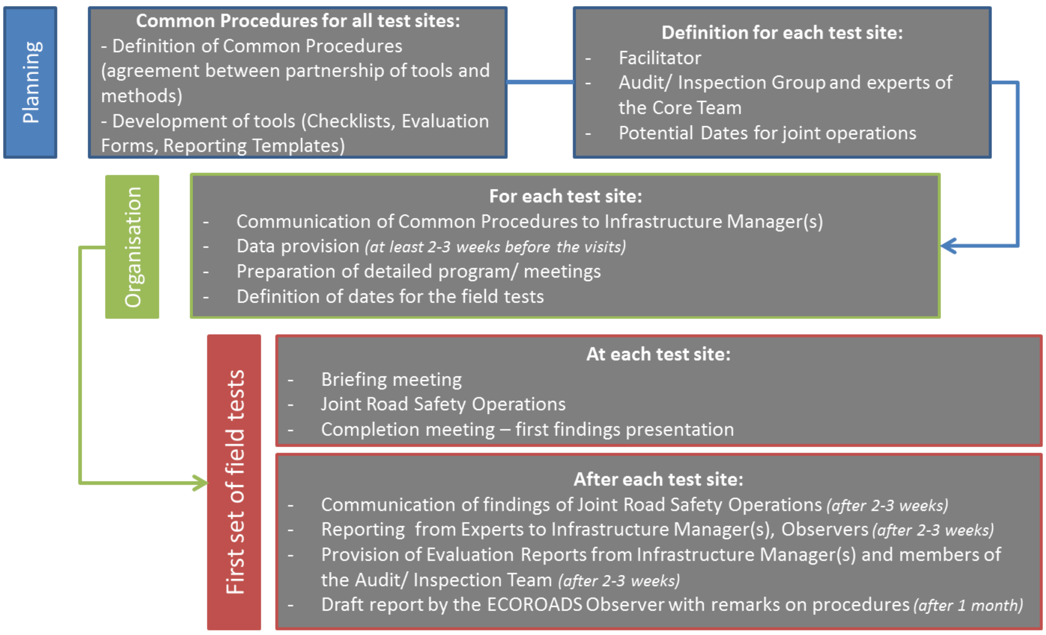

Fig. 2.
ECOROADS organisational and planning process for the field tests

2.3. Tools and methods

Generally, the tools and methods defined by the ECOROADS Common Procedures (technical equipment, checklists, templates for reporting and evaluation) are in accordance with international and national best practices and recommendations, slightly modified and adjusted to serve the project aims and needs. These comprise, inter alia, the following:

Provision of all necessary data: it is fundamental for the success of the RSA/RSI operations. The required data and documents are explicitly defined for RSI, whilst for RSA vary depending on the project maturity and the RSA level to be carried out, considering that the prepared or on-going (under construction) projects are well advanced in terms of design, as well as that RSA at different road project phases are not always performed by the various countries where the test sites are located.

Exploitation of pictures and video recordings: they should be used for preparation purposes, as well as for the preparation of RSI report. The exploitation of such material is encouraged, considering the limited time on site and for ensuring the least exposure of the RSA/RSI Group to traffic during inspections. Given also the project particularities that require mobilization of people from different European countries, the most advanced equipment and practices usage is encouraged during the field tests, ensuring less time-consuming operations and at the same time less exposure of the RSA/RSI Group to traffic.

Ensuring safety during site visits: especially regarding safety, both for the road users and for the RSA/RSI Group, appropriate measures are taken, in cooperation with the IMs and Traffic Police. The particularity of carrying out inspections on high speed roads and in tunnels requires more radical safety measures, with closures of traffic lanes), which requires appropriate warning signage (road works and directional signs, flashing lights) at specific distance before the closure occurs.

Tunnel inspections are preferably carried out during the closure of tunnel tubes for maintenance. Days and hours of the field tests should be decided according to the project needs, the traffic conditions and the possibilities for infrastructure closure, and thus with a concern to balance project needs with safety requirements. This enhances the need of dedicating more time in preparatory, in-house work and exploitation of any data and material that would be made available before the field tests.

The use of official cars for the transfer to the site and during the inspection would be most preferable, having appropriate warning signage (flashing lights). Members of the RSI Group have to respect the road/ tunnel rules and when outside from the inspection car - where this is permitted - should wear phosphorescent vest and take care not to burden the traffic and road users' behavior with any unpredicted behavior or risky activities on site.

Use of checklists: their use is recommended, as a mean that ensures a homogeneous approach and assessment of road safety and at the same time the avoidance of failures of noticing all safety problems, minimizing the possibility of overlooking some important safety elements due to a more loose approach by the experts, due to their expertise on specific aspects.

For the scope of the ECOROADS exercise, the RSA/RSI checklists proposed by PIARC are adopted as a basis of work specifically for open roads, as also used in the SEETO checklists (COWI, 2014). Especially concerning tunnels and transition areas, two checklists were composed, comprising aspects that influence road safety in these sections (e.g. sharp curves of the alignment near the tunnel, unprotected edges at portals, use of ordinary road markings instead of rumble strips), taking into account:

- the relevant EU Directives' criteria;
- elements for tunnel safety assessment included in checklists in various countries;
- relevant national RSA/RSI guidelines that include such provisions for RSA/RSI in tunnels (ARSF, 2014), (NPRA, 2014);
- the findings and recommendations of the "Human Factors and Road Tunnel Safety Regarding Users" (PIARC, 2008), and
- the RSA training material for safety in tunnels (Nitche P., 2010),

provided that the aspects to be checked in ECOROADS tunnels and transition areas should not be all those of the Tunnel Directive, but the main criterion of their inclusion in checklists should be oriented to road user' safety.

The elements of the checklists drafted for tunnels and transition areas are presented in **Tables 1 and 2**, respectively.

Table 1
Elements of Checklists for tunnel interior

A. Function, operating elements and surrounding/ road environment: 1. Information about previous RSA/RSI or Tunnel Safety Inspection final results. Issues from accident data; 2. Type of tunnel (twin tube, bidirectional, urban); 3. Design (tubes, lanes, special lanes for HGVs) and traffic characteristics (volume, HGVs proportion); 4. Transport of dangerous goods. Drainage for flammable and toxic liquids; 5. Tunnel height. Height control system for HGVs. Overtaking of trucks prohibited; 6. Water supply at appropriate intervals (250m); 7. Ventilation system/ Congestions likelihood and adequacy of ventilation system; 8. Provisions for prevention of spreading of fire and liquids inside and between tubes; 9. Equipment sufficiency (type, location, fire resistance); 10. Means for prevention of smoke and heat from reaching escape routes; 11. Emergency power supply; 12. Special weather conditions (humidity, fog, etc.) causing lack of sight due to vehicles air-conditioning/ ventilation; 13. Clean/ pleasant/ comfortable driving environment; 14. Overtaking or reversing in bidirectional tunnel; 15. Evacuation plans.
B. Cross section: 1. Same number of traffic lanes maintained outside and inside the tunnel; 2. Lanes' width; 3. Existence of emergency lane or paved shoulder (at grade or elevated)/ emergency walkways; 4. Means used along the median for separation of the two directions of traffic in bidirectional tunnels; 5. Cross-connections for emergency services for twin tubes longer than 1500m, ensuring safety of turning movements, considering the traffic density.
C. Alignment, horizontal & vertical: 1. Longitudinal gradient > 3 and ≤ 5%; 2. Cross falls; 3. Curvature (big radii).
D. Intersections/ Interchanges: 1. Junctions inside the tunnel. Adequacy of geometrical characteristics of intersection/ interchange and of entry/ exit lanes. Existence of dangerous weavings; 2. Adequacy of directional signing; 3. Sight distance; 4. Drainage system.
E. Laybys/ Emergency stations/ Emergency exits: 1. Lay-bys provided (especially when no emergency lanes exist). Adequacy of location/ density (1km intervals). Visibility. Design and dimensioning appropriate (length, width, transition sections). Distances to the portals and/or emergency exits indicated. Inclusion of emergency station; 2. Emergency stations sited at appropriate intervals (every 150m) and adequately equipped (telephone, extinguishers). Equipment available operational and offered for use by different type of users, incl. vulnerable ones (e.g. height for access); 3. Passive safety devices (barriers, impact absorbers); 4. Emergency exits for the users. Adequate number/ density (500m intervals); 5. Information provided to users and guidance/ channelization to reach emergency exits/ escape routes; 6. Appropriateness of emergency exits' type (direct to outside/ connection to other tube/ exit to emergency gallery/ shelter with escape route separate from tunnel tube) for different types of users, incl. vulnerable ones (walking length, existence of stairs, gradients, etc.); 7. Existence of emergency driver information systems (sirens, flashing lights) indicating emergency exits.
F. Traffic signals/ ITS: 1. Traffic lights or message signs; 2. Existence/ location/ intervals of signals (in long tunnels every 1km) indicating that no special conditions emerged and that the tunnel is continuously monitored; 3. Existence of VMS systems. Categories of information (congestion/ breakdown/ accident/ fire/ open-close-divert/ speed limit/ lanes allocation to vehicle categories). Understandable messages. Appropriate VMS category for switching engines off in case of congestion. VMS only in text or accompanied by pictograms; 4. Existence of tunnel control centre (for the specific one or centralized for several tunnels); 5. Video monitoring system; 6. Automatic incident detection and/or fire detection; 7. Radio re-broadcasting frequencies for emergency services and users. Radio frequency adequately communicated to the users. Loudspeakers or other communication equipment in shelters and exits.
G. Traffic signing, marking and lighting: 1. Appropriate signs used for Lay-bys, Emergency exits, Escape routes, Emergency stations, Radio, Indication of the remaining length; 2. Signs succinct in form and repeated for clarity; 3. System of signs and signals based on use of graphic symbols and/or narrative labels; 4. Signs and signals perceivable, simple, readable, credible, reliable, memorable and easily to understand (also for non-nationals); 5. Intervals of each signing category appropriate, harmonised with the driving speed; 6. Signs and signals well dimensioned, coloured, lighted and repeated frequently in a proper way; 7. Information system not complicated (e.g. numerous written instructions); 8. Sufficient (regular) chainage information, providing indication where the vehicle's position is inside the tunnel (remaining distance/ distance covered); 9. Warning signs before the last interchange that a tunnel is ahead to avoid stressful driving, over-height vehicles and provide exit of vehicles carrying dangerous loads; 10. Horizontal signing used at the roadside edge; 11. (Reasonable) compulsory driving distance between vehicles and relevant marking and signing (e.g. chevrons); 12. Use of profiled markings. Need for LED lighting; 13.Visibility in the tunnel sufficient (normal, safety, and evacuation lighting assessment); 14. Guidance systems in good condition (e.g. soiling of reflectors or functionality of LED lamps on raised shoulders); 15. Junctions, facing walls, and the like sufficiently shielded.
H. Roadside features and passive safety installations: 1. Restraint systems/ guardrails; 2. Crash cushions and impact attenuators and type; 3. Need for refurbishment to avoid risks for users from degradation of outdated equipment; 4. Emergency phones; 5. Fixed objects that could cause possible collision: Structural elements (vault, angle niche/ cross-connection, etc.), Roadside elements (guardrail, redirection profile, sidewalk, etc.), Non-structural elements (system or equipment support, fan, VMS, etc.); 6. General risks of collision between vehicles.

Table 2
Elements of Checklists for transition areas

A. Function, operating elements and surrounding/ road environment: 1. Information about previous RSA/RSI or other safety assessment (Tunnel Safety Inspection) final results. Issues from accident data; 2. Radio re-broadcasting frequencies. Radio frequency adequately communicated to the users; 3. Information provided to the users about their correct behaviour while driving through a tunnel (use headlights, avoid sunglasses, keep distances, observe signs and signals, switch the radio on and tune to indicated frequency); 4. Information provided to users about the possible incidents in tunnels and appropriate reaction; 5. Special lanes for HGVs or reduced speed limit for trucks. Affection of traffic flow. Overtaking of trucks prohibited; 6. Water supply provided near portals; 7. Gradual reduction of speed from open road to the tunnel speed limit.
B. Portal: 1. Safe design of tunnel portal for all vehicle types (funnel shape and gradual height reduction); 2. Risk of heavy vehicles hitting the tunnel ceiling or walls; 3. Portals sufficiently shielded; 4. Entrance having slowing down effect due to its design (not informative, dangerous, confining).
C. Cross section: 1. Paved area narrowed and lateral clearance reduced at entrance causing speed reduction and driving in more distance to tunnel sidewalls; 2. Same number of traffic lanes maintained outside and inside the tunnel. Sufficiency of different traffic lanes' widths; 3. Crossing of central reserve ensured outside each portal; 4. Appropriate means used along the median for separation of the two directions of traffic in bidirectional tunnels.
D. Alignment, horizontal & vertical: 1. Alignment (straight, not on curve); 2. Cross-fall; 3. Longitudinal gradient > 3 and ≤ 5%.
E. Intersections/ Interchanges: 1. Junctions inside or before-after the tunnel; 2. Adequate directional signing; 3. Dangerous weavings.
F. Traffic signals/ ITS: 1. Located well ahead the portal (150m-200m), where the drivers do not pay attention, as they are focused to the tunnel entrance; 2. Located before the entrances to ensure the closure of the tunnel in case of emergency; 3. Visibility of the traffic signals ahead of the portals in good time; 4. VMS systems. Categories of information (congestion/ breakdown/ accident/ fire/ open-close-divert/ speed limit/ lanes allocation to vehicle categories); 5. Understandable VMS messages. Messages only in text or accompanied by pictograms; 6. Possibility of posting speed limit signs at sufficient intervals to safely reduce driving speeds; 7. Need for Automatic Traffic Control.
G. Traffic signing, marking and lighting: 1. Proper distance between signs, harmonised with the driving speed; 2. Objects/ reasons of distraction of drivers from concentrating on tunnel entrance (irrelevant signs/ advertisements); 3. Signs succinct in form and repeated for clarity; 4. Signs perceivable, simple, readable, credible, reliable, memorable and easily to understand (also for non-nationals); 5. Signs and signals well dimensioned, coloured, lighted and repeated frequently in a proper way; 6. Information system not complicated (e.g. numerous written instructions); 7. Warning signs before the last interchange that a tunnel is ahead to avoid stressful driving, over-height vehicles and provide exit of vehicles carrying dangerous loads; 8. Horizontal signing used at the roadside edge; Road markings – profiled markings used. Need for LED lighting; 9. Rumble strips (acoustic lane markings) located ahead of the portals; 10. Right illumination level chosen at the entrance zone, transition zone. Illumination level satisfies all lanes; 11. Entrance into the tunnel adequately lighted; 12. Adaptation lighting (adjustment of the light intensity level) at the beginning and end of the lighting/tunnel; 13. Sight conditions at entrance poor (ocular blinding, stray light, etc.); 14. Vehicles' headlights usage obligatory and this clearly communicated with appropriate signing; 15. Entrance zone designed to provide as low adaptation luminance as possible.
H. Roadside features and passive safety installations (incl. plantings, civil engineering structures and other obstacles): 1. Restraint systems/ guardrails; 2. Need for guardrail in the portal zone. Guardrail well anchored and extended back both outside and inside the tunnel; 3. Passive objects for minimising the consequences of accident at the portal area. Crash cushions and impact attenuators and type; 4. Lay-bys for emergency, height controls etc. ahead of the portal; Emergency phones; 5. Buildings, installations and equipment for operational reasons (e.g. winter service). Appropriateness of location (distance from carriageway - more than 7m aside, distance from portal – not more than 50m), architectural design, access roads and other characteristics; 6. Paths for service or emergency vehicles to U-turn before the tunnel entrance. Grade separated (bidirectional tunnels) or at grade (unidirectional); 7. Need for refurbishment to avoid risks for users from degradation of outdated equipment.

3. Evaluation of the experience from the two first test sites

The joint road safety operations at the test sites of the first set of field tests, namely at Kennedy (RSI) and Krrabe (RSA/RSI), have already been performed in March and April 2016, respectively (see pictures in **Figures 3 and 4**).

In both cases, inspections in tunnels were held during night closures, while inspections during daylight were performed by official cars with appropriate signage, under ordinary traffic conditions and accompanied by the IM personnel. The length of the transition areas in the case of Kennedy tunnel was considered 432m on both sides of the tunnel and in the case of Krrabe tunnel 340m and 455m (one tube longer than the other).

The length of open road sections considered varied between 1200m and 2600m, depending on the local conditions and particularities of each test site (access/exit roads, ramps, alignment, etc.).

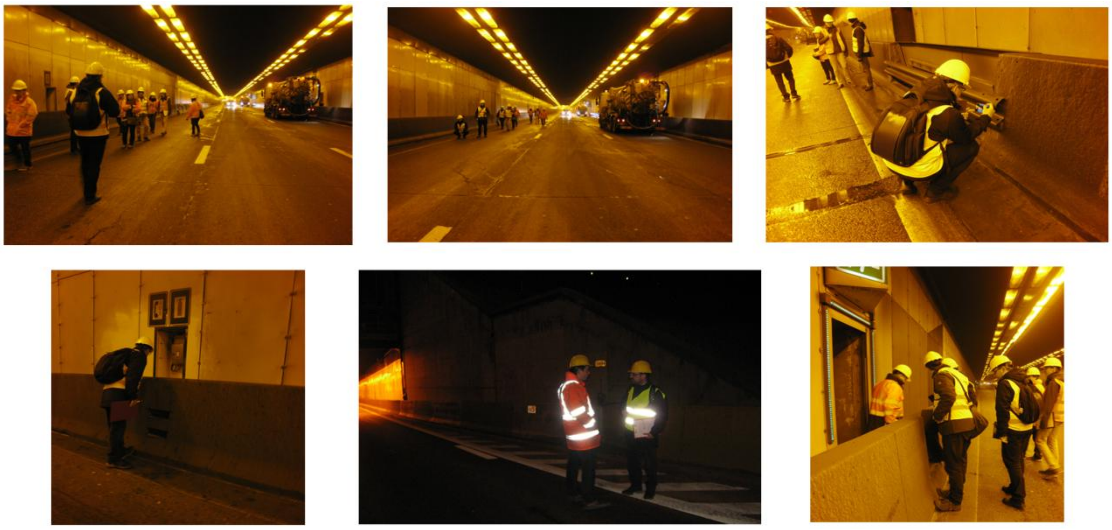

Fig. 3.
ECOROADS joint road safety operations at Kennedy tunnel, Antwerp

Fig. 4.
ECOROADS joint road safety operations at Krrabe tunnel, Albania

Both operations were considered successful, and their outcomes fed the discussions during the 2nd Workshop with stakeholders, held in June 2016. The third field test at Rennsteig in Germany was performed in mid-August 2016, having to take into account the following Workshop's outcomes for fine-tuning the Common Procedures that should be applied at the remaining test sites, of the 2nd set of field tests (ECOROADS Consortium, 2016b):

- the focus should be placed in tunnels and transition areas. Open roads should not be inspected, unless serious issues emerge from the preliminary analysis or if there is a specific written request by the IM. For this, the transition area length may be extended over the minimum value defined in the Common Procedures.
- External Observers, once admitted to participate in a field test, commit themselves to replace any eventual absent member of the Core Team, according to their expertise, and this should be taken into account while preparing the composition of the RSA/RSI Group of a field test.
- the Facilitators of the test sites shall request in advance all the video recordings available for the concerned infrastructure as well as any other historic record of accidents in tunnels and open roads.
- all the written and oral communication before, during and after the field tests must be strictly in English.
- the use of Checklists is compulsory and it is left to the Core Group to decide which parts of the Checklists shall be used at a field test.
- the IMs should provide their feedback, at least on the most important observations, within the requested deadline set by the Facilitator.

4. Conclusion – Further actions and the role of SEETO

The ECOROADS exercise differentiates from the formal procedures, in order to take advantage of its experimental character, to build on best practices and to provide solid and well documented outputs and recommendations. The common approach developed comprises a methodological framework that is based on most recent research and guidelines for RSA/RSI. The proposed tools are deviating somehow from the classic ones used, in order to cover the segmentation of road infrastructure as defined by ECOROADS, i.e. open roads, transition areas and tunnel interiors, and checklists for tunnels and transition areas, with focus on road users' safety, have been drafted (Miltiadou M. et al, 2016).

This approach has been applied during the first set of ECOROADS field tests and in its fine-tuned version is applied in the remaining three field tests. In the remaining time of the project (foreseen completion in May 2017), the performance of the last two field tests is scheduled for Autumn 2016, in order to discuss the results of the second set of the field tests during the next project meeting by the end of the year and formulate sound recommendations by the end of the project.

SEETO as a key-player for Transport Policy in the region of South East Europe, and with high concern on Road Safety, is the facilitator of all the field tests in the region (Albania, Serbia and the Former Yugoslav Republic of Macedonia). SEETO provides the possibility to national road safety experts from the region to participate in the joint road safety operations. Specifically, each time two experts from two different Regional Participants participate at one field test (apart from the experts of the host organization – Ministry/ IM/ Road Authority). Furthermore, SEETO, as the partner responsible for the Common Procedures definition, participates in all the field tests and undertook the important role of the Internal Observer of the project, ensuring the appropriate monitoring of homogeneous implementation of the procedures. Last, but not least, SEETO is involved in the task of formulation of the policy recommendations of the project, which is the overall target of the project towards improving road safety on open roads and in tunnels.

SEETO, as a regional transport organization which puts a great importance on Road Safety, will continue to lead and facilitate the work with the national administrations on their capacity building in the area of road safety audits and inspections, which is an area now recognized as one of the most tangible transport policy (soft) measures on the extended Core TEN-T in the Western Balkans, according to the High Level Western Balkan Summits held in Vienna and Paris in 2015 and 2016, respectively.

Acknowledgements

The authors wish to acknowledge the contribution of the project coordinator (FEHRL) and all the ECOROADS partners (AIPSS, ERF, ASECAP, ETSC and FEHRL third parties) for the cooperation in the framework of this project that brings important results for further consideration of the improvement of road safety in wider Europe and in the region of South East Europe. Moreover, they wish to acknowledge the constructive cooperation and the efforts of the Regional Participants for the organization of the field tests in Albania, Serbia and the Former Yugoslav Republic of Macedonia and for their active participation in the project activities and especially in the field tests.

IMPROVEMENTS OF ROAD INFRASTRUCTURE AND SIGNALIZATION ACCORDING TO "ADAS" REQUIREMENTS

Ana Trpković[1], Branimir Stanić[2], Draženko Glavić[3], Marina Milenković[4]
[1,2,3,4] University of Belgrade, Faculty for Transport and Traffic Engineering, Vojvode Stepe 305, 11000, Belgrade, Serbia

Abstract: The past decade has witnessed the development of highly advanced systems for assisting drivers while driving. The main objective has been the improvement of safety of traffic participants, alongside all the accompanying positive performances of these systems. The biggest companies in the automotive industry have already begun to implement and test the most modern technological achievements in their vehicles. However, the effectiveness of the modern Advanced Driver Assistance Systems (ADAS) can be compromised if there is no interaction between the road infrastructure (horizontal signalization – road markings and vertical signalization – traffic signs) and the vehicles which use it. Despite the brilliant possibilities of ADA systems, which can save thousands of human lives, the desired results cannot be attained without the active cooperation between the road sector and automotive industry. Large investments in the development of cars and new technologies do not correspond to the resources allocated for improving the quality of the markings which drivers follow while driving. The question can be raised: Are today's roads sufficiently "readable" for modern vehicles? According to the conducted research, the performances of built-in cameras and sensors helping the driver to react to potential dangers are significantly reduced or completely neutralized if the signalization is improper and signs damaged. The impossibility of "reading" the markings on the road using ADAS compromises the reliability of these systems and their safe application in case the quality of traffic signalization is not appropriate. The paper will more closely present and explain the issue of road „readability", as well as the possibilities of overcoming this problem. In addition, the review of the previous research and work in this field will be provided.

Keywords: driver assistance systems, traffic signalization, safety.

1. Introduction

In many countries, improving the safety performances of vehicles has represented one of the most significant causes of the reduction of traffic accidents with fatalities in the last decade. On the other hand, there has also been significant investing in infrastructure and the actions related to seat belts, drinking alcohol and speed. Unfortunately, there are still traffic accidents resulting in 300,000 deaths and serious injuries annually in Europe, which represents a 2% loss of GDP (EuroRAP and EuroNCAP, 2011).

The recent successes regarding safety in the European Union are encouraging. However, if the "vision zero" strategy is to be achieved, it will be required to raise the level of each individual element of the system "driver – vehicle – road" in the following years. Figuratively speaking: "5-star driving in 5-star vehicles on 5-star roads" (ERF and EuroRAP, 2015). Thus, modern vehicles and roads have a crucial role in returning drivers into a safe driving "mode" when their human performance fails.

Modern cars have a significantly greater role in saving human lives than they had in the recent past. Due to various technological advancements, nowadays there are vehicles on the roads which can significantly assist drivers while driving and thus raise drivers' safety and the general safety. Today vehicles can warn, guide and direct via navigation systems and take control over the braking system in dangerous situations. Modern vehicles are equipped for "reading" roads in terms of interacting with other drivers and the surroundings and in terms of recognizing traffic signalization and specific road equipment elements. However, the heterogeneous vehicle fleet with drivers of different characteristics is found on European roads which are differently equipped and signalized. Thus, using the modern driver assistance systems should reconcile these variations, contribute to the feeling of safety and increase the general level of road safety. It has been predicted that as early as in 2025 half of the travel on Europe's roads will be in vehicles equipped with some of the advanced systems. However, even the most modern vehicles, and drivers, cannot function well if road markings and traffic signs are worn out, confusing, inconsistent, non-compliant with international conventions or even non-existent. It is evident that significant results cannot be expected if the development of technology and advanced systems is not in compliance with the development of infrastructure and road possibilities. Vast financial resources are allocated for the automotive industry, while this tendency is not of the same intensity when it comes to the investment in infrastructure. According to John Dawson, the chairman of EuroRAP UK, large amounts of money are spent for the development of safety technologies but little attention is paid to the quality of road markings and signs. This results in the impossibility of using all the potentials of advanced systems. Also, the safety can be compromised if basic traffic conditions are not fulfilled – i.e. the existence of quality signalization which can be "read" by some of the ADAS technologies applied in modern vehicles.

This topic had been disregarded until 2011 when the experts from two leading European organizations in the field of road infrastructure and safety, EuroRAP (European Road Assessment Programme) and EuroNCAP (European New Car Assessment Programme) worked together with the aim to connect the automotive industry and road sector. Their basic idea was to enable the comprehensive use of the potential of the new technologies applied in modern vehicles. In this manner, thousands of human lives could be saved across Europe and the world. The working group consisting of the

[1] Corresponding author: a.trpkovic@sf.bg.ac.rs

acknowledged experts prepared a consultation paper named “Roads That Cars Can Read” and provided basic guidelines for reaching this objective, which will be thoroughly described in the following text. It should be underlined that the European Union Road Federation (ERF) offered its help and support on this project. As a result, these two organizations were organized under the auspices of EuroRAP to investigate how the road markings and traffic signs manufacturers could collaborate with the European automotive sector represented by the European Automobile Manufacturers' Association (ACEA) to bring this idea closer to realization.
The basic question raised in the consultation paper is: How can road markings and signs be optimized and improved in order to maximize the potentials of ADAS? First, it was necessary to define the current requirements of the car manufacturers, as well as the ones which could be reasonably expected in the near future, in order to enable reliable and effective utilization of advanced systems and trustworthy „reading“ of the roads. It was also required to define the priority activities at the level of the network and applied technologies. Then, it was necessary to examine the differences in infrastructure elements on the priority roads, as well as their impact on the effectiveness of the applied driver assistance systems. Thus, the conditions were set for defining the guidelines for improving traffic signalization, markings and signs on the European road network.
In accordance with the above mentioned, this report identified local and national variations in standards for basic road markings and traffic signs which could be eliminated at low cost during normal cycles of replacing signs and renovating markings, if the existing standards on the European Union level are adopted and applied in all countries. This refers mainly to ensuring consistency in the width of white lines of the horizontal signalization and retro-reflecting characteristics of the materials applied on the carriageway. It also refers to the continuity of the horizontal markings, especially of the edges of roads. The signs of vertical signalization have to be consistent regarding fonts, colours, shape, sizing, in accordance with the international convention. The weaknesses of the main European roads’ infrastructure have been analyzed in the road safety research and ranking led by EuroNAP. At the moment, there are differences regarding road elements across Europe. Michiel van Ratingen, EuroNAP’s secretary general, believes that the existing road network has not been designed in concordance with new technologies because they did not exist at the time of construction. Also, national differences are significant; thus, for example, in Germany everything could function well, but if you travel to another country, the effectiveness of these systems’ use could decrease by 10%, 20% or even more, solely due to the lack of suitable signalization or other infrastructure limitations. (TTI, 2012)
It is a fact that the majority of travel and traffic accidents happen on Europe’s roads of economic importance which comprise just ten percent of the entire European road network. Bearing this in mind, this part of the European road network and the significance of its quality equipment and maintenance have been the centre of this project, with the aim of increasing the effectiveness of the advanced systems.
Generally, the combination of various manners of road maintenance and different national regulations regarding road markings and signs throughout Europe represent a major obstacle for the effective implementation of the ADAS technologies.

2. Driver assistance systems – advanced vehicle systems

The characteristics and possibilities of modern vehicles differ significantly from those of the cars that were produced in the recent past. The cars of today include systems for driver navigation, offer different traffic information, contain built-in systems for avoiding collision, adapting speed, night vision, cruise control, etc. All these advanced technologies have been implemented in order to ensure maximum safety and additional driving comfort.
Within these systems, two systems have been most frequently implemented and regarded as the most significant, and they demand the improvement of infrastructure:

1. Lane support system - (LSS), within which the following can be singled out:
    - Lane Departure Warning (LDW)
    - Lane Keeping Assistance (LKA)
2. Traffic Sign Recognition (TSR)

Each of the above mentioned systems assists the driver in a different manner.

2.1. Lane support system - (LSS)

The Lane Keeping Assistance (LKA) and the Lane Departure Warning (LDW) can “read” the road markings and give a visual, acoustic or tactile warning if the vehicle, suddenly, changes the lane. Drivers can feel like running over a rough surface even though there are no physical changes on the carriageway. The Lane Keeping Assistance System (LKA) gives the driver significant steering support.

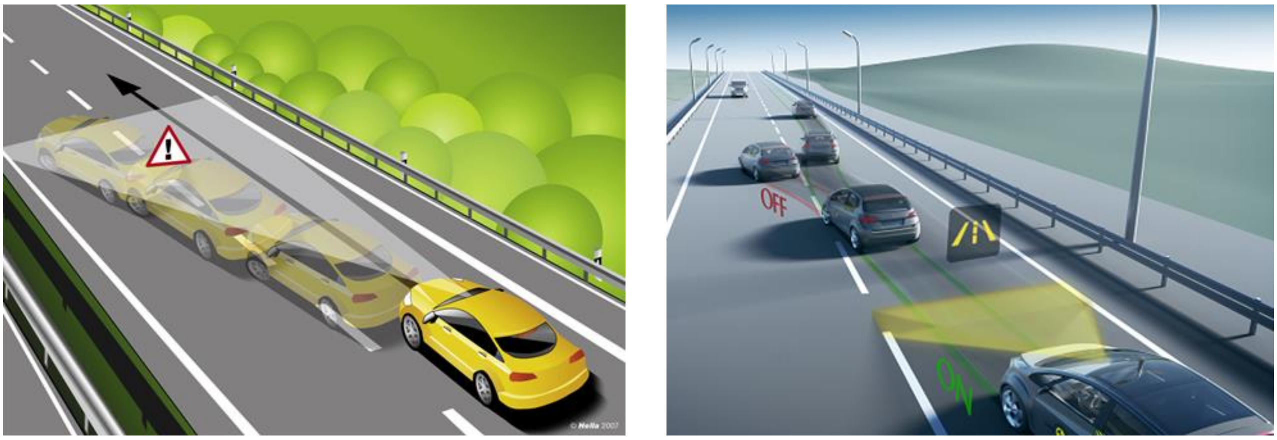

Fig. 1.
Lane Support System - (LSS)
Source: http://www.inautonews.com/wp-content/uploads/2009/10/lane-keeping.png

It is obvious that these systems demand for road markings to be visible, of good quality, same colours and dimensions, and this has not been fulfilled in the existing road network.

2.2. Traffic Sign Recognition (TSR)

Recognizing traffic signs is enabled by the built-in systems which can read and interpret various types of signs, including speed limit signs. Thus, within this group of advanced systems, Speed Alert Systems (SAS) are extremely significant and traffic signs play a major role in their effective functioning.

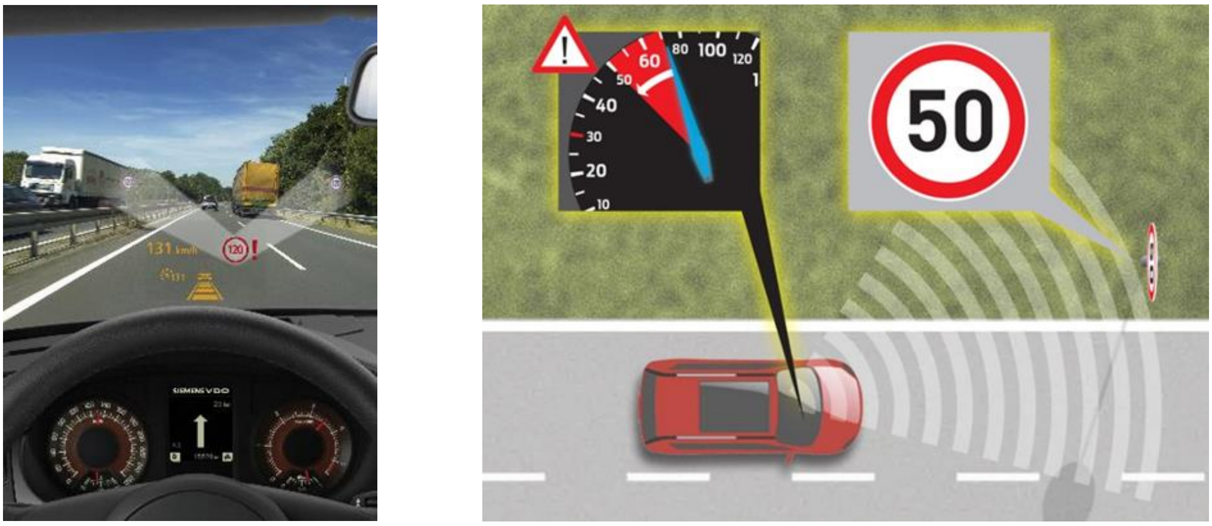

Fig. 2.
Speed Alert System (SAS)
Source: http://images.dailytech.com/nimage/2728_sc_upload_file_sv200608005_300dpi_1396442.jpg

Until recently, only the driver has absorbed the information given by road markings and traffic. The maintenance, consistency and uniformity of road markings are even more significant now that both drivers and vehicles have to “read” the posted traffic signalization. It is of utmost importance that the driver and the vehicle interpret road markings and signs in the same manner, since otherwise the safety would be in danger and consequences fatal.
The technology applied in ADA systems is similar to the human eye. It “reads” road markings and traffic signs, it assists the driver to keep in lane, keep on the correct side of the road and warns about potential hazards ahead. But like the human eye, the technology cannot work effectively if it cannot “see” road markings and traffic signs which are faded or hidden, or unclear or confusing. The mentioned advanced systems LKA, LDW and TSR “supplement” the human eye, guide and/or warn and thus ensure safe and comfortable driving.
The guidelines obtained as the result of research and analyses are primarily directed at the improvement of quality standards for road markings and traffic signs on the main European road network. Two key elements of road infrastructure which have to be adapted in order to optimize the effectiveness of ADAS in the vehicle are: road markings and traffic signs.

3. The improvement of road markings

The basic rule of the road markings' quality is: *road markings must be identically visible to the driver, day and night, and in all weather conditions* (Stanić B. et al, 1997). Their effectiveness depends on their luminance and the retro-reflectivity of the material, as well as on the surface where the markings have been applied. The European standards stipulate the minimum levels of retro-reflectivity of road markings in various weather conditions. The quality level a "good" road marking should be achieved for both wet and dry traffic conditions, which is technically feasible and cost effective in most European countries.

According to the requirements of advanced vehicle technologies, factors which can affect the operation and performance of lane departure warning (LDW) and lane keeping assisting (LKA) systems have been identified, and they are related to the road network infrastructure. According to their importance, these factors have been put in three categories:

- High Factors: road surface condition, worn out markings, multiple (confusing) road markings, old road markings which are not completely removed;
- Medium Factor: road gradient, road curvature, boundaries between several lanes;
- Low Factors: lane width, visibility;

Since road markings are applied on the road surface, it was required to define the above mentioned.

In order to obtain better road markings' characteristics, it is primarily required to improve and enhance the existing standards which road authorities have to implement in order to optimize driver assistance systems. They should be applied during the standard maintenance and replacement cycles, which would be cost-efficient and effective. On the basis of the collected data of interventions on the network and maintenance standards from a number of European countries, the ERF has defined the basic characteristics of a "good" road marking as a road marking whose **minimum performance level under dry conditions is 150 mcd/lux/m² and which has a minimum width of 150 mm for all roads**. For wet conditions, the minimum performance level should be 35 (European Union Road Federation, 2013) These requirements have been fulfilled in part of the EU member countries, so the application of this standard can be considered realistic, technically feasible and cost-effective.

Fig. 3.
New road markings
Source: http://www.geveko-markings.com/uploads/pics/ViaTherm-thermoplastic-road-marking-material.jpg

The consultation paper "Roads That Cars Can Read" provides the following guidelines and proposals for improving road markings:

- All roads should be properly marked and the markings maintained regularly to be clearly visible and not confusing;
- Using retro-reflective markings which are visible under all weather conditions;
- Synchronizing the colour and dimensions of road markings;
- Using continuous lines to delineate the edge of the carriageway;

These measures would be applied on the network of Pan-European roads which are economically significant. The implementation costs are mostly low if compared with the expected safety, while the feasibility is very high. The cooperation and harmonization between the member countries is requisite for some measures, such as the use of the continuous line for the edge of road, in order to ensure effective implementation.

4. The improvement of traffic signs

The Traffic Sign Recognition technology functions using built-in cameras which can “see” and “interpret” the traffic sign’s colour, shape, message, etc. However, in order to be effective, a sign has to be visible to both the human eye and the technology which is reading it. Thus, the principles of retro-reflectivity must be applied equally to traffic signs, i.e. the sign’s visibility is determined by the amount of the reflected light according to the European standard EN 12899.

Similarly to road markings, the factors impeding the effective recognition of conventional traffic signs have been ranked:

- High factors: vandalism/graffiti, sign position, hidden signs;
- High-medium factors: incorrectly positioned signs, the angle of position;
- Medium factors: the quality of the sign surface, inconsistent placement of the signs, differences in colour and shape;
- Low factors: confusion of multipurpose signs positioned at the same location, ambient illumination;

It should be noted that the group Variable Message Signs (VMS) causes difficulties to camera sensors. The major part of the European road network is equipped with VMS, so the requirements should be defined and proposed to be fulfilled by VMS in order to be accurately and easily read.

One of the major problems related to using new technologies in vehicles are the differences in traffic signs present throughout Europe (Table 1).

Table 1
Differences in basic traffic signs in Europe

Traffic signs	Great Britain	Greece	Netherlands	Poland	Serbia
STOP	STOP	STOP	STOP	STOP	STOP
Give way	GIVE WAY				
No entry for motor vehicles					

Source : http://www.euroncap.com/files/Roads-that-cars-can-read---0-41b5e8b7-ae0d-4fd0-abc3-0c4548cd697e.pdf

In order to use the potential of the advanced systems and reach the optimal performances of traffic signs recognition, some prerequisites must be met and they represent basic guidelines defined by the working group in the above mentioned consultation paper "Roads That Cars Can Read" (EuroRAP and EuroNCAP, 2011):

- Harmonisation of traffic signs across Europe (colours, shapes, fonts) with the Vienna Convention (Table 1)
- Standardization of European instructions for mounting signs, defining the number of signs, installation angle, etc;
- Use of more durable materials which do not lose their visibility over time;
- Regular maintenance of signs which ensures clear visibility in all weather conditions
- VTS must be developed so it can be “read” by advanced technologies as well as by the human eye;

The main aim of the application of these proposals for improving traffic signs is the more efficient use of ADAS systems and improvement of the general safety on the European road network. The costs of the implementation of these measures have been estimated as low, in comparison with the expected safety and efficiency benefits. The feasibility is high, except for the proposal referring to synchronizing the main traffic signs regulations which demands harmonizing the legislation at the highest level.

5. Conclusion

It has been predicted that until 2025 most people will travel in vehicles equipped with implemented advanced technology, which can “read” the road ahead. Due to the persistent improvement of some elements of the traffic system, modern roads and road infrastructure impede the process, i.e. it is difficult to integrate new systems into the existing infrastructure. Thus, the process of road and road infrastructure development has not been completed yet (Stanić B. et al, 2013). In the following period, the existing road infrastructure across Europe should be adapted to the requirements of intelligent vehicles in order to obtain their maximum effectiveness and safe traffic flow.

This paper offers a short review of the previous research and results in this field. It identifies the scope, feasibility, costs and limitations for improving traffic signalization which can be read by both drivers and advanced systems. Guidelines have been defined for improving traffic signalization and they should be conducted in the following period. These proposals can contribute to better interaction between vehicles and traffic signalization on the road. Some of the measures can be implemented immediately, some require further research before the application, and others can represent separate research projects which demand broader consensus of the interested parties and this can prolong the implementation.

In addition, the phenomenon of ageing of the European population should be underlined. It is expected that by 2020 approximately 25% of the drivers on European roads will be older than 65 years. Due to their decreased abilities, this category of users will need clear and visible guidance on the road. These facts indicate the necessity of rapid reaction and adaptation of the road infrastructure.

The recommendations set out in this paper represent cost-effective proposals which, if implemented, would bring significant reductions in traffic accidents with casualties and fatalities and would improve driver comfort. It should be noted that most of the proposed measures are considered to be relatively "inexpensive" in relation to the benefits which could be gained. In this manner, the existing roads would be properly adapted and prepared for the era of intelligent vehicles and the new structure of users.

Abstract: The traffic volume is frequently used as a measure of road capacity. For many types of roads significant changes in traffic intensity occur within 24 hours a day. If the traffic volumes are measured during the day at hourly intervals, usually happens that the course of traffic volumes during the day has two maxima – morning peak hour and another peak hour in the afternoon. The authors of the article deal with modeling of the course of daily traffic volume using known probability distribution, while the authors use data obtained from real measurements of traffic volumes on the various categories of roads. In the paper the authors proposed procedure that can be applied to determine the resulting daily traffic volumes from short-term measurements of traffic volumes. Proposed procedure is suitable for urban planning, construction and upgrading of roadways or land-use planning decisions, while it is necessary to plan the construction of road infrastructure on the basis of prognosis of road traffic.

Keywords: AADT, traffic volumes, individual car transport, traffic statistics.

1. Introduction

Traffic volume indicates the use and the capacity of road infrastructure. In traffic engineering the traffic volume is generally stated as so-called Annual Average Daily Traffic (abbreviated AADT) for the section of the roadway in both travel directions in the number of vehicles per day, i.e. 24 hours. AADT is the total volume of vehicle traffic of a highway or road for a year divided by 365 days.
Traffic volume is measured by manual or automated counting of vehicles on the road section. Since the traffic survey is generally time-consuming action, mostly a short-term vehicle counting is carried out (usually a few hours in the morning and in the afternoon rush hours in one day), based on which we calculate Daily Traffic Volume and Annual Average Daily Traffic, together with other transport engineering indicators (for example Design Hour Volume). In the Czech Republic the method given by the Technical Conditions no. 189 (2012) is used to recalculate the values obtained by the short-term traffic survey (vehicles counting). Similarly, the methodology for detecting traffic forecast in the future period is introduced (TP 225).
Determining and subsequent forecasting of traffic volumes serve as a basis for the designing and planning of road construction, for the processing of concepts for the development of the road network, plans for construction and repair, maintenance planning, documentation of road structures, protection solution against excessive noise, etc. In the field of traffic-engineering traffic volume is an important aspect, which also serves to develop models of the transport network and simulation of its load and to assess the capacity of roads and of level intersections. It is therefore a very important input in many applications and it is necessary to determine traffic volumes to create models that reflect the actual state of traffic on the road network In the next chapters the authors deal with modeling of the course of traffic intensity within 24 hours by using Gaussian curves. By this method ideal daily traffic intensity on specific road can be modeled from the values obtained by short-term traffic counting (Bartuska, 2015).

2. Current methodology to determine AADT in Czech Republic

The current methodology as outlined in TP 189 is used to determine the annual average daily traffic volumes on the basis of short-term traffic surveys. In practice this means, that the traffic volumes can be measured (vehicles counting) in the profile of the roadway in the range of several hours in one day, and on the basis of the hour traffic volumes daylong intensities (24 hours within that day) can be calculated using conversion coefficients for the rest of hours of a day. Thereafter the weekly variations have to be taken into account – The daily average within the week (conversion coefficients for 7 different days) is determined. Finally, monthly variations are taken into account and on the basis of conversion coefficients the AADT is calculated (Freimann, 2004).
Particular above-mentioned conversions are carried out using conversion coefficients which are determined from long-term research for specific categories of roads, days of the week, time of the year and for specific types of vehicles as well. These coefficients are listed in TP 189 "Determination of traffic volumes on roads (II ed.)" from June 2012. Formula for determining the standard AADT on the basis of the coefficients is as follows (TP 189, 2012):

$$RPDI_x = I_m \,.\, k_{m,d} \,.\, k_{d,t} \,.\, k_{t,RPDI}\ , \tag{1}$$

[1] Corresponding author: bartuska@mail.vstecb.cz

Where; $RPDI_x$: Annual Average Daily Traffic to be determined (AADT) [cars/24 hours within day], I_m: traffic volume of a given type of vehicle identified during the traffic survey [cars/traffic survey duration], $k_{m,d}$: conversion coefficient of traffic volume acquired during the survey to daily traffic volume [-], $k_{d,t}$: conversion coefficient of daily traffic volume within the day of survey to average daily traffic volume within the week (all seven days in a week) [-], $k_{t,RPDI}$: conversion coefficient of weekly average daily traffic volumes to an annual average daily traffic volume [-].
The authors in another part of the paper deal with the daily variations in traffic, especially the extent to which the current values p_i^d can be applied to determine the daylong value of traffic volume, which constitutes the first step towards determining the final AADT. Values p_i^d indicate the percentage of hourly traffic volumes *i* on total daily traffic volume and can be used to determine coefficient $K_{m,d}$ (TP 189, 2012):

$$K_{m,d}=100\% / \sum p_i^d \ [-] \qquad (2)$$

Where; $\sum p_i^d$: combined share of hour traffic volumes within the duration of traffic survey to total daily traffic volume [%].
Values p_i^d are given in the methodology TP 189 for the types of vehicles, the character of traffic on the road and the time of year and were determined from long-term measurements. Values $k_{d,t}$ a $k_{t,RPDI}$ can be obtained analogously in a similar way as the coefficient for conversion to day variation $k_{m,d}$.

3. Daylong traffic volume on urban roads – theoretical approach

The authors conducted a short-term manual traffic counting on the II. class road going throw the city (according to the Czech categories of roads - Law No.13 / 1997 Sb) in order to demonstrate the calculation of daylong traffic intensity from the short-term survey using daily variations determined in the methodology TP 189. Traffic survey was carried out in spring workday in one point of the road and the vehicles were summed overall, regardless of the individual categories. The following table shows the resulting number of vehicles according to hourly intervals (Table 1).

Table 1
Number of vehicles in hour intervals obtained from traffic survey and hourly traffic volume ratios p_i^d determined by the methodology TP 189 for II. class roads

Hour	Number of vehicles	hourly ratios p_i^d (TP 189)
07:00-08:00	580	6,79 %
08:00-09:00	956	6,63 %
09:00-10:00	838	6,34 %
10:00-11:00	856	6,17 %
Total	3 364	25,93 %

Source: Authors

As mentioned in the previous chapter, hourly ratio p_i^d is the percentage of the hourly traffic intensity on a total-daylong volume of traffic (values are given in the methodology TP 189 and in this case, the values are relevant for the spring period, vehicles in total and for the II. class road). Daily traffic intensity should thus be determined for vehicles in total by using the equation:

$$I_d = I_m \, . \, k_{m,d}, \qquad (3)$$

Where; I_d: Daily traffic volume within the day of traffic survey [cars/24 hours within day], I_m :Traffic volume determined within the traffic survey [cars/duration of traffic survey], $K_{m,d}$:- conversion coefficient of traffic volume acquired during the survey to daily traffic volume [-].
We can now determine the conversion coefficient $k_{m,d}$ from the previous chapter (equation 2) when the result is $k_{m,d}$ = 3,8565. Daylong traffic volume should be therefore I_d = 12 973 vehicles.
If we apply an hourly percentages (ratios p_i^d) on the determined daily traffic volume, we get the ideal course of the traffic intensity on the roadway throughout the day. From this perspective it is evident that the longer the short-term traffic survey, the more accurate the calculation of daily traffic volume and consequently the calculation of AADT. For most of the transport engineering applications the duration of the survey about 8 hours at appropriate times of peak hours (usually chosen time 7:00-11:00 and 13:00-17:00 during weekdays) is sufficient, when it can be expected to achieve the deviation from the actual AADT to 10%.
The following chart shows course of the traffic intensity created on the basis of number of vehicles counted during a short survey and by using percentage of hourly ratios within the working day.

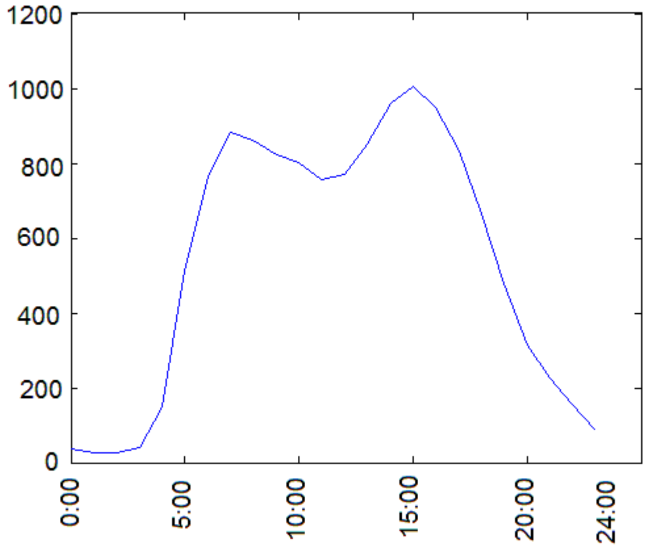

Fig. 1.
Hour traffic volumes within a day on II. class roads (according to the Czech methodology TP 189)
Source: Authors

This procedure is considerably simplified for the purposes of demonstration in this article. Methodology TP 189 is much wider due to the fact that in the calculations additional factors are taken into account, but for purposes of this article these factors are irrelevant.

4. Creating the model of daily traffic volumes

To create a model of all-day traffic intensity on selected roads it was necessary to carry out a long-term traffic survey. For three working days (Tuesday - Thursday) the number of vehicles on selected II. class roads (urban roads connecting suburban areas with the rural areas) by automatic detectors was detected. The automatic radar based traffic detection Sierzęga SR4 was used for traffic survey with appropriate software, which can evaluate other important traffic characteristics acquired by device (vehicle speed, frequency, distance between vehicles, etc.). The data from long-term survey were averaged and divided into 15-minute intervals within the specific day (Bartuska, 2015).
In our opinion, time development of traffic volumes can be described by a function

$$I_t = N_1 \cdot e^{-\frac{(t-t_1)^2}{s_1}} + N_2 \cdot e^{-\frac{(t-t_2)^2}{s_2}} \tag{4}$$

Meaning of the parameters in this formula is as follows: t_1 and t_2 are time moments when maxima of traffic intensity occur. We suppose two maxima during a day (morning and afternoon rush hours). Parameters s_1 and s_2 describe length of time intervals of maxima and, finally, N_1 and N_2 reflect traffic intensities in maximal points (Douglas, 2003).
Function given by the previous formula is, in fact, a sum of two different Gaussian functions. Recall that the Gaussian function is given by formula

$$y = \frac{1}{\sqrt{2\pi} \cdot \sigma} \cdot e^{-\frac{(x-\mu)^2}{\sigma^2}} \tag{5}$$

with parameters μ and σ (σ > 0). This function is important especially in mathematical statistics, where it describes probability density of normal distribution. Gaussian function have one maximum, which occurs at point μ on x-axis. We assume that the traffic intensity have two maxima during a day, therefore we use a function which is sum of two Gaussian functions and, consequently, have two maxima along x-axis. Moreover, morning and afternoon maximum can be of different heights, therefore we use parameters N_1 and N_2 (Douglas, 2003).
From the data divided to 15 minutes intervals we get the function

$$I_t = 178.9 \cdot e^{-\frac{(t-9.22)^2}{8.157}} + 236.3 \cdot e^{-\frac{(t-16.33)^2}{25.65}} \tag{6}$$

Calculations were done using software MatLab that provides functions for curve fitting. Software uses iteration methods - using least squares method would be not appropriate in this case. Original data in 15 minutes intervals and model function given by MatLab are depicted in figure 2.

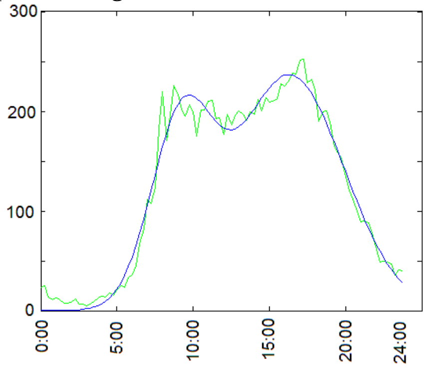

Fig. 2.
Average 15-min traffic volumes within a day on a urban II. class road: green – actual data, blue - model
Source: Authors

When comparing original data with model function, it can be observed that the function closely fits the data during intensity increase in the morning and also decrease at the afternoon and evening hours. Also note that, in reality, decrease during noon is not as obvious as in the model function.
Trend function is least precise in hours after midnight. This is caused by the fact that the minimum traffic intensity occurs around 3:00 and not at the midnight. From mathematical point of view, it would be better to model the traffic intensity from 3rd hour of one day to 3rd hour of a following day. Traffic intensity in these hours is very low (when compared to the working hours), therefore this inaccuracy can be neglected.
Daily traffic volume in the measured section of the road was 12 098 vehicles in average, trend function gives 12 039 vehicles (this value can be obtained using numerical integration).
With given trend function, we tried to model traffic intensity during 24 hours on a different road of the same type. For this prediction, we use only data acquired in 4 hours during morning peak (7:00 – 11:00). We estimate that the time moments of maxima are same for all roads of the same type. Figure 3a shows traffic intensity predicted by trend function (blue line) and real situation (green). Red color in the graph highlights the time period 7:00 – 11:00. Daily traffic volume on the measured road was 13 500 vehicles, prediction by our trend function is 13 687 vehicles. (Compare this with the result given by the methodology TP 189 according to section 3.) Same algorithm was used to predict traffic intensities on three other roads of various types (figures 3b – 3d).

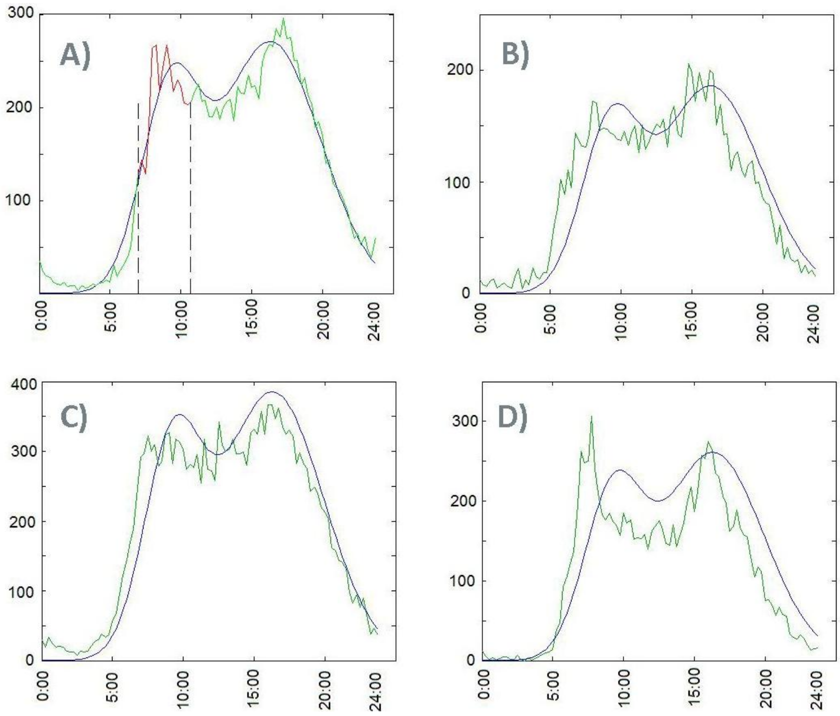

Fig. 3.
15-min traffic volumes within a day on a urban and regional roads: green – actual data, blue – intensity predicted by model
Source: Authors

It should be noted that the authors conducted traffic survey in the first three cases on II. class roads in urban areas and in the fourth case it was an all-day traffic survey on the road of the same category, but outside the city in a rural area (road D, fig. 3 d). From these measurements it is evident that the model cannot be used on the roads with different characters of traffic, although it is the same category of roads. Methodology TP 189 is considering a comprehensive set of coefficients for vehicle counting on all of these roads of the same category. The number of vehicles determined on the monitored road section with the designation “D” throughout the day is in fact significantly less than what used model calculates from short-term measurements, but also what the methodology TP 189 calculates. To properly predict the traffic intensity on this type of road (similar traffic character), long-term data are needed and new trend function for this traffic character must to be created. All-day traffic volumes on four road sections are shown in Table 2.

Table 2
Total numbers of vehicles within 24 hours on II. class roads in urban and rural areas

	real daily traffic volume	**theoretical daily traffic volume (TP 189)**	**theoretical daily traffic volume (model)**
A	13500	12973	13687
B	9268	8909	9401
C	19006	18454	19473
D	11165	12503	13194

5. Conclusion

The authors proposed a model for calculating the daily traffic volumes on particular roads using the probability distribution. From the conducted long-term survey (vehicles counting) the model of daily intensities was developed, which was applied to the resulting data from short-term measurements on different roads of same category (survey duration of 4 hours in the morning rush hour). Based on the model, it was possible to calculate the theoretical daily traffic volumes on the roads of the same category but different traffic characteristics. It was mainly the urban character of traffic and inter-town regional traffic character.

Follows from the above it is evident that as a model of Gaussian curves, neither TP methodology 189 cannot be used on a road of the same category with the heterogeneous character of the traffic. For more accurate results of theoretical daily traffic volume and subsequent Annual Average Daily Traffic (AADT) calculated from short-term surveys the additional factors should be taken into account, affecting more or less the character of the traffic on the specific road in network (Hanzl, 2016). The daily traffic volume is traffic load index on road section in particular working day of the year. For the calculation of AADT weekly and annual variations should be considered and proposed model can take these values into account after enlargement. However, the model doesn't determine the peak hour traffic intensity (Designed Hour Volume), which is significant for comparison with the capacity of the infrastructure and is needed for other traffic-engineering applications. The authors will deal with determining the optimum calculation of the DHV in their subsequent work (Kampf, 2004).

DEVELOPING A LOCATION MODEL FOR FAST CHARGING INFRASTRUCTURE ON MAJOR HIGHWAYS

Abdolmatin Shirmohammadli[1], Dirk Vallée[2]

[1,2] Institute of Urban and Transport Planning, Department of Civil Engineering, RWTH Aachen University, Mies-van-der-Rohe-Strβe 1, 52074 Aachen, Nordrhein-Westfalen, Germany

Abstract: During recent years, establishment of E-Mobility gained a significant attention of politicians and eco-friendly groups as a sustainable solution in transport sector resulted from increasing greenhouse gases and local issues such as emissions and noise. Nevertheless, the acceptance of E-Vehicles among people was not so promising due to several issues especially the limited range of E-Vehicles, long charging time and lack of enough public charging stations on the highways. Consequently EV's usage is limited only to the daily inner-city trips but not to the longer-distance weekend or vacation trips. The objective of this research is to develop an efficient and transparent location finding model for Fast Charging Stations (FCSs) on the highways based on user's point of view to cover this problem. Different use-case scenarios were developed in the proposed model which are based on traveler's charging behavior e.g. state of charge of battery by arrival and departure or range anxiety as well as their travel behavior in term of their detour acceptance to reach a charging station. Determination of optimal location for FCSs meets different user behavioral assumptions in each use-case scenario. Apart from the use-case scenarios, significant criteria were investigated and utilized in the location model such as traffic volume of commuters and foreign travelers. The input data such as highway network and existing charging stations as well as the location finding criteria and their weights are analyzed, edited and depicted in form of different layers in Geographic Information System (ArcGIS software), which enables the users to spatially couple the different information together. The proposed location model helps the authorities and investors to establish an appropriate network of FCSs on the major highways and increase the acceptance of EVs which could be considered as a midterm solution for the limited range of E-Vehicles before it is technically solved.

Keywords: e-mobility, location model, fast charging station, highways.

1. Introduction und literature review

Nowadays, the climate change is one of the most important and complex issues which gained a significant attention of different groups and societies. In this context there are plenty of efforts and policies in national and international levels to improve the efficient energy consumption in different sectors such as industry, household and transport. The potential of optimizing the energy consumption in transport sector attracted different groups of stakeholders which resulted in clean and high efficient technologies in automotive industry such as hybrid, hydrogen and Electric Vehicles (EVs). E- Mobility, as an important component of sustainable mobility development, cleans up the local air pollution, slashes global CO2 emission and through efficient energy consumption in compare with conventional internal combustion engine vehicles, allows the growing renewable energies play even more significant role in reducing the fossil fuel dependency.

Due to these excessive ecological advantages, the EVs (battery or plug-in hybrid) are expected to have a major impact on car industry however, its acceptance among people was not so promising by today. There are still significant barriers such as resistance of consumers to new and unproved technologies (Egbue, 2012), high purchase price and lack of public charging stations. Beside the mentioned reasons, technical deficits such as limited range and long charging time, which limits EV's usage mainly for short inner city trips (Frenzel et al., 2015 and Rezvani, 2015), are still significant barriers for slowing down the widespread adoption of EVs. Competing against internal combustion vehicles which can be filled up in just a few minutes and can cover a range of several hundred kilometers per tank, the biggest obstacle for spreading the EVs seems to be their range and the time it takes for an EV battery to be charged because the feeling of having a limited range and a longer fueling time isn't one that most of users are comfortable with. Capturing new groups of EV users requires fulfill this gap and enabling users to have longer intercity trips which needs at least one intermediate stop for recharging the battery. The current paper highlights the importance of a comprehensive fast charging infrastructure on highways in order to address this major concerns. Whereas the users could make use of their activity time for their daily routine activities in the urban areas such as shopping and leisure activities in order to charge their EVs, the travelers on major roads aim to reach the destination as soon as possible and there is no routine activity during the travel time. Based on this assumption, there is no usage for slow or normal charging infrastructure on the major roads but only for Fast Charging Stations (FCSs).

Whereas the conventional charging process takes several hours the fast charging technology could load the battery of EVs within 30 till 60 minutes (depending on efficiency of charging stations and battery capacity) which enables traveling a distance beyond the limited range of EVs. In this regard, FCSs could be considered as an intermediate solution for the limited range of EVs and long charging time before it is technically solved. However, high installation cost of FCSs is a significant barrier to establish an extensive fast charging network and in this regard, the determination of optimal location for fast charging infrastructure plays a key role to ensure their long-term profitability and operatability. This research introduces an efficient and transparent location model in order to find the optimal location of FCSs on the major highway network. The problem of determining the optimal location for FCSs could be approached from different point of views. Some researchers tried to optimize the electricity supply grid considering

[1] Corresponding author: shirmohammadli@isb.rwth-aachen.de

some objectives such as reducing power loses or/and reducing the voltage deviation (Wang, 2013; Mohsenzadeh, 2015; Bayram, 2013). Some others investigated the economics and business cases of this technology focusing on profitability objectives such as return of investment based on some assumptions and scenarios e.g. development and penetration of EVs in the market, utilization level of charging stations and the price of electricity in the charging stations (Wirges, 2012; Schroeder, 2012; Zhu, 2016). Some other researchers investigated the optimal location of (fast) charging infrastructure based on user's behavior, which is the case in this paper as well. This approach is generally divided into two categories of major highways and urban areas. Concerning the limited range of EVs and perceived range anxiety of users for long-distance trips, the provision of FCSs on the major highway have been the first priority of many researches and policies in the recent years (Nicholas, 2012; Sathaye, 2013; Zhang, 2015; Li, 2016). The presented location model in this paper focuses on covering the demand on major highways and explores this problem from user's behavior point of views as well as transportation criteria.
The reminder of this paper is organized as follows: Next chapter gives an insight into important characteristics of FCSs and EVs, especially those which are related to travel and charging behavior of EV users, so that the utilized criteria in the model is more comprehensible. Chapter 3 introduces the algorithm and calculation method of the model including input parameters, utilized criteria in the model and their weighting system. The proposed model will be implemented by means of Geographical Information System Software (ArcGIS Software) in the real case of Germany and the results will be presented in chapter 4. The last chapter is dedicated to discuss the validity and plausibility of the results and other possible application of the proposed model.

2. Overview of some technical attributes

The main technical characteristics of charging infrastructures and EVs will be introduced in this chapter without investigating them in detail which gives an overview about the utilized criteria and parameters in proposed location model.

2.1. Range of Electric Vehicles

The range of EVs is an important criterion in the proposed location model which is described in more detail as follows. The official announced range of an EV is measured under a very restricted standard conditions so that the range of different EVs are comparable to other EVs. However, the actual range of EVs in real driving conditions may be much less than the laboratory announced range. Environmental Protection Agency in United States (EPA[1]) simulates the real-word driving conditions and estimates the range of EVs based on a wide range of factors such as driving style and behavior of drivers, utilizing additional energy consumer devices such as air condition, radio, differences between urban or highway trips, etc. Although the EPA's estimations are not perfect however their approximation provide a reliable basis for comparison of real-word range of different EVs. Table 1 presents the range of some selected EV models measured by EPA:

Table 1
Comparison of measured range of EVs for a fully charged battery, source: EPA

EV Model	Nissan leaf[2]	Chevrolet Spark EV	BMW i3	Mercedes-Benz B250	VW-e-Golf	Tesla Model S[3]
Max. Range (km)	135-172	131	130	140	134	376-435

Another important factor which reduces the Range of EVs is the charging behavior of users because a full-charged battery is considered in calculation of mentioned ranges in Table 1 which is not a realistic supposition. Smart et.al. (2013) show that only 40% of charging processes run till full-charge and the majority of users do not charge their battery completely. Therefore the above mentioned ranges should be adjusted in accordance with charging behavior of users. Since this research does not have enough data about charging behavior of users, it is assumed that the state of charge of battery by departure is 80% which is a realistic assumption based on charging time of a battery using a FCS.

[1] Environmental Protection Agency of US https://www3.epa.gov/
[2] 24-30 kWh battery
[3] 70-90 kWh battery

Table 2
Comparison of range of EVs considering the charging behavior of users

EV Model	Nissan leaf[1]	Chevrolet Spark EV	BMW i3	Mercedes-Benz B250	VW-e-Golf	Tesla Model S[2]
Max. Range (km)	108-138	104	104	112	107	300-348

In order to cover the charging demand of all EV models, this research considers the least available range and according to the Table 2, the minimum range of EV considering charging behavior is equal to 104 km. This range will be utilized in order to develop different scenarios in the presented location model in the following chapters.

2.2. Fast Charging Infrastructures

The charging infrastructures could differ depending on charging method and technology, input electricity type and charging performance. These characteristics and also capacity of battery influence mainly the charging time of EVs that could vary from 30 minutes until twelve hours. Charging methods could be inductive in which the energy is transferred via a magnetic field, battery swapping in which the battery is not charged directly but the depleted battery is replaced with a fully charged one or the most common method of cable charging, which is equipped with a connector on the end of charging cable that can be coupled to a socket on the EV. In addition to transferring the electricity in cable charging method, the coupling could allow additional features such as starting or stopping the charging operation or energy meter. Regardless of charging method, the power levels of charging infrastructure play a key role for determining the charging time of EVs which can be divided into three charging levels. Level 1 is the lowest common voltage level available and considering the average capacity of a battery as 20 kWh, it takes roughly 6-8 hours to fully charge an empty battery. Utilizing a single or three phase AC electricity source with 3.7-22 kW power the Level 2 charging stations could reduce the charging time up to one hour. Both level 1 and 2 chargers provide AC current which should be converted to DC in order to charge the battery. It happens via an on-board AC/DC rectifier in the EVs, which take input power from an AC source and converts it to DC current. The AC/DC conversion process via on-board rectifier of EVs causes a large loss of power, therefore the level 3 charger was developed which supply the battery of EVs directly with high DC power. Although the FCSs could also work with AC electricity, but generally the term “Fast Charging Station” refers to those chargers, which provide DC electricity. According to EU definition (directive, 2014/94/EU), charging stations which transfer the electricity with a power of more than 22 kW are labeled as fast charging stations and below than this power refers to normal powered stations. The most installed FCSs in the practice have the power between 50 kW and 120 kW which are able to charge a 20 kWh battery to 80 percent of its capacity within 15-30 minutes. Many studies explored and reviewed the technical features of DC charging stations in detail (e.g. Channegowda, 2015) which is not the case in this paper. Another important characteristic of EVs is their plug-in system. Most of the EVs have a standard connector based on the SAE J1772 standard which enable them to use Level 1 or Level 2 chargers which eliminate drivers concerns about whether their vehicles are compatible with charging infrastructure or not. However, considering the level 3 chargers, there are three DC plug-in charging types by now: The CHAdeMO system developed by the Japanese auto industries which provides a current source up to 62.5 kW and it is capable generally with their EVs as well as Peugeot and Renault; Supercharger which provide 120 kW power to Tesla EVs and Combined Charging System (CCS) introduced by German engineers which utilizes a single connector allowing 50+ kW be delivered to the battery of car makers companies of BMW, Daimler, Ford, General Motors, and Volkswagen. The main point with the mentioned fast charging systems is that they are not compatible with all EVs which is an important drawback from users’ perspective.

3. Methodology

The optimal location of FCSs on the highways in this research is determined according to following steps:

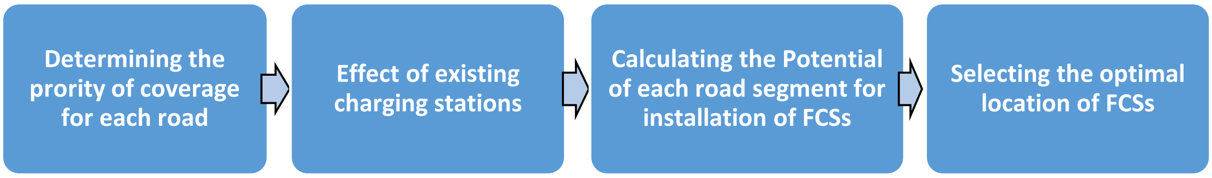

Fig. 2.
Main steps of location model for determining the optimal location of FCSs

The first step investigates and determines the priority of each road segment for covering with FCSs, which depend on different criteria and their weights. The effect of existing charging stations on potential of each road segment will be investigated in the second step. The potential of each road segment will be calculated in third step, which is based on priority of each road and influence of existing charging stations. The optimal location for new charging stations will be determined based on calculated potential in the last step. It should be regarded that the results of this algorithm could vary according to different assumptions about user behavior, parameters and weights for criteria. The input data of the location model are in geospatial vector data of shapefile format, which contains different attributes in their attribute table.

3.1. Coverage Priority of each road segment

This section differentiate the major roads in term of their priority for covering with FCSs. The coverage priority could be determined based on wide variety of criteria. Due to data gathering difficulties and also in order to avoid too much model complexity, this research utilizes the following three criteria for determine the coverage priority: daily traffic volume on roads, importance of roads as part of international road network and highway network accessibility. An important point for determining the coverage priority is that the importance of mentioned criteria could be different depending on goals of project or decision-makers' opinion. For example, if the main goal is to provide the FCSs to as many EVs' users as possible (efficiency goals), so the criterion of "daily traffic volume" should get a higher weight in compare with other two but if the provision of service to poorly accessibly areas are more important (equity goals), then the criterion "autobahn accessibility" plays more important role for determining the coverage priority.

3.1.1. Daily Traffic Volume

It is assumed that more traffic volume on a road results in more EVs (or potential EVs) on it and therefore the demand for FCSs will be higher. Considering this assumption, the data of daily traffic volume (DTV) is fed in the presented location model in a way that the higher traffic volumes on a road increase the coverage priority and conversely the lower traffics decrease it. However, this increase and decrease are not constant values but depend on assigned weight for this criterion. In order to consider this criterion and its weight in location model, the values of daily traffic volume are categorized in 10 levels, whereas the level 1 indicates to the roads with least traffic volume and the level 10 to the roads with highest traffic volume. The weights of this criterion could vary from “no weight” (the traffic volume criterion is not considered at all) to “very important” (which cause an extreme differences for different traffic volumes). The levels of daily traffic volume and the assigned weight for this criterion will determine the coverage priority each road segment using a linear function as below:

$$\mathrm{Priority_i} = \quad \mathrm{L}_{DTV} + \frac{\mathrm{U}_{DTV} - \mathrm{L}_{DTV}}{DTV_{\mathrm{Max}} - \mathrm{DTV_{Min}}} (DTV_{\mathrm{i}} - DTV_{\mathrm{Min}}) \tag{1}$$

$\mathrm{Priority_i}$: Calculated coverage priority for the road segment i
L_{DTV}: Lower limit corresponding to the assigned weight for DTV
U_{DTV}: Upper limit corresponding to the assigned weight for DTV
DTV_{i}: Level of daily traffic volume on road segment i (1, 2, … , 10)
$\mathrm{DTV_{Min}}$: Minimum level of daily traffic volume ($\mathrm{DTV_{Min}} = 1$)
$\mathrm{DTV_{Max}}$: Maximum level of daily traffic volume ($\mathrm{DTV_{Min}} = 10$)

Table 3
Lower and upper limits of the formula (1) according to the assigned weight for the criterion

	No weight	Very low	Low	Medium	High	Very high
Lower limit	0.5	0.4	0.3	0.2	0.1	0
Upper limit	0.5	0.6	0.7	0.8	0.9	1

The formula (1) calculates the priority of each road segment considering daily traffic volume and the assigned weight, which varies between lower and upper limits. If the assigned weight is “no weight” then the priority of all roads regardless of the level of daily traffic volume will be the same and equals to 0.5. The weight “very high” will cause the extreme differences of the calculated priority in a way that the lowest DTV level results in priority = 0 and highest DTV level results in priority=1.

3.1.2. Foreign Daily Traffic Volume

Depending on goals of the research, planners/decision-makers might be interested to cover the demand for FCSs on those highways which are important for international traffic. In this case the assumption is that the more foreign daily traffic volume (FDTV) on a road, the coverage priority of this road is higher (depending on the weight of this criterion). The values of FDTV is categorized in eight levels (FDTV= 1, 2, …, 8) in which the level 1 indicates to a road segment with the least foreign traffic on it and level 8 indicates to highest foreign traffic. Same as previous section, in this section also a linear function is utilized for considering the weight of foreign traffic for calculating the coverage priority of a road.

$$\mathrm{Priority_i} = \quad \left[\mathrm{L_{FDTV}} + \frac{\mathrm{U_{FDTV}} - \mathrm{L_{FDTV}}}{\mathrm{FDTV_{Max}} - \mathrm{FDTV_{Min}}} (\mathrm{FDTV_i} - \mathrm{FDTV_{Min}})\right] \tag{2}$$

$\mathrm{L_{FDTV}}$: Lower limit corresponding to the assigned weight for FDTV
$\mathrm{U_{FDTV}}$: Upper limit corresponding to the assigned weight for FDTV
$\mathrm{FDTV_i}$: Level of foreign daily traffic volume on road segment i (1, 2, …, 8)
$\mathrm{FDTV_{Min}}$: Minimum level of foreign daily traffic volume ($\mathrm{FDTV_{Min}} = 1$)
$\mathrm{FDTV_{Max}}$: Maximum level of foreign daily traffic volume ($\mathrm{FDTV_{Min}} = 8$)

The assigned weight for the criterion FDTV determines the values of lower and upper limits ($\mathrm{L_{FDTV}}$ and $\mathrm{U_{FDTV}}$) according to the Table 3.

3.1.3. Accessibility for federal highway

Generally, the highways are classified according to their capacity and function. In Germany, the road type “autobahn” with largest capacity and highest traffic speed, is the most important road category for long-distance trips. The second major through-roads are labeled as federal highway (Bundesstraße in German), which have a lower traffic capacity in compare to autobahns, however they are also expected to carry a large volume of inter-city traffic. The federal highway network is more important for the regions, those accessibility to the autobahn is difficult because the inter-city trips of residents in these regions relay mainly on federal highways. Focusing too much on only efficiency criteria such as traffic volume or foreign traffic volume will result to cover only the demand on autobahns (with normally higher traffic volume on them) and the federal highways will be ignored, which could result in inequity issues for the residents of difficult accessible regions. On this account, the decision-makers could be interested in covering the demand for FCSs not only based on efficiency criteria but also with consideration of equity goals by providing the FCSs for the regions which are located relatively far from the autobahn network, In order to consider this criterion in the presented location model, the autobahn accessibility (AAC) of each federal highway is calculated and categorized in 5 classes. The class 1 indicate to those federal highways, which could access an autobahn within 15 minutes and proceeding with 15-minutes steps, the class 5 refers to those, for them the accessibility of an autobahn is more than 60 minutes. A higher coverage priority will be assigned to the federal highways which are far from Autobahn network but those which are in close vicinity of autobahns will be regarded with less priority (depending on weight of this criterion). Calculation of coverage priority of federal highways considering the autobahn accessibility is as below:

$$\text{Priority}_i = \left[\text{L}_{\text{AAC}} + \frac{\text{U}_{\text{AAC}} - \text{L}_{\text{AAC}}}{\text{AAC}_{\text{Max}} - \text{AAC}_{\text{Min}}}(\text{AAC}_i - \text{AAC}_{\text{Min}})\right] \quad (3)$$

L_{AAC}: Lower limit corresponding to the assigned weight for AAC
U_{AAC}: Upper limit corresponding to the assigned weight for AAC
AAC_i: Level of foreign daily traffic volume on road segment i (1, 2, … , 5)
AAC_{Min}: Minimum level of foreign daily traffic volume ($\text{AAC}_{\text{Min}} = 1$)
AAC_{Max}: Maximum level of foreign daily traffic volume ($\text{AAC}_{\text{Max}} = 5$)

The assigned weight for the criterion AAC determines the values of lower and upper limits according to the Table 3. Since the autobahn accessibility is relevant only for secondary roads (the accessibility of an autobahn to autobahn network makes no sense), the average value of lower- and upper limit (0.5) will be added to all priorities of autobahns, so that the priorities of autobahns and secondary roads remains comparable with each other.

3.1.4. Coverage priority: Combination of criteria

Considering more than one creation for determining the coverage priority, the relevant components (formulas 1, 2, 3) will be summed together e.g. considering all three criteria, the following formula will be utilized for determining the coverage priority of federal highway segments:

$$\text{Priority}_i = \left[\text{L}_{\text{DTV}} + \frac{\text{U}_{\text{DTV}} - \text{L}_{\text{DTV}}}{\text{DTV}_{\text{Max}} - \text{DTV}_{\text{Min}}}(\text{DTV}_i - \text{DTV}_{\text{Min}})\right] + \left[\text{L}_{\text{FDTV}} + \frac{\text{U}_{\text{FDTV}} - \text{L}_{\text{FDTV}}}{\text{FDTV}_{\text{Max}} - \text{FDTV}_{\text{Min}}}(\text{FDTV}_i - \text{FDTV}_{\text{Min}})\right] + \left[\text{L}_{\text{AAC}} + \frac{\text{U}_{\text{AAC}} - \text{L}_{\text{AAC}}}{\text{AAC}_{\text{Max}} - \text{AAC}_{\text{Min}}}(\text{AAC}_i - \text{AAC}_{\text{Min}})\right] \quad (4)$$

And coverage priority of autobahn segments will be calculated according to the formula 5.

$$\text{Priority}_i = \left[\text{L}_{\text{DTV}} + \frac{\text{U}_{\text{DTV}} - \text{L}_{\text{DTV}}}{\text{DTV}_{\text{Max}} - \text{DTV}_{\text{Min}}}(\text{DTV}_i - \text{DTV}_{\text{Min}})\right] + \left[\text{L}_{\text{FDTV}} + \frac{\text{U}_{\text{FDTV}} - \text{L}_{\text{FDTV}}}{\text{FDTV}_{\text{Max}} - \text{FDTV}_{\text{Min}}}(\text{FDTV}_i - \text{FDTV}_{\text{Min}})\right] + 0.5 \quad (5)$$

3.1.4. Example for calculation

The priority of each road segment has been calculated considering the following weights for different criteria and the attribute table of highway network shapefile is depicted in the Fig. ***6***.

- Daily Traffic Volume: High
- Foreign Daily Traffic Volume: Very high
- Accessibility for secondary highways: Low

3.2. Effect of existing FCSs

This section analyses the effect of already installed charging infrastructures on covering the demand on the highways because it could be possible that despite a high priority of a road segment, the demand is already satisfied. In order to investigate the effect of existing FCSs in the location model, some technical properties of FCSs and EVs as well as traveler's behavior in term of their detour acceptance should be analyzed which are described in the following sub-chapters.

3.2.1. Type and Efficiency of FCSs

As it is described in second chapter, two key technical characteristics of FCSs are their plug-in system and charging efficiency. The presented location model differentiates between FCSs in terms of these two characteristics (see **Fig. 3**) because different types of plug-in systems are not compatible with all EVs and also the charging efficiency determines the charging time of battery. In order to simplify the calculations in location model, the charging efficiency of FCSs are aggregated into two groups of 50 kW (22 kW up to 50 kW) and 50 + kW (50 kW and more).

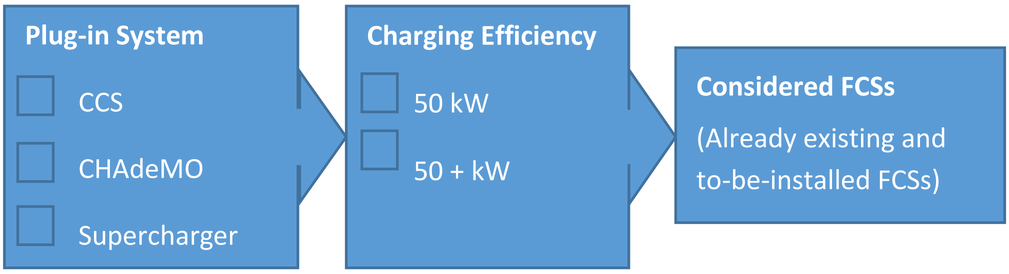

Fig. 3.
Plug-in system and charging efficiency of to-be-installed FCSs

As it is mentioned, the most installed FCSs in practice provide the charging power of 50 kW and more (the 50+ kW group by above grouping), which are able to charge a 20 kWh battery to its 80 percent of capacity within only 15-30 minutes. Considering the significant shorter charging time by 50 + kW FCSs in compare with 50 kW, as well as the use-case of FCSs on the highway network, in which the users aim to charge their battery as quick as possible and proceed their trip for next stage, the regarded FCSs in this paper are 50 + kW FCSs, which are significantly faster than the other group and increases the flexibility of travelers considerably.

3.2.2. Detour to FCSs

The next step is to identify and determine those roads which are affected by the FCSs. In order to do that, we look to the traveler's behavior in term of their detour acceptance. The assumption is the better accessible charging stations located directly to the road are, the easier and more comfortable is its utilization for travelers and by getting far from the road, the attractiveness of FCSs decrease because of larger imposed detour. The FCSs which are located beyond maximum acceptable detour by travelers are not attractive anymore for covering the demand on highways. Here it is necessary to mention that the analyzing the travelers' detour behavior requires a comprehensive user study which is not the topic of this paper. However, a simplified approach with reasonable assumptions has been employed in order to model the travelers' detour behavior, which is depicted **Error! Reference source not found.**. This approach is implemented using network analyses of the ArcGIS software whreas the first class indicates to roads with maximum 2 km detour, the second class indicates the accessible roads with 2-5 km detour **Fig. *1***and the last class specifies those roads from them the FCS is reachable within 5-10 km detour. In the specific example of the Autobahn A96 is located directly to the FCS (passing through the first detour class) and the travelers can utilize it conveniently, while federal highway B17 is reachable with 5-10 km detour which is the third detour class.

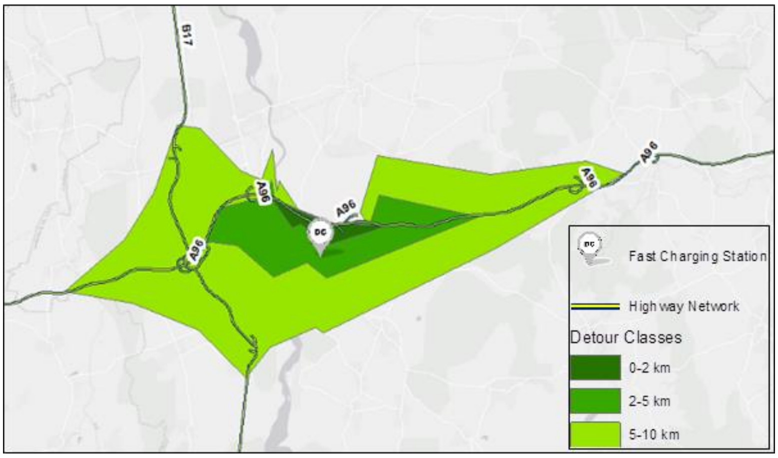

Fig. 4.
Modelling the detour acceptance behaviour of travellers and creating the detour classes using the network analyses in ArcGIS software

3.2.3. Covering the demand on highways

After defining the to-be-considered FCSs in term of plug-in system and charging efficiency as well as identifying the effected roads in different detour classes, it will be analyzed how far along the effected roads the demand will be covered. At this point the range of EVs plays the key role which is described in section 0. In order to setup a comprehensive network of FCSs which supports all EVs with different ranges, the minimum range of 104 km in Table 2 has been utilized. This range is considered as maximum traveled distance until the battery of EV is empty which we call it here as "available range". However, we do not expect that the travelers will make use of all energy of battery till it is depleted. We assume that, before the battery is empty, the travelers search for a charging station in order to avoid the possible staying on the road due to empty battery. A research conducted by Franke (2014) shows that the travelers consider 20-25 percent of the available range of EVs for searching a charging station. After subtracting 25% of available range as buffer for finding a FCSs, we call the remaining range as "comfortable range", which is equal to 78 km. The following scenarios for covering the demand on roads based on the calculated ranges is depicted as below:

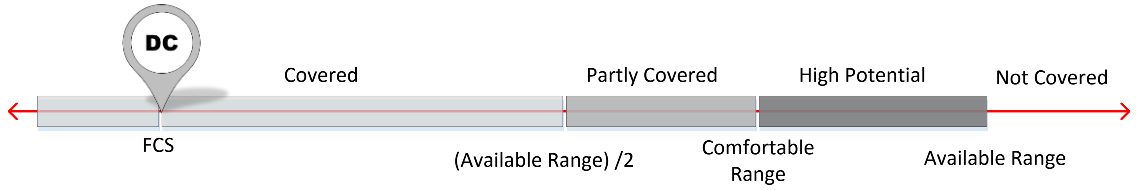

Fig. 5.
Coverage status of highways based on different scenarios of user-charging behaviour and range of EVs

Considering the Fig. ***5***, travelers can depart from depicted FCS until half of available range of EV and come back without intermediate charging (depicted in light grey) which is labelled as "covered" because installing a FCS in this area is not necessary. The dark grey colored road, which is labelled as "high potential" segment is an optimal area for installing a FCSs because, it is the area in which the traveler is searching for a FCS to refuel the battery. Installation of a FCS on the road segments farther than dark grey depicted area is not interested anymore because of range limitation. If installing a charging stations is not possible in the "High Potential" depicted road segment (due to technical issues, installation cos, etc.), then the middle grey colored area is in second priority, which is farther than half of available range but the traveler is still in the comfortable range. The mentioned approach is performed with consideration of FCSs with CCS plug-in system and minimum charging efficiency of 50 kW as well as the three detour classes mentioned in previous section. In so doing, the attribute table of highway shapefile will contain three columns corresponding to the three detour classes and the content of them is the coverage status of each road segment (see the Fig. ***6***).
If a road segment is influenced by more than one FCS, which is located in a same detour class, e.g. a road segment is considered as "covered" regarding a FCS and at the same time it is considered as "high potential" regarding another FCS, then only one coverage status should be written in the corresponding column of attribute table, which is determined according to the Table 4. For example in above mentioned case, only the status "covered" will be assigned to the road segment.

Table 4
Determining the coverage status in case of several coverage statuses in a same detour class

Several coverage statuses in a same detour class	Coverage status in the attribute table
Covered, partly covered, high potential	Covered
Partly covered, high potential	Partly covered

3.3. Calculating the potential of each road segment

This section aims to calculate the potential of each road segment for installing a FCS based on coverage priority and effect of existing FCSs for satisfying the demand on highway. The coverage priority of each road segment has already been quantified in the section 0 and now the effect of existing FCSs, which is reflected as coverage statuses of a road segment in different detour classes (see the section 0), will be quantified and utilized as a weight in order to calculate the potential of road segments. A better contribution of a road segment for setting up a FCSs network in combination with existing FCSs results to higher weights for this road segment. In addition to coverage status of a road segment, the travelers' detour acceptance behavior also should be regarded for determining the weights, which are described in following assumptions:

- If a road segment is located in "covered" area of a FCS in detour class 1 (light grey segment in Fig. ***5***), it means that the demand for FCS is satisfied with a very good service quality and consequently the potential of this road section will be very low (almost zero). However, if the charging station is located in second or third detour classes, then the travelers need to take a longer detour to reach it therefore, installing an additional FCS in close vicinity of highway (which is accessible within the detour class 1) increases the travelers' comfort. Therefore, if a road segment is covered with second or third detour classes, the potential of this road segment, due to its potential to increase the user's comfort, will be higher than a road segment covered in first detour class.
- If a road segment is located in "high potential" area (dark grey colored segment in Fig. ***5***), then installation of a new charging stations could optimally contribute for setting up a FCSs network and covering the demand on highways. For this reason, the highest weight will be assigned to this road segment. However, the

assigned weight varies according to the detour classes in a way that the higher weight will be assigned to “high potential” segment in detour class 1 and the weights decreases for farther located FCSs.

- The “partly covered” road segments (middle grey area in Fig. ***5***) are considered as second priority area, in case the installation in “high potential” areas is not possible due to technical or financial issues. The weights in compare with “high potential” areas are lower but they are higher than covered areas. The corresponding weights will be determined again in accordance with detour classes.
- The “not covered” road segments are not influenced by existing FCSs therefore, the assigned weights to them are assumed to be higher than “covered” areas and lower than “partly covered” and “high potential” road segments. Since they are not influenced by existing charging stations, the detour classes is meaningless in this situation.

Considering the above mentioned assumptions and the fact that their order and interrelationship are important, the number of possible combinations is 4*4*4 = 64. It should be noted that, there is no single correct way for determining the value of weights but the important point is to respect the mentioned assumptions, which make the assigned weights comparable to each. We assigned appropriate weights for each combination by consideration of the above mentioned assumptions as well as calibration of them in several pre-implementations of the location model. The calculated values of coverage priority and the assigned weights for each road segment are now determined and the potential of each road segment will be calculated by multiplying these two values (see the Fig. ***6***).

Highway Network

Fig. 6.
Attribute table of highway shapefile after calculation of the potential of each road segment

3.4. Selecting the optimal locations

The first optimal location for FCSs on highways is determined based on highest calculated potential of road segments. The selected location, which is assumed as middle point of the road segment with highest calculated potential, is considered as a new charging station and its effect on covering the demand on highways and subsequently on potential of road segments will be investigated. It should be noted that the to-be-installed charging station is located in detour class 1 of the road segment with highest potential, because it is supposed that the new station will be installed directly to the highway due to travelers comfort. By doing this, the status of those road segments, which are affected by the new charging stations and consequently the assigned weights of them should be updated. The potential of road segments also will be calculated again according to the new assigned weights and the next optimal location will be selected according to the updated potentials. In each iteration for selecting the next optimal location, the conditions for ending the selectin loop should be checked otherwise the selection loop will continue until all road segments will be selected. The terminating condition could be defined based on research goals and decision maker’s opinion for example ending the iteration after selection of specific number of optimal locations or covering a specific percentage of highway network with specific detour class.

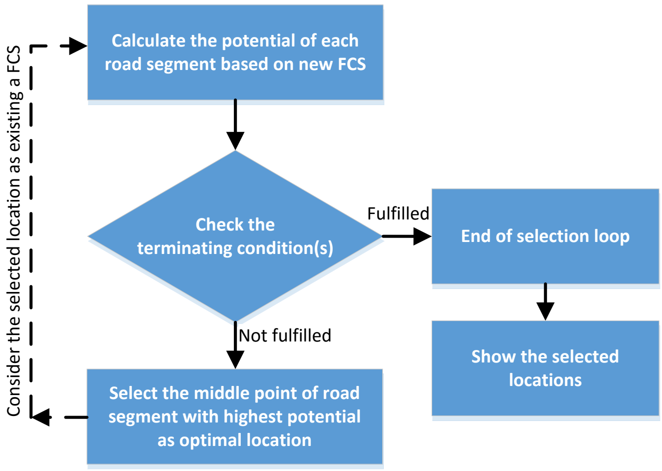

Fig. 7.
Iteration process of location model in order to select the optimal locations

4. Results

In order to implement the introduced location model in real case, the highway network of Germany with nearly 13,000 km autobahn and 38,000 km secondary roads (Bundesstraße in German), which is one of the most dense highway networks in Europe, has been selected. The required input data for the location model in this area has been collected from different sources which will be introduced in the relevant sections. The gathered data are prepared and edited in form of georeferenced shapefile layers, so that they could be combined and spatially analyzed in ArcGIS software. According to the first step of the location model methodology the coverage priority of road segments has be determined. It should be noted that there is no single correct way to determine the coverage priority and it depends on goals of projects from decision makers' point of view and assigned weights to different criteria. This research utilized following weights shown in Table 5, which focus rather on efficiency of to-be-installed FCSs and the optimal locations will be determined based on this scenario.

Table 5
Source and weight of network data and criteria for determining the coverage priority of road segments

Data/Criteria	Source	Weight
Highway network shapefile data	HERE Maps (Release date: Q3 of 2016)	--
Daily Traffic Volume (DTV)	Automatic counting System, BASt (2015) [1]	Very high
Foreign Daily Traffic Volume (FDTV)	Bast (release date: 2013)	High
Autobahn Accessibility (AAC)	BBSR (release date: 2015) [2]	low

The prioritized road segments were categorized in five different levels from "very low" to "very high" priority and illustrated on the right side of Fig. **8**.

Source: Here Maps; Background: Openstreetmap.org

In order to investigate the effect of existing charging infrastructures, first the type of to-be-considered FCSs should be defined. This research considers the FCSs with plug-in system of Combined Charging System (CCS) and minimum charging power of 50 kW. The required input data of existing charging infrastructure have been retrieved from GoingElectric.de website[1] which is converted in shapefile format by means of ArcGIS software. The total number of existing CCS charging stations with minimum 50 kW power is 239. Three detour classes of 2 km, 5 km and 10 km were adopted for reflecting the different comfort levels of users in term of their detour acceptance and in so doing, those roads their demand is influenced by existing FCSs in different detour classes have been identified. By applying the available and comfortable range of 104 km and 74 km, respectively, the location model shows that 71% of autobahns are already covered considering the maximum detour of 10 km, which is shown at the right side of Fig. 9. It should be noted that the road segments with "very low" coverage priority have not been shown in the depicted highway networks of Fig. 9 due to simplification and better visualization. By the way, their potential, which are important for selection of optimal locations, is still calculated in the location model.
After clarifying the coverage status of each road segment in different detour classes and assigning the corresponding weight, the potential of each road segment will be calculated by multiplication of the assigned weights and the calculated coverage priority. The first optimal location will be selected based on the highest calculated potential and then it will be considered as an existing charging station for next selection. The iteration loop for selecting the locations of new charging stations has been executed until one of the following terminating conditions for ending the selection process is fulfilled:

- Selection of maximum 40 new locations for fast charging stations or
- Coverage of minimum 90% of Autobahns with detour class 3.

The first condition represents the limitation in number of to-be-installed charging stations, which refers to possible restrictions in term of available budget and could be interesting condition especially form decision makers' point of views. The second condition is considered due to efficiency of to-be-installed FCSs in the network and it is not set on coverage of 100% of autobahns because in some cases, especially at the close vicinity of borders, where covering a small road segment of highway network could cost an additional FCS and might be not so interesting in term of cost-benefit consideration. On the other hand, the uncovered road segments at the edge of borders could be already covered by FCSs beyond the borders in the neighbor countries, which are not regarded in this research. It should be also mentioned, that the utilized conditions for ending the iteration loop could differ according to the research's goals however, these two conditions were adopted in order to generate a scenario-based result of the developed location model. By running the location model and after the selection of first 20 optimal locations, the covered area of autobahns

[1] Retrieved at 01.07.2016 from website of http://www.goingelectric.de/

increases to 80% (depicted map at the middle of Fig. **9** and by continuing the selection process until 40 optimal locations, the coverage status of autobahns reaches 86% coverage of whole autobahn network. Since the first condition for ending the selection loop is satisfied, the location model stops selecting further locations.

5. Conclusion

As any other motorized transport mode, EVs also need an appropriate refueling infrastructure for their energy source. Regarding the current limited range of EVs, the users expect a fast, reliable and easy accessible charging infrastructure on the main roads for their intercity and long distance trips. The proposed model in this paper aims to develop an efficient and transparent model, in order to cover the growing demand for FCSs of current EV users on the major roads which is also one step forward to increase the acceptance of electro mobility as a very important component of sustainable transportation. The proposed location model in this paper tries to determine the optimal location of FCSs on the major highway network based on different criteria from decision-maker's and end-user's point of view. By means of prioritizing the highway network via assigning different weights for coverage priority criteria, the decision makers are able to determine the optimal location of new FCSs in accordance with goals of project. The prioritizing criteria include two efficiency criteria of Daily Traffic Volume (DTV) and Foreign Daily Traffic Volume (FDTV) as well as an equity criterion of Autobahn ACcessibility for federal highway (AAC), which enables the decision makers to combine them with different weights in order to calculate their scenario-based results. There is no interrelationship between the utilized criteria however, they could be insufficient and other relevant criteria could be added to these list. In addition, the three different detour classes in the location model consider the user's behavior in term of detour acceptance and represent the comfort levels of users in the location model. The utilized values for detour classes in this paper are estimated based on the distance of rest areas on the highway however, a comprehensive user-study is required in order to determine them. Moreover, the user's charging behavior is simulated in the location model by considering the range of an EV and range anxiety of users, which is reflected in different coverage statuses. Although utilizing the range of EVs in real world condition and considering the 80% as state of charge of battery by departure however, a hidden assumption in location model is that the users have all information about location of next FCSs and they won't miss a charging station mistakenly which is an ideal assumption and the validity of these assumption should be also proved.
Considering above mentioned assumptions a scenario-based result has been calculated, which shows a reasonable and acceptable result. A more precise look into the determined locations shows that a considerable number of selected locations are at the close vicinity of borders. Beside high assigned weight of foreign traffics, which could be a reason for these selections, the accurateness and validity of these selections should be proved by considering the stations in the neighbor countries, because existing charging stations right beyond the border on the same road could satisfy the demand on the road so that an additional FCSs is not required anymore. Finally, it is worth mentioning that although the pillar of this research is dedicated to find the optimal location of fast charging infrastructure however, the proposed model is developed in a way that is adaptable for other refueling infrastructures such as Hydrogen or CNG (Compressed Natural Gas) stations.

Acknowledgements

We are grateful to Mrs. Nasim M.Nejad Fard and Mr. Yordan Monolov for their assistance with implementation of the model, especially by their outstanding programming skills, which improved the manuscript significantly.

ANALYSIS OF RAILWAY INFRASTRUCTURE CHARGES FEES ON THE LOCAL PASSENGERS LINES IN CROATIA

Borna Abramović[1], Jasmina Pašagić Škrinjar[2], Denis Šipuš[3]
[1,2,3] University of Zagreb, Faculty of Transport and Traffic Sciences, Vukelićeva 4, HR – 10000 Zagreb, Croatia

Abstract: According to the document by the European Commission entitled White Paper, railway transport is the road-map to a Single European Transport Area – towards a competitive and resource efficient transport system, and one of the pillars of future development of transport and traffic in Europe. The document also emphasizes the importance of mobility in passengers transport and highlights the significance of an integrated passenger transport system not only in urban but also rural areas. Railway lines in rural areas are very often referred to as local railway lines. The backbone of an integrated passenger transport system is the railway, which offers some interesting advantages: (1) speed, (2) capacity, and (3) comfort. Except for some passengers services in Croatia, the railway system across the European Union is fully liberalized. In that kind of railway system there are two pillars: (1) infrastructure managers and (2) railway undertakings. Railway undertakings must pay the infrastructure managers charges fees for the train running. Pursuant to the EU directive 2012/34 there are four services that can be provided by infrastructure manager: (1) minimum access package, (2) track access to services facilities, (3) additional services, and (4) ancillary services. On other hand, railway undertaking must at least pay for the minimum access package, while other services depend on the strategy from railway undertakings. The last few years in Croatia have seen a very dynamic change of the fees paid by the railway undertaking to the infrastructure manager in Croatia. In our research we investigate how the principals and amount of fees influence train running service on local passenger lines. The fee amount is the direct expenditure for railway undertaking and directly determines the ultimate ticket fare. We therefore compare the revenue with the cost of minimum access package to establish appropriate sustainable connection both for railway undertaking and for infrastructure manager.

Keywords: railway infrastructure, charging system, integrated passenger transport system, Croatia.

1. Introduction

In 1991 the European Union issued the 91/440/EC directive on the common development of railway transport, thus setting the framework for liberalization of services in railway traffic. The most important step therein was to enable all the interested parties to use the railway infrastructure. For that to be viable two important aspects needed to be considered: (1) technology of operations and (2) safety. The technology of operation understands new rules of traffic organization in instances of several operators. The principles of transparency and neutrality needed to be laid down in the new regulations. Also, an important factor in technology of operations is the model of railway infrastructures fees. Namely, each operator is obliged to pay the infrastructure manager a certain fee due for the service provided on the railway infrastructure. The basic principles for constructing such a model must include: (1) simplicity, (2) transparency, (3) neutrality and (4) cost dependency. The simplicity basically indicates that there are no additional hidden or ambiguous calculation terms in the practical application of the model. Also, the term refers to the clear and logical workings of the calculation. The transparency means that regardless of the operator, the fees will be consistent and fair, so the operators will be able to check among themselves the amount each has paid for the services. Neutrality is the infrastructure manager having an equal approach and attitude towards every operator. Since the fee model involves charging for various services, the model itself must be based on the actual generated costs for a specific service. This way directly covers the principles of simplicity, transparency and neutrality.

The last few years has seen a new wave of changes in the legal basis of the EU in terms of railway traffic, the so-called fourth railway package. It contains the 2012/34/EU directive which is defined as a directive recasting the establishment of a single European Railway Area and Regulation 2015/909 on the modalities for the calculation of the cost that is directly incurred as the result of operating the train service. Naturally, the main reason for the fourth railway package was the lack of success of the previous model shifts. In fact, there was no significant model shift from road to railway transport, but rather a freeze of the model split in favor of the roadway traffic. The directive states two basic principles of charge fees for the railway infrastructure, while the Regulation strictly defines the way of determining the charges and the charges of the railway infrastructure usage.

The underlying document that regulates the relationship between the infrastructure manager and operator is called Network Statement. It regulates the manner and procedure of drawing up contracts about the access to the railway infrastructure, the technical and technological parameters, and the technology of charging fees for the use of the railway. There is only one railway infrastructure manager in Croatia - HŽ Infrastruktura Ltd., which publishes the Network statement for the railway lines in the country, in Croatian and English. The Network statement is available on web page of infrastructure manager.

In the Republic of Croatia, the railway lines are divided into: (1) international, (2) regional and (3) local. Based on the railway length, the international lines make up 60.5 %, the regional 21.6 % and the local 17.9%. The local railways are in various technical conditions, which requires establishing several categories of the railway conditions: (1) closed to traffic, (2) open to traffic, (3) open to freight traffic, and (4) bus replacement service. The last decade has been marked by a reduction of the number of trains operating on local lines, particularly on Saturdays and Sundays, or replacing the train services with buses. It is therefore possible to investigate the relation between the railway infrastructure charges

[1] Corresponding author: borna.abramovic@fpz.hr

and the total income of sold tickets. This way we can determine the infrastructure cost share in the total income of sold tickets. This approach can also set up the basis for optimizing expenditure entries in the operation of railway transport on local lines.

2. Analysis of Local Railway Lines in Croatia

The railway network Croatia is comprised of 2,722 km, 2,468 km (90.7%) single-track and 254 km double-track lines (9.3 %). There are 980 km of electrified railway lines, 977 of which use the 25 kV/50 Hz electrification system, and 3 km use 3 kV ((Šapjane – Ilirska Bistrica (SI)). The railway infrastructure of the Republic of Croatia is connected to the railway infrastructure Slovenia, Hungary, Serbia and Bosnia and Herzegovina. The changes of haul systems are available on two border crossings, with the Republic of Slovenia in train station Šapjane, on section Rijeka - Šapjane - DG - Ilirska Bistrinca and in station Dobova, on section Dobova - DG - Savski Marof - Zagreb GK. The division of the railway lines in the Republic of Croatia has been made pursuant to Decision on Classification of Railways in three categories: (1) international lines, (2) regional lines, and (3) local lines. The total length of the local railway line is 518.5 km comprising 19.1% of the total length of railway lines. All local lines in Croatia are Diesel only operation. Figure 1 shows the railway network in the country and Table 1 provides the list of all local lines. There are 16 local lines altogether, some of which do not provide any kind of services: (1) L102 Savski Marof – Kumrovec – State border – (Imeno), (2) L210 Sisak Caprag – Petrinja and (3) L213 Lupoglav – Raša, and the following lines operate only freight trains: (1) L207 Bizovac – Belišće, (2) L211 Ražine – Šibenik Luka and (3) L212 Rijeka Brajdica – Rijeka. The rest of the local lines operate train services but the following lines use bus replacement services: (1) Daruvar – Pčelić rasputnica (part of L204) and (2) Pleternica – Našice (part of L205). Only 8 local lines (50% local railway lines) have passengers train services. Looking at the number of trains per day, the line L101 Čakovec – Mursko Središće has 5 departures, L209 Vinkovci – Županja 7 departures, lines L103 Karlovac – Ozalj – Kamanje, L201 Varaždin – Ivanec – Golubovec, L206 Pleternica – Požega – Velika, and L208 Vinkovci – Gaboš – Osijek 8, and L202 Hum-Lug rasputnica – Gornja Stubica and L203 Križevci – Bjelovar – Kloštar has 11 departures. Usually, diesel rail cars HZ series 7121 (Plavac) and HZ series 7122 (Sved) are used on local railway lines.

Table 1
Local railway lines in Croatia

Code of track	Railway line name	Length [km]
L101	Čakovec – Mursko Središće – State border – (Lendava)	17.942
L102	Savski Marof – Kumrovec – State border – (Imeno)	38.522
L103	Karlovac – Ozalj – Kamanje – State border – (Metlika)	28.799
L201	Varaždin – Ivanec – Golubovec	34.596
L202	Hum-Lug rasputnica – Gornja Stubica	10.820
L203	Križevci – Bjelovar – Kloštar	62.047
L204	Banova Jaruga – Daruvar – Pčelić rasputnica	95.752
L205	Nova Kapela-Batrina – Pleternica – Našice	60.493
L206	Pleternica – Požega – Velika	24.955
L207	Bizovac – Belišće	12.940
L208	Vinkovci – Gaboš – Osijek	33.770
L209	Vinkovci – Županja	28.073
L210	Sisak Caprag – Petrinja	11.018
L211	Ražine – Šibenik Luka	3.714
L212	Rijeka Brajdica – Rijeka	2.037
L213	Lupoglav – Raša	52.996

3. Legal Basis of Infrastructure Charges Fees in the European Union

The legal basis of the EU railway network is laid out in its four railway packages and is constantly evolving with a framework of directives and regulations. It is important to recognize the difference between a directive and a regulation. A directive is a recommendation that the EU makes regarding the best practice, and parties usually have a two-year period to adhere to such a guideline. However, a regulation is a legally binding instruction to whomever it concerns and must therefore be complied with. Directives are implemented in the local law, but regulations apply directly to the national legal system. Fourth railway packages contain the Directive 2012/34/EU which is defined as a directive recasting the establishment of a single European Railway Area and Regulation 2015/909 on the modalities for the calculation of the cost that is directly incurred as a result of operating the train service.

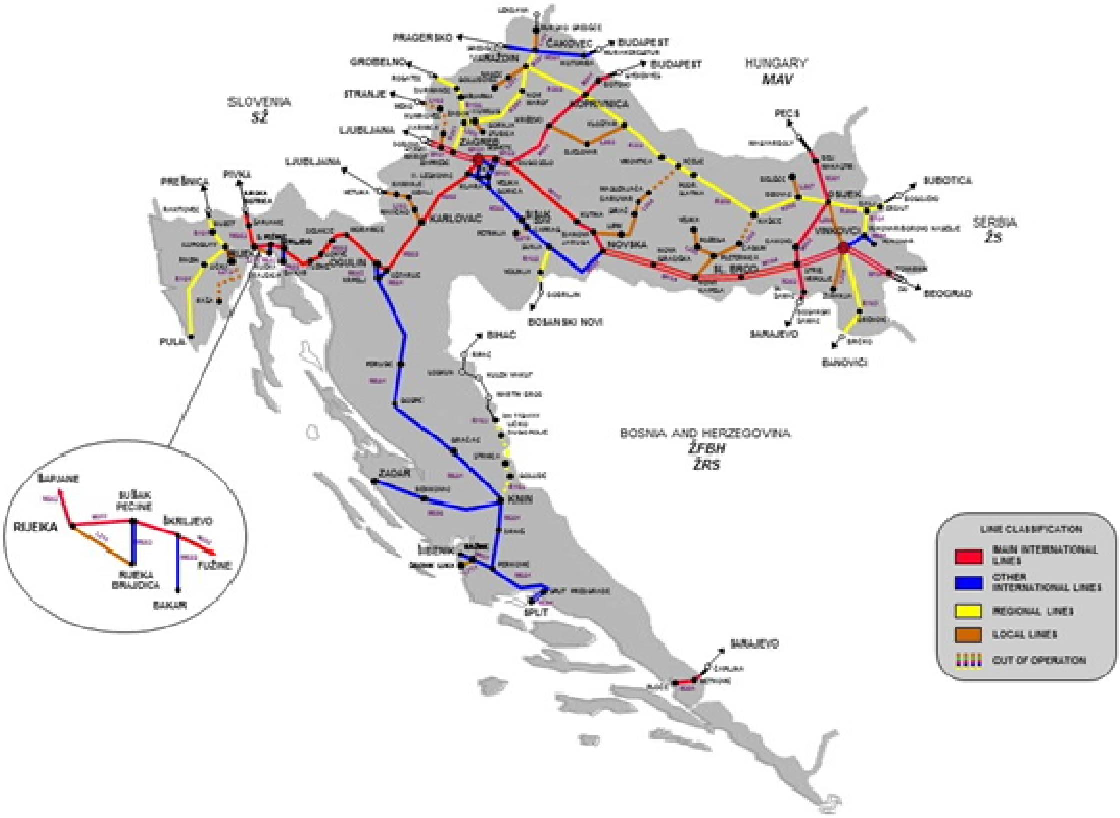

Fig. 1.
Railway classification lines in Croatia
Source: Network Statement, HŽ Infrastructure Ltd (2016)

For operation purposes, the most important document for railway undertakings (RU) is the Network Statement (NS), which is a legal foundation for cooperation between railway infrastructure managers (IM) and railway undertakings. All infrastructure managers of a country must publish a network statement that is available for consideration by all rail operators. It has to be published both in the native language of the country and in English. All operators must have similar structures to allow the ease of access and the liberalization of the European Rail network. Their main contents consist of 6 sections:

1. General Information,
2. Access conditions,
3. Infrastructure,
4. Capacity allocation,
5. Services, and
6. Charges.

Network Statement explains much more clearly how railway undertaking can use railway infrastructure and run the train – service. Pursuant to the Directive there are four different railway services:

1. Minimum access package,
2. Access to services facilities and supply of services,
3. Additional services, and
4. Ancillary services.

All of those services are very clearly and completely explained in the Network Statement. The most important for train running is, of course, the minimum access package. It contains the following services:

- Handling of requests for railway infrastructure capacity,
- The right to utilize capacity which is granted,
- Use of the railway infrastructure, including track points and junctions,
- Train control including signaling, regulation, dispatching and the communication and provision of information on train movement,
- Use of electrical supply equipment for traction current, where available, and
- All other information required to implement or operate the service for which capacity has been granted.

Access to services facilities and supply of services concerns railway undertakings access to service facilities such as access to passenger stations, freight terminals and sidings. In practice, this means any facility on the network that is run or controlled by the infrastructure manager.
Additional services can refer to a number of extra services such as a traction current, control of transport of dangerous goods or assistance in running exceptional consignment trains.
Ancillary services may comprise services such as access to telecommunication networks or ticketing services in passenger services.
The charges section simply focuses on the charging principles in operation in that country, the specific tariffs, any financial penalties and incentives, and billing arrangements. A measure that has been incredibly helpful in this section is the use of EICIS (European Infrastructure Charging System) which provides a single online location where any rail operator can calculate potential infrastructure charges. This is a hugely liberalizing innovation which brings more transparency to a sometimes confusing system.

4. Infrastructure Charges Fees on the Local Passenger Lines in Croatia - A Case Study

For our research we have chosen only local railway lines that run trains: L101 Čakovec – Mursko Središće, L103 Karlovac – Ozalj – Kamanje, L201 Varaždin – Ivanec – Golubovec, L202 Hum-Lug rasputnica – Gornja Stubica, L203 Križevci – Bjelovar – Kloštar, L206 Pleternica – Požega – Velika, L208 Vinkovci – Gaboš – Osijek and L209 Vinkovci – Županja.
According to the official tariff of HŽ Passenger Transport we have determined the fare of a one-way, second class ticket. HŽ Passenger Transport uses the principle of distance for determining the fare, in particular the so-called tariff distance, not the real distance. The tariff distance is on average 5.23 % higher than the real distance. The calculated relationship between the ticket fare and tariff distance is illustrated in Figure 2. The relation should generally be slightly degressive when applying the principle of distance in the calculations, which would indicate that by increasing the distance the fare would drop. Our case leads to the conclusion that there was no digression. Most interestingly, the fare for distances 17, 34, and 71 kilometers remains approximately the same. Observing the obtained results independently shows a digression up to the 25th kilometer, which disappears and reappears after the 28th tariff kilometer. This indicates the existence of two zones of digression. Such a case can be explained by the fact that the fare was formed based on the actual tickets sold, based on the distance, and the zones with a sudden increase in the number of passengers resulted in the increase in ticket fares.

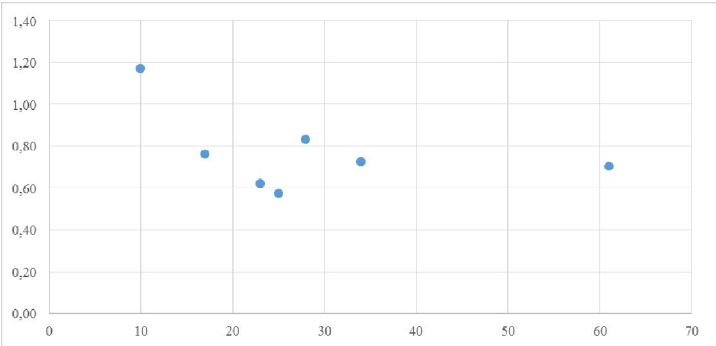

Fig. 2.
Correlation between tariff length and ticket price
Source: Authors

HŽ Infrastruktura is the only infrastructure manager of railway infrastructure in the Republic of Croatia publishing the Network Statement. The charging principles for railway usage charges fees are found in section 6 of the Statement. Our research was limited to calculation of the minimum access package. The formula for determining the minimum access package is listed below:

$$C = (T + d_m + d_n)\cdot\sum(L\cdot l)\cdot C_{vlkm}\cdot K \text{ [HRK]} \quad (1)$$

C – minimum access package charge [HRK]
T – train path equivalent
d_m – additional charge for train mass
d_n – additional charge for the use of tilting technique
L – line parameter
l – train path length [km]
C_{vlkm} – basic price [HRK/trainkm]
K – price correction coefficient

The equivalent of the train route is defined separately for passenger and freight traffic. The former is defined in 5 categories, with trains ranked in one of them. Since only the passenger rank trains operate on the local railway lines, all share the same equivalent of 0.95. Our research did not require calculating additional charges (mass greater than 1500 t and tilting technique). The following data used for the calculation is the line parameter. The railway lines are divided into six categories, which is unrelated to the Decision on Classification of Railways. For instance, the railway line L208 Vinkovci – Gaboš – Osijek belongs to category 3, with parameter 0.9, while other lines belong to category six with parameter 0.3.
The charge calculations use the real distance covered by the train.
The basic cost is defined separately for the passenger and freight transport, the former at 5.99 HRK per train kilometer.
The calculation also uses a price correction coefficient of 0.5 determined by the infrastructure manager with the consent of the Ministry of Maritime Affairs, Transport and Infrastructure.
The calculation is made for each individual railway line, with added VAT of 25%.
After that we were able to determine which type of railway vehicle is used most frequently on a specific local railway line. Railway lines that use the HZ series 7122 (Sved) are L101 Čakovec – Mursko Središće, L103 Karlovac – Ozalj – Kamanje and L209 Vinkovci – Županja. The passenger capacity for HZ series 7122 (Sved) is 64. Lines L201 Varaždin – Ivanec – Golubovec, L202 Hum-Lug rasputnica – Gornja Stubica, L203 Križevci – Bjelovar – Kloštar, L206 Pleternica – Požega – Velika i L208 Vinkovci – Gaboš – Osijek use the HZ series 7121 (Plavac). The passenger capacity for HZ series 7121 (Plavac) is 144. The average train occupancy in local railway traffic regardless of the route is set at 30%.
This was followed by a calculation of the relation between the railway infrastructure charges fees and total income of sold tickets. Since railway line L208 Vinkovci – Gaboš – Osijek is the only one categorized differently compared the the rest of the lines, it will be analyzed separately. The share of the charges fees is 9.99% which is a relatively reasonable percentage. If this line belonged to the rest of the railway lines, the share would drop to only 3.33 %.
It is interesting to note that the rest of the railway lines all belong to a single category, with charges fees share ranging from the incredibly low 2.24% to actual 10.74%. It can be determined that when using trains with a higher capacity (HZ series 7121) the share ranges between 2.24 and 4.23%, while in the lower capacity trains the share ranges from 6.76 - 10.74%.The charges fees share compared to the total income for all local railway lines is shown in Figure 3.

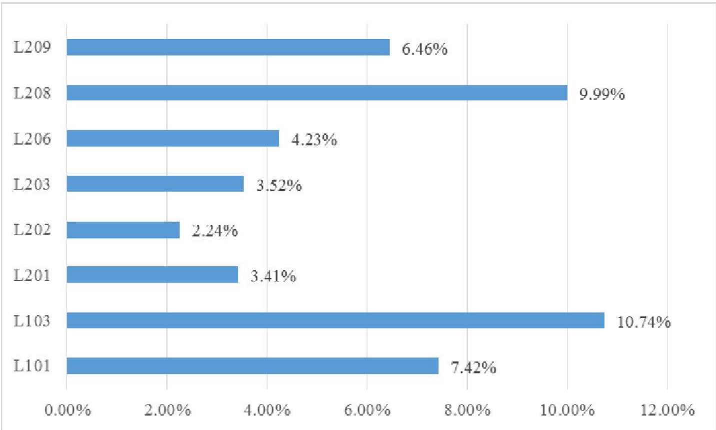

Fig. 3.
Share of infrastructure charges fees and income from ticket sale

5. Conclusion

From the standpoint of the traffic policy of the EU, local railway lines occupy an important place in strategic goals, particularly considering the mobility of rural population and the ecological advantages of the railway over road transport.
This research has shown calculations of charges fees for railway infrastructure on local railway lines that run trains, and the total income based on the average train occupancy. The analysis of the obtained data shows that charges fees for using railway infrastructure are completely linear with the distance, train category and line parameter. This approach ensures an easier use of the fees and operators can understand the calculation with no difficulty. It might be a good idea to use the same line parameter on all railway lines. Furthermore, the analysis of the ticket sale income leads to the conclusion that the biggest problem is the low average train occupancy of merely 30%, so the income can only be boosted by increasing the number of passengers. The rise in ticket fares would deter passengers to other means of transport (bus or personal vehicle).
The set of measures to increase the number of passengers requires a complete change of the politics at the levels of state, local, and railway infrastructure, and the operators. The local traffic, namely, is regulated by strict laws in rural areas.

Finally, the relation between the charges fees for railway infrastructure use and the total income of ticket sales ranges from low 2.24 to 10.74%. This clearly indicates the strategy of railway infrastructure manager towards operators in terms of further development of railway traffic on local railway lines.

THE COMPARISON OF THE PARKING SPACE DIMENSIONS TO THE MODERN CAR FLEET OF THE SELECTED EUROPEAN COUNTRIES

Radka Matuszkova[1], Michal Heczko[2], Michal Radimsky[3], Petr Kozak[4]
[1,2,3,4,] Brno University of Technology, Faculty of Civil Engineering, Veveří 331/95, Brno, Czech republic

Abstract: Nowadays there is a trend to buy and produce larger vehicles which provide the best comfort possible. This trend is, however, very slowly followed by dimensions of parking places with regards to standards changes and also with regards to economical behavior of developers. Developers tends to design parking spaces to fit in as many lots as possible, to do so, they use as small dimensions as limits allow. Paper analyzes vehicle fleet used in different countries and compares the most used vehicles to parking place dimensions.

Keywords: parking, width, length, parking place, vehicle fleet.

1. Introduction

The current trend is to manufacture and buy still bigger vehicles, which provide the best possible comfort. This trend is slowly followed by the size of parking spaces, by changes in regulations and national standards and followed by infrastructure investors. Investors tend to maximized marked parking spaces on parking lots by lowering dimensions of the parking spaces to the minimal values set by the national standards.
However, designing insufficient parking spaces, which doesn't correspond to the requirements of the current car fleet, may lead to a higher risk of traffic accidents, especially during the parking maneuvers. Another possible problem is a lower parking lot's turnover caused by more necessary car movements during parking. That is why the parking space dimensions set by the national standards in different European countries were compared to the cars dimensions inside modern car fleets in those countries (katalogautomobilu.cz, 2016). This paper doesn't compare the manipulation space of each parking stall and also doesn't cover the parking maneuvers.
The comparison of the parking spaces was done for these European countries: The Czech Republic, the Slovakia Republic, Germany, Poland, France, The United Kingdom and Italy. The countries were chosen to get the most diverse car fleets. For example, it is known that the Germans use bigger cars, and on the other side the Italians use smaller ones.

2. The analysis of the car fleet

The analysis of the car fleet was based on the statistic of the most selling cars during the last year (2015). Another possibility how to analyze the car fleet would be using the data from the state's central register, but these might not reflect the current trends of the newest vehicles. That's why the statistics of the most selling cars were chosen.
Twenty the bestselling vehicles from each country were selected and according to their technical specification their length and width were assigned to them (Bekker, 2016; Statista, 2016; Zverkova, 2016; Prokopec, 2016). Also the total number of sold vehicles for each car type was recorded. While only 20 the most selling car types were analyzed, the market share of analyzed vehicles was between 40 % and 54 %. Additionally, also the car fleet of whole Europe was analyzed (Bekker, 2016). The minimal and the maximal length and width were evaluated, together with an arithmetic average and a weighted arithmetic average of the vehicles.
The highest average width of a vehicle is in France, lowest in the United Kingdom, which is also same as the average in Europe (Fig.1.). The lowest weighted average of the vehicle width was in Italy, the highest in France. Between the top twenty bestselling vehicles was the widest in Poland (Ford Mondeo) and the narrowest in Italy (Fiat Panda).

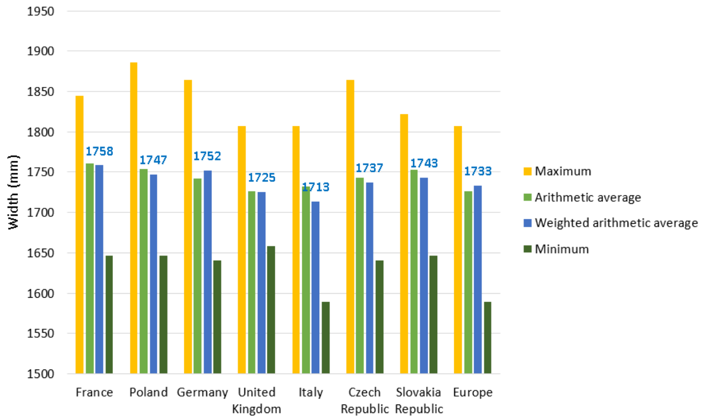

Fig. 1.
Width of vehicles
Source: (Authors)

[1] Corresponding author: matuszkova.r@fce.vutbr.cz

The highest average vehicle length was in Poland, the lowest in Italy. The lowest weighted average length was again in Italy and the highest weighted average length was again in Poland (Fig.2.). The longest model from the top 20 was sold in Germany (Audi A6) and the shortest in Italy (Fiat Panda).

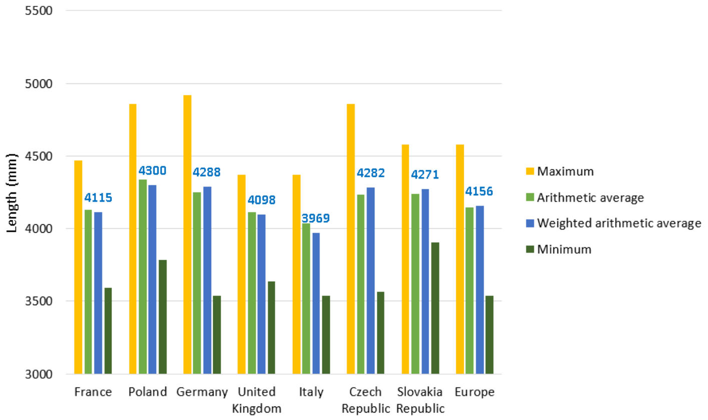

Fig. 2.
Length of vehicles
Source: (Authors)

The analysis of car dimensions confirmed that Italy has the lowest dimensions of the currently selling cars. Even lower than European in average. The analysis also showed that the highest car dimensions are in Germany and also in Poland.

2. The parking spaces requirements set by the national standards

2.1. Angle

The first criterion to compare the car dimensions is the selection of the angle of a parking space. Every one of analyzed national standards consider three basic angles 0° (parallel parking), 45° (angle parking) and 90° (perpendicular parking). Czech, Slovak and French national standard uses the same basic angles (Muller et al., 2011; Marrast et al., 2011). Different angles, like 60° or 75°, are mentioned only in some of the national standards. Only one national standard considers as the possible parking angle also angle lower than 45°, Italian regulation uses 30° (Leonardi et al., 2005). The British standard issued in 1992 also allowed to use 30° parking angle, however in the current standard (2016) is not mentioned anymore (Planning Service, 2015). Another exception is Germany, where the parking angles are set between 50 grads and 100 grads with 10 grads increments in-between (Schnabel et al., 2011).

2.2. Width

To determine the width of a parking space is used the basic model of a car without side view mirrors. Basic model is expanded by the space necessary for the door opening, which is shared with the neighbor parking space. Also the reserve space can be added when the parking space is next to a solid obstacle (like a wall or a pillar). This paper considers only the pure parking spaces without additional side spacing. Each of the national standards sets the dimensions of the basic car model and also the necessary space for a door opening or a cargo loading.
The width of perpendicular and angle parking spaces are between 2.2 m and 2.5 m. The exception is France where a parking space width for a perpendicular and an angle parking is different by 0.1 m, other states use the same width for both (Marrast et al., 2011). The width for a parallel parking is lower, between 2.0 m and 2.4 m. The interesting fact is that Poland and the United Kingdom use the same width for all three parking types, but in the Czech Republic or Germany are widths different by up to 0.5 m (Muller et al., 2011; Schnabel et al., 2011; Bykowski et al., 2011).

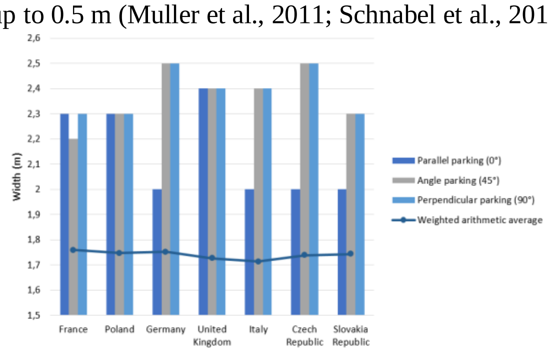

Fig. 3.
Width of parking space
Source: (Authors)

2.3. Length

To determine the length of the parking space is once again used the basic car model. For a perpendicular or an angle parking is added or subtract overhang of front/back bumper over wheels. When the parking space is next to a footpath, which is wide enough, the overhang is added, when there is a solid obstacle it is subtract.
The length set by the national standards is more diverse than the width. The longest spaces are mostly for the parallel parking, then the perpendicular parking and then the angle parking. For the parallel parking is length set between 5.0 m and 6.0 m, for the perpendicular parking between 4.5 m and 5.5 m and for the angle parking it is between 4.0 m and 5.5 m.

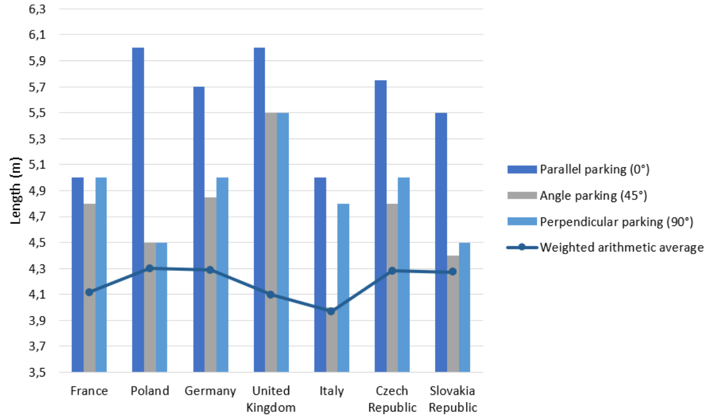

Fig. 4.
Length of parking space
Source: (Authors)

3. Conclusion

After the analysis of the car fleets in each country and the dimensions set by the national standards it is possible to do the conclusion. The following graph (Fig.3.) shows that the differences between the widths are not that significant in the different countries. While during the parallel parking it is considered to get out of a side of a vehicle and the width of the parking space is not so important, during the perpendicular or angle parking it is. Poland, Germany and the Czech Republic use almost the identical parking space dimensions, but the width used in Poland for the angle and the perpendicular parking is by 0.2 m lower than in the Czech Republic and Germany. The lowest difference between the width of the parking space and the width of the average modern car is in France, for the angle parking it is only 0,45 m.

The length dimensions are much more diverse. For example, Italy has the length of the angle parking same as is the weighted average length of Italian car fleet (Fig.4.). The longest cars are sold in Poland, Germany and the Czech Republic, which also correspond with the longer parking spaces. But in the United Kingdom, where are sold the second shortest cars among analyzed countries, the national standards set one of the longest parking spaces. Meaning that the United Kingdom leaves relatively big reserve for the parallel parking, especially when compared to the other European countries. The opposite situation with the parallel parking is in France and Italy, where the difference, between the average sold vehicle and the parking space size, leaves just one meter for the parking maneuver.

SESSION 16: TRANSPORT MODELING AND DECISION MAKING

THE LINK BETWEEN TRANSPORT NETWORKS' AND TERRITORIAL SYSTEMS' PROPERTIES

Vasile Dragu[1], Mihaela Popa[2], Ştefan Burciu[3], Cristina Oprea[4], Alina Roman[5]

[1,2,3,4,5] *Transport, Traffic and Logistics Department, Transport Faculty, University Politehnica of Bucharest, Bucharest, Romania*

Abstract: The increasing number and density of urban population due to the polarization of socio-economic activities led to an increased travel need. Satisfying the increased travel need within urban areas by using personal car led to an exacerbated growth of negative externalities with negative implications on life quality. Among the most irritating negative externalities of modern society we find congestion. Punctual solutions of developing infrastructures cannot be applied nowadays. One must find solutions like correlated development between urbanism and transport, reducing the need for travel, intermodality or modal distribution in favor of public transport modes. These goals can be achieved only if the public transport networks grow correlated with the served territory and become attractive for personal car users that can change their option of modal choice. The paper aims to define the transport networks' proprieties (conexity, connectivity, isotropy, homogeneity, nodality) and to put them in accordance with socio-economic characteristics. The case study examines how Bucharest's underground network development has been conducted (the network's proprieties for two moments of time are identified) so that it satisfies population travel needs and modifies the modal split in its favor. An analysis of the accessibility index within territory is realized by using the underground network's poles (directly accessible or with one transfer). Finally, a hierarchy of the underground network poles that are compared with the served areas characteristics is realized, setting up an intensity of the correlation.

Keywords: transport network, underground network, topology, network-territory link.

1. Introduction

The most irritating aspect of life for big cities inhabitants is traffic congestion. In 10 Romanian cities, the motorization rate is over 600 vehicles per 1,000 inhabitants. Bucharest became a city with more cars than Amsterdam, Copenhagen, Prague or Rome (Engineering Universe, 2015). Bucharest Metropolitan Transport Association proposed a plan that aims to create a complex public transport network in order to solve the actual congestion problems. A target for 2030 to increase the number of public transport users from 20%, today to at least 80%, has been set. This objective must be achieved in an area with the highest population density in the country – over 8000 inhabitants/km^2.

Unlike other consumer goods, the possession of a car has consequences beyond the private sphere. First of all, it can satisfy the people's travel need, enlarging activities space, and second of all, it can change the urban geographic form because of a strong relation between the motorization rate and urbanization. It states that the motorization rate can enhance the geographical link between urban zones (Yeh, 2009, Newman&Kenworthy, 1996, Raicu, 2007, Popa, 2009).

According to the Sustainable Urban Mobility Plan 2016-2030 – Bucharest-Ilfov Region, Bucharest was the city with the highest congestion in Europe in 2014 and one of the most affected cities in the world. This study presents the congestion index for some cities in the world, showing that Bucharest has a congestion index of 41%, occupying the 8th place (from 146 analyzed countries) in world rankings and the last place in Europe (Fig. 1).

With all this, in 2012 Warsaw was leading with a congestion index of 42%, followed by Marseille (40%) and Palermo (39%), while Bucharest was far behind them. While these cities were able to reduce their congestion level, the problem in Bucharest got worse.

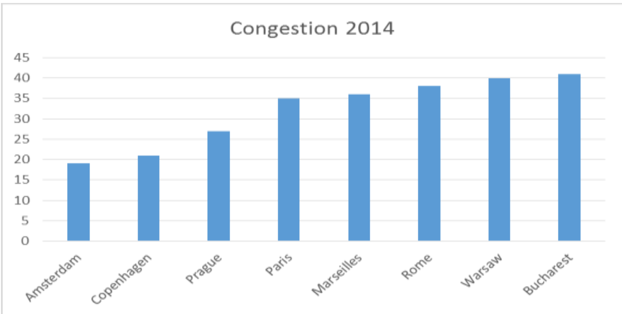

Fig. 1.
Congestion index
Source: Sustainable Urban Mobility Plan 2016-2030 - Bucharest-Ilfov

Dependency and the intensive use of private vehicle in daily trips accentuated externalities and led to unbearable congestion levels. Not long ago the congestion used to be reduced by developing the road infrastructure, not taking into

[1] Corresponding author: stefanburciu@yahoo.com

consideration that it is a limited resource that no matter how much it expands its capacity will always be reached. (Dragu et al., 2015).

In conclusion, transport externalities occur when the effective solicitation is near the analyzed element's capacity, in which case the dependence of the two no longer complies with reduced solicitations established laws (Raicu, 2007).

In the case of road traffic, when the effective solicitation approaches the road capacity, the congestion appears, reducing the capacity and worsening traffic conditions.

The classic measures of reducing congestion aim exclusively road infrastructures development leading to land occupation, natural landscape degradation, increased risk of accidents and attracting new traffic, which will reach again congestion, the process being cyclical until road infrastructure expansion is no longer possible. A vicious circle of possibilities to eliminate congestion is described (Raicu, 2005, Banister, 2008, Holden et al., 2013).

A severe difficulty in examining the dynamic relation between transport offer and demand is represented by the non-transferable character of the transport demand. This makes the offer of transport infrastructure impossible to be examined globally but only in relation with the topology and geography of a network that serves a territory. Between spatial distribution, technical and functional characteristics of infrastructure elements and the characteristics of the territory served, there are precise dependencies that may be expressed synthetically. If the network is presented as a planar graph then it is noted that both for arcs and for nodes, offer's quality parameters depend on the solicitation level (Raicu, 2007).

One of the most widespread measures for reducing the effects of congestion is to change the modal split in passenger transport by increasing the market share of high capacity public transport (metro, tram or light rail) in favor of individual transport with private vehicles. This can be achieved only when the corresponding transport networks are developed in accordance with the cities' development and faithfully serve the analyzed areas. There is an assertion according to which cities should not be allowed to develop more than they can be served by high capacity public transport (Khalil, 2012).

The present paper analyzes the development of Bucharest's metro network and the correlation of network parameters with the served territory parameters. The main properties of the transport networks are defined and one of them (connectivity) is calculated for the metro network, for different time horizons. The accessibility is also determined for different assumptions in making the trip (with or without transfer in a certain time period).

2. Transport networks characterization

Network is not only a consequence of technological innovation but a consequence of a planning idea that marks a connection between technical capabilities and territory covering (Raicu, 2007).

The ones participating in conceiving, developing and planning the networks are not fully aware of the essential links between networks and territories, ignoring almost completely the fact that networks serve the same territory and are part of the same social-economic framework.

The correlations between urbanism and public transportation need complex examinations that take into consideration traffic flows, infrastructure, transport means' and technologies' characteristics and also urban development as only together they determine transport system's performances.

By the relational properties assured by the network, in concordance with urban development logic, the territory is organized, space is differentiated and authority spreads.

Transport networks properties, essential for territory system functioning and assuring the correlations between networks and territory system evolution, are defined next.

A network serving a territory system can be characterized by conexity, connectivity, homogeneity, isotropy and nodality properties (Raicu, 2007, Raicu et al., 2010).

According to Dragu et al. 2011 *conexity, connectivity, homogeneity, isotropy and nodality* are defined and determined as follows:

Conexity is a topological concept from graph theory, which for network analyse is limited to strong and simple conexity; to the R network, adapted to S territory system, the G[R] orientated graph is associated, defined by the $[\rho_{ij}]$ matrix, with the elements $\rho_{ij} = 0$, if the a_i entrances do not depend on a_j exits and $\rho_{ij} = 1$, on the contrary.

G[R] is strongly conex if $(\forall)$ (i,j) , $i \neq j$ there is $\rho_{ij} = 1$, or $k, l, m, ..., s$ ($\neq i$ and j), for which ρ_{ik} x ρ_{kl} x ρ_{lm} x ...x $\rho_{sj} = 1$. The meaning is that of the existence of a road among i and j, so, a sequence of orientated links.

To define the simple conexity the R network is considered to have associated an unorientated graph G'[R], defined by $[\rho'_{ij}]$ matrix with elements: $\rho'_{ij} = 1$, if ρ_{ij} or $\rho_{ji} = 1$, $\rho'_{ij} = 0$, if ρ_{ij} or $\rho_{ji} = 0$.

The network is conex (simple conex) if $(\forall)$ (i,j) , $i \neq j$ there is $\rho'_{ij} = 1$ or $(\exists)$ $k, l, m,...,s$ ($\neq i$ and j) for which ρ'_{ik} x ρ'_{kl} x ρ'_{lm} x ...x $\rho'_{sj} = 1$. on the contrary R is no conex.

Conexity has an immediate signification as a transport network with this property interlocks different elements of territory system and assures the minimum condition of its cohesion.

Connectivity allows evaluating the multiplicity of the links assured by the transport network within territory system. Quantitative determinations of direct and alternative links offered by the network can be achieved. To establish connectivity α, γ and β indexes are used.

α index represents the ratio among the number of existing circuits in G'[R] graph and the maximum number of circuits that might exist in the graph for the same number of nodes;

- for the non-planar graph
$$\alpha_{np} = \frac{\sum_{i,j} \rho'_{ij} - n}{\frac{n(n+1)}{2} - n} \quad (1)$$

- for the planar graph
$$\alpha_p = \frac{\sum_{i,j} \rho'_{ij} - n}{2n-3} \quad (2)$$

Where; $\sum_{i,j} \rho'_{ij}$ **:** the number of links, $n+1$:bthe G’[R] graph number of nodes.

γ index is a measurement of the direct links assured by the transport network within the territory system. Adding a direct link among two nodes of the initial network, already connected (indirect), leads to creating a “net” (alternative links). γ index might be considered a measurement of net density and can be obtained as the ratio among G’[R] graph number of links and the maximum number of links possible in a graph with the same number of nodes;

- for the non-planar graph
$$\gamma_{np} = \frac{\sum_{i,j} \rho'_{ij}}{\frac{n(n+1)}{2}} \quad (3)$$

- for the planar graph
$$\gamma_p = \frac{\sum_{i,j} \rho'_{ij}}{3(n-1)}. \quad (4)$$

β index is the ratio among the number of links and the number of nodes of the G’[R] graph. It can be easily determined but the image for the network connectivity is less precise.

Homogeneity is the way different elements of the territorial system depend one on another by network, no matter particular characteristics of the links affecting space-time correlation. In other words, a_j entries must only depend on a_i exits no matter (i,j) time or space connection. Homogeneity is characterized by H(R) index, which can be defined for a link, a path or the whole network. This way, indexes for measuring the homogeneity rate of a part or of the whole network, were established: line losses, charge losses, depending on physical phenomena appearing in the network.

$$H(R) = \frac{1}{\sigma^2(\frac{d}{v})} = \frac{1}{\frac{1}{n}\sum_{i=1}^{n}[\frac{d}{v} - (\overline{\frac{d}{v}})]^2} \quad (5)$$

Where; $\sigma^2\left(\frac{d}{v}\right)$: the chosen attribute dispersion (travel time on networks link, in this case).

Networks *isotropy* evaluates the links degree of equivalence under the aspects of assured relations among the system elements. A total homogenous network is also isotropic. In case of partial heterogeneousness the rate of isotropy can be determined. There is different isotropy for links between a_i and a_p elements. This isotropy rate can be evaluated starting from the considered roads’ homogeneity rate. In alternative routes hypothesis from a_i to a_p, $H(a_i \to a_p)$ will have more values, and the isotropy rate for $a_i \to a_p$ links might be determined with the following relation:

$$I(a_i \to a_p) = \frac{1}{\sigma^2_{H(a_i \to a_p)}} \quad (6)$$

Where; $\sigma^2_{H(a_i \to a_p)}$: $H(a_i \to a_p)$ dispersion.

Nodality allows characterizing networks’ nodes under relational capacities for the system aspect. Whether connectivity allows global evaluation of establishing direct and alternative routes among nodes for the entire network, nodality differentiate systems’ elements by the mutual relations among them. As nodality indexes one can identify: generalized nodality, Shimbel nodality, nodal accessibility (Raicu, 2007).

3. Case study

In the case study, the underground network connectivity (α, γ, β indices) was studied for 2009, and also for two expected development situations in 2017 and 2030, according to the estimations published on www.metrorex.ro.

In table 1 Bucharest underground network characteristics are presented. Table 2 contains Bucharest underground network connectivity indexes determined for the underground network associated graph, for the three moments of time.

Table 1
Bucharest underground network characteristics

Main lines		2009		2017	
		Length [km]	**Number of stations**	**Length [km]**	**Number of stations**
M1	Pantelimon – Dristor	29,1	22	29,1	22
M2	Berceni – Pipera	18,9	14	18,9	14

Network density [km/km^2]		0,281		0,320	

Table 2
Bucharest underground network's connectivity indexes

Network topological characteristics		Present network	Projected network	
		2009	**2017**	**2030**
Number of nodes		12	13	24
Number of links		13	14	30
Connectivity indexes	alpha	0.015	0.013	0.021
	gamma	0.166	0.154	0.1
	beta	1.083	1.077	1.25

The underground network nodal accessibility was determined for the network to be commissioned in 2017, considering the network being described by its stations that represent the poles (45 poles in 2009 and 53 poles in 2017).
In figure 2 the underground network is presented by highlighting the three moments of time. In table 3 the accessibility of every sector is determined (for 2017) considering that the subway is the only transport mode used for travelling.

For every pole of the underground network 7 comparison criteria were considered:

- NA – number of links with the origin in a considered pol,
- NL – number of transport lines that cross a pole,
- PDA – number of direct accessible poles,
- PIA – number of poles accessible with one interchange,
- FRV – traffic frequency (number of trains that get through the pole in one hour),

- PA 15 min – number of accessible nodes in 15 minutes,
- PA 30 min – number of accessible nodes in 30 minutes.

For determining those criteria we considered a headway (I) of 6 min, the time lost per stopping at one station (t_{st}) of 30 sec, the station to station medium travel time (t_m) of 3 min and the transfer time (t_{tr}) of 6 min.
In table 4, the underground network characteristics for every administrative sector for the years 2009 and 2017 are presented. The characteristics for 2009 were determined in Dragu et al., 2011.

Table 4
Underground network characteristics in every administrative sector

Sector / Indice		Sect. 1	Sect. 2	Sect. 3	Sect. 4	Sect. 5	Sect. 6
Population [inhabitants]		225400	345400	385400	287800	271600	367800
Population density [inh./km²]		3220	10794	11335	8465	9053	9679
Number of poles 2009		8	4	12	8	3	8
Number of poles 2017		10	4	12	8	4	15
N A 2009		18	7	26	15	7	15
N A 2017		22	7	26	15	10	28
N L 2009		11	4	17	9	5	8
N L 2017		13	4	17	9	7	15
P D A 2009		121	73	266	119	69	130
P D A 2017		139	73	266	119	85	186
P I A 2009		172	94	232	210	56	196
P I A 2017		236	124	346	220	96	462
PA 15	2009	67	27	100	60	35	57
	2017	85	27	101	60	41	101
PA 30	2009	202	112	297	181	114	181
	2017	230	112	306	183	152	325

The accessibility for every sector at the two analyzed moments (2009 and 2017) is indicated in figure 3, for PA 15, and in figure 4, for PA 30.

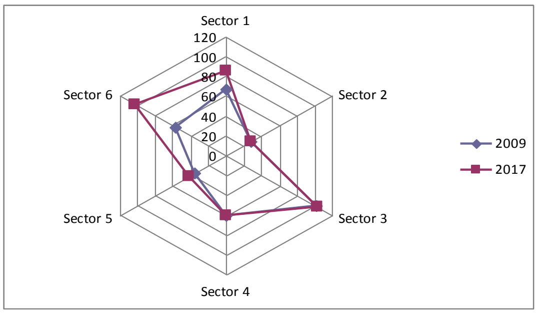

Fig. 3.
Administrative sectors accessibility PA 15 (2009 and 2017)

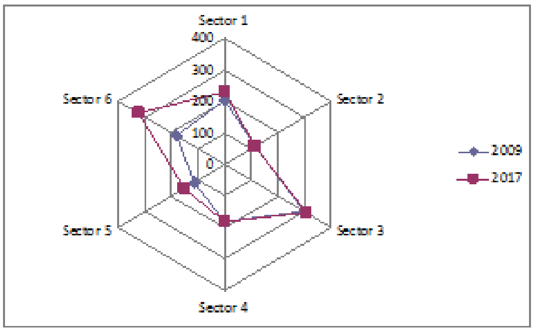

Fig. 4.
Administrative sectors accessibility PA 30 (2009 and 2017)

Analyzing figures 3 and 4 it can be seen that the accessibility for Sector 6 is considerably improved, while the nodes from Sector 2 have the smallest accessibility; the values for sectors 3 and 4 remain unchanged. In conclusion, it would be recommended that the following developments of the underground transport network would be made in the Sector 2 in order to realize an equilibrium regarding territory covering with high capacity public transport network.
Table 5 illustrates population values, population density and the accessibility of Bucharest administrative sectors.

Table 5
Demographic characteristics of administrative sectors

Sector	Population [inhabitants]	Population density [inh./km²]	Accessibility 2017	
			PA 15	PA 30
Sector 1	225400	3220	85	230
Sector 2	345400	10794	27	112
Sector 3	385400	11335	101	306
Sector 4	287800	8465	60	183
Sector 5	271600	9053	41	152
Sector 6	367800	9679	101	325

Adjustment functions and correlation coefficient (R2) between population, respectively density and accessibility for PA 15 and PA 30 are presented in table 6.

Table 6
Adjustment functions and correlation coefficients

Correlation / Adjustment functions	PA 15		PA 30	
	Population Number – Accessibility	**Population Density– Accessibility**	**Population Number – Accessibility**	**Population Density– Accessibility**
Linear	$y = 545.95x + 276138$ $R^2 = 0.0761$	$y = -13.746x + 9708.4$ $R^2 = 0.022$	$y = 314.31x + 245380$ $R^2 = 0.185$	$y = 0.9359x + 8553.6$ $R^2 = 0.0007$
Exponential	$y = 279011e^{0.0015x}$ $R^2 = 0.049$	$y = 9896.9e^{-0.0028x}$ $R^2 = 0.036$	$y = 252111e^{0.0009x}$ $R^2 = 0.146$	$y = 8233.2e^{-5E-05x}$ $R^2 = 8.00E-05$
Logarithmic	$y = 17675\ln(x) + 240911$ $R^2 = 0.0233$	$y = -1282.4\ln(x) + 14053$ $R^2 = 0.056$	$y = 46709\ln(x) + 65586$ $R^2 = 0.096$	$y = -546.34\ln(x) + 11662$ $R^2 = 0.006$
Polynomial of 2 degree	$y = 84.042x^2 - 10576x + 574218$ $R^2 = 0.691$	$y = 3.3191x^2 - 452.96x + 21480$ $R^2 = 0.458$	$y = 10.139x^2 - 4215x + 689802$ $R^2 = 0.801$	$y = 0.459x^2 - 204.11x + 28673$ $R^2 = 0.575$
Polynomial of 3 degree	$y = 1.8966x^3 - 281.43x^2 + 10655x + 212871$ $R^2 = 0.805$	$y = 0.1565x^3 - 26.836x^2 + 1298.8x - 8334.5$ $R^2 = 0.81$	$y = -0.0086x^3 + 15.636x^2 - 5310.8x + 757252$ $R^2 = 0.802$	$y = 0.0025x^3 - 1.129x^2 + 112.5x + 9185.7$ $R^2 = 0.614$
Polynomial of 4 degree	$y = 0.1437x^4 - 35.127x^3 + 3072.5x^2 - 114212x + 2E+06$ $R^2 = 0.992$	$y = 0.0062x^4 - 1.4345x^3 + 117.28x^2 - 4066.9x + 60052$ $R^2 = 0.968$	$y = -0.0011x^4 + 0.9621x^3 - 283.73x^2 + 33775x - 1E+06$ $R^2 = 0.862$	$y = -0.0001x^4 + 0.0912x^3 - 28.495x^2 + 3685.5x - 156663$ $R^2 = 0.841$
Power function	$y = 262414x^{0.0392}$ $R^2 = 0.0104$	$y = 20784x^{-0.2268}$ $R^2 = 0.068$	$y = 153823x^{0.1309}$ $R^2 = 0.069$	$y = 15289x^{-0.1184}$ $R^2 = 0.011$

From table 6 it can be seen that the curve that best adjusts the registered values, both for PA 15 and PA 30, is the polynomial function of 4th degree. The observation is that this function has many inflection points and can't make a rigorous forecast on future network's development, considering that the expansion of the network was realized within the underserved areas. The exception for future development is Henri Coanda airport that aims to satisfy a point of great attractiveness with high capacity public transport.
The correlation between population density and accessibility of Bucharest's 6 administrative sectors for PA 15 and for PA 30 is presented in figures 5 and 6.
In figure 5 it can be observed that there are 3 inflection points and a minimum point on the definition domain; in figure 6 there are 2 maximum points and one minimum point. The two functions most closely approximate the points with known values but the trust for future extrapolation is minimal because of the inflection points that limit the possibilities of extrapolation.

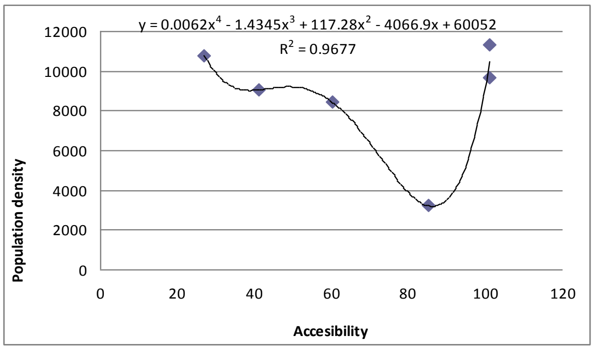

Fig. 5.
The correlation population density - accessibility for PA 15

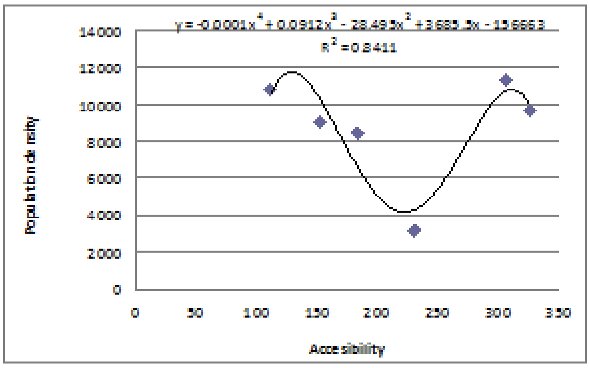

Fig. 6.
The correlation population density - accessibility for PA 30

4. Conclusions

By analyzing the underground network connectivity indices at the three moments of time, it can be concluded that the resulted values are small both in the present and the future, because the public authority is orientated to the extension of the network towards Bucharest adjacent villages and not to the multiplication of the existent links. The extension aims to increase the accessibility of Henri Coanda airport by developing a link between it and the city. In the network's extension for 2017 the connectivity indexes are smaller because in the extended network there were no alternative links that consolidate the network's density that is vulnerable in case of events that can disrupt circulation. The extremely low values of the connectivity indexes lead to the conclusion that the examined network is extremely vulnerable in terms of providing connections between areas and steps should be made to increase connectivity (multiplying the links) that support the development of a reliable network in terms of ensuring the travels' continuity in case of incidents.

From the accessibility point of view for PA 30, it can be seen that the network's development in 2017 led to changes in Sectors' hierarchy. In 2009 the Sectors' hierarchy was: S3, S1, S4, S6, S5, S2. By opening Drumul Taberei-Eroilor line the Sectors' hierarchy will be: S6, S3, S1, S4, S5, S2. Sector 6 occupies the first place, the last two places being occupied by Sector 5 and Sector 2 both in 2009 and 2017. The first position is argued by the construction of the new line exclusively in Sector 6, the accessibility being significantly improved. By analyzing the correlation population – accessibility (table 6) it can be concluded that there are no correlations between the elements using classical functions (linear, exponential, logarithmic or parabolic), this being highlighted by the extremely low value of the correlation coefficient R^2. In conclusion, the development of the metro network should be done with priority in Sectors 2, 4 and 5 that, according to figures 3 and 4, have the lowest values of accessibility.

IMPACT OF POPULATION DEVELOPMENT AND EMPLOYMENT ON THE TRANSPORT PERFORMANCE IN THE EU

Bibiana Bukova[1], Eva Brumercikova[2], Pavol Kondek[3]
[1,2,3] Universty of Zilina, Faculty of Operation and Economics of Transport and Communication, Department of Railway Transport, Zilina, Slovakia

Abstract: The article is focused on chosen internal and external determinants of the EU transport market. The chosen external transport market determinants processed in the article include the economic development of the world economy, specification of the EU regions and countries, the GDP and the population trend in the EU. Internal determinants affecting the EU transport market affect the EU transport policy, state of the transport infrastructure and its development, new transport technologies and innovations, carriers' flexibility and their competitiveness. The problem area is very large, hence, the article is focused only on the analysis and prognosis of the external EU transport market determinants. The chosen external transport market determinants processed in the article are the population trend and the employment in the EU. The reason of the selection of the determinants is given by the authors' long-time research and also the actual development of the EU employment. The article shows regression models of the partial determinant impact on the EU transport performance. The impact is verified by the Fisher rule. The conclusion is focused on the estimation of the EU transport performance trend based on verified regression models.

Keywords: determinants, transport, population, employment, GDP.

1. Introduction

Globalization **-** as part of economic processes affects the three levels of world economy at the same time: the company level, the state level and the level of international trade. It significantly affects international relations, trade and of course transport. Transport is becoming an important element of a comprehensive system of international business, providing the meeting of the needs of subjects of the transport market (Brumercik, Lukac, Caban 2016).

2. The importance of transport

Europe needs efficient transport links in order to promote international trade and overall economic growth and thus is associated with the growth of employment of the population. The high level of transport infrastructure is the foundation of supply chains and the basis of the economy of each country. It enables efficient distribution of goods and the movement of the population. It ensures the availability of cities, unites and brings together the Europeans, while increasing their living standards (Cerna, Masek 2015). Table 1 shows the transport performance in passenger transport and also the index comparison of performances with the previous observed time period. The processed data in the table show that the transport performance of the EU 28 does not have a growing trend, more precisely the development is stable and at the same level. In certain years a performance increase can be observed, but it is not significant (Bukova, Brumercikova, Kolarovszki 2014).

Table 1
Comparison of transport performance of the EU

3. Development of population

The EU population aged over 60 years is now increasing twice as fast as before 2007 (by about two million every year compared to one million in the past). In regard to stating the dependence of the development of transport performances on the development of the population, specific data regarding the transport performance in passenger transport and the development of the population in the EU were processed in the following Table 2.

Table 2
Comparison of transport performance and the population of the EU

Year	**Population EU (28) in mil**	**Transport performance in bil pkm**	**Year**	**Population EU (28) in mil**	**Transport performance in bil pkm**
2000	486,830	5 963	**2008**	500,297	6 486
2001	488,052	6 064	**2009**	502,090	6 492
2002	488,963	6 132	**2010**	503,171	6 445
2003	490,692	6 197	**2011**	504,494	6 480

Source: authors on the basis of statistics available on http://ec.europa.eu/eurostat

Based on the processed data from Table 2, a development of passenger transport depending on the EU population was determined with different probabilities (96.58% and 81.22%). The result is graphically shown in Figure 2.

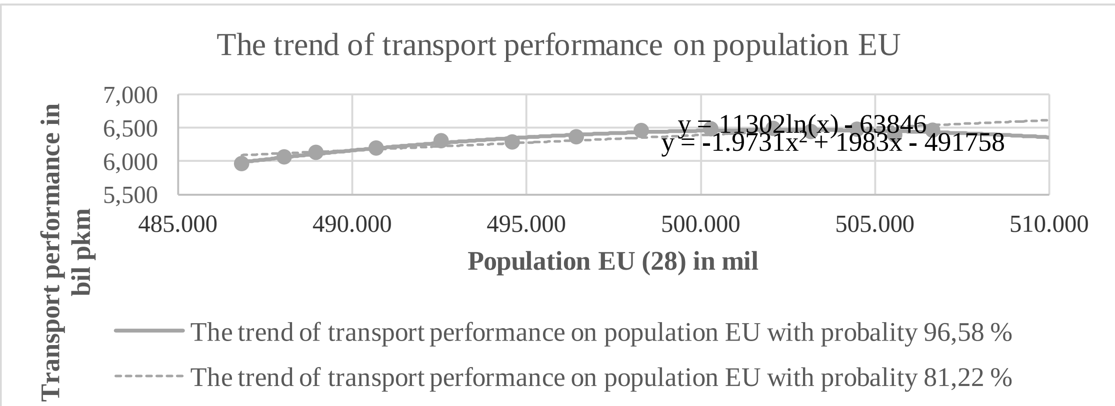

Fig. 2.
The trend of transport performance on the EU population

Figure 2 shows that if the EU population increased, the transport performances would decrease with a probability of 96.58%. However, if the population increased, the transport performances would have an increasing trend with a probability of 81.22%. As the population in the observed time period from 2000 to 2015 increased, it can be assumed that the transport performances will continue to increase in the future. Both trends were verified by the Fisher rule.

4. Employment of the population

Employment rates in Europe are reaching an average of 69% for people aged 20-64 years, which is significantly lower than in other countries of the world. Employed are 46% of older workers (aged 55-64 years) compared to 62% in the US and Japan. In addition, the employees in the EU have an average of 10% fewer working hours than the employees in the US or Japan.

The employment of citizens of the European Union (28 Member States) is being observed since 1997. As presented in Table 3 it had an increasing trend until 2008, when in 2009 it decreased due to the economic crisis, and this trend has continued until 2014, when in 2015 the employment began to increase again and reached the level of 70.1%. Table 3 is based on the information published on the Eurostat website. The table shows the transport performances in passenger transport, so that the regression role of the dependance of the transport performance on the employment could be processed (Figure 3).

Table 3

Employment rate, age group 20-64 in % and transport performance in bil pkm, EU 28

Year	Employment rate, age group 20-64, in %, EU 28	Transport performance in bil pkm	Year	Employment rate, age group 20-64, in %, EU 28	Transport performance in bil pkm
2001	66,9	6 064	2009	69	6 492
2002	66,8	6 132	2010	68,6	6 445
2003	67	6 197	2011	68,6	6 480
2004	67,3	6 307	2012	68,4	6 394
2005	67,9	6 288	2013	68,4	6 465
2006	68,9	6 366	2014	69,2	N/A
2007	69,8	6 460	2015	70,1	N/A
2008	70,3	6 486			

Source: authors on the basis of statistics available on http://ec.europa.eu/eurostat

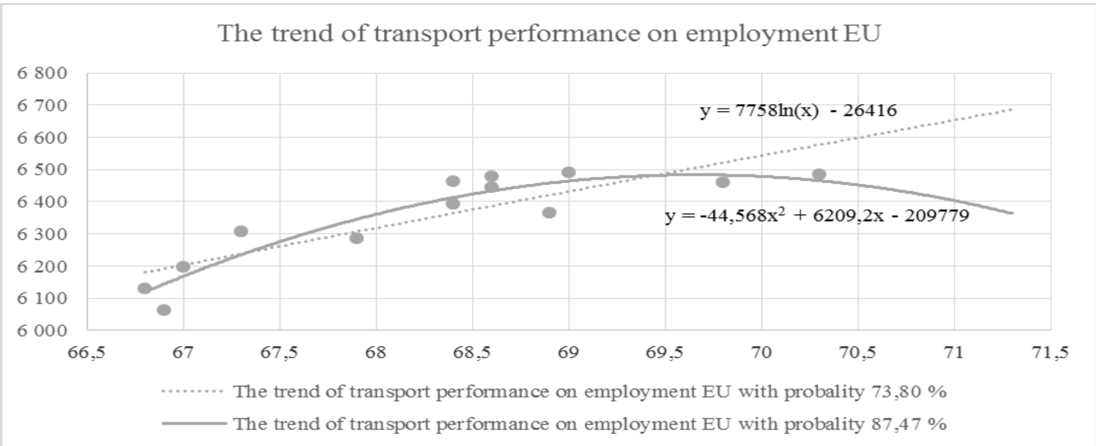

Fig. 3.

The trend of transport performance on the EU 28 employment

Figure 3 shows that if employment increased by 1%, then the probability of reducing the transport performances would be 87.47%. This fact will apparently not occur. The transport services in the time period from 1995 to 2013 were almost constant, only with minor diversions. The second trend with a probability of 73.80% assumes an increase in the transport performance together with an increase of employment of the population of the EU 28. Both trends were verified by the Fisher's rule.

5. Conclusion

The European Commission assumes that by 2020, the employment of the population aged 20-64 years will increase to the level of 75%. Based on the stated trend such a result is unrealistic. The optimistic trend is that the employment will rise, in 2015 it was 70.1% and in 2016 the assumed increase should reach 71.50%. In case of the assumption for 2020, the trend with the lower probability assumes the employment rate of 72.60% and the trend with the probability of

82.68% projects the employment rate of the EU population in 2020 of only 67%, which is 8% less than the stated objective of the European Commission.
Another indispensable factor is the sustainable mobility - which represents the implementation of the principles and objectives of a sustainable development in transport and economic policy with the focus on forming resources and effective use of investments both in transport infrastructure, as well as the development of transport services. Factors affecting the development of transport include the liberalization of the transport market and harmonization of legislative, technical and operational conditions, new forms of international business and new forms of technology management, introduction of intelligent transport systems and the level of transport telematics (Bukova, Brumercikova, Kondek, 2016).
The lack of competition and extensive state regulation combined with state ownership in the past resulted in a slow reaction of railroad "monopolies" to the changing demands and needs of carriers, leading to the decline of interest in rail transport and an increased use of a more flexible road transport.
The trends in transport depend on the development of the EU industry, changes in price sensitivity, changes in the demand for transport services and the quality of additional services of carriers (Bukova, Brumercikova, Kondek, Sojcak 2016)
Finally, we include a statement of the European Central Bank, in particular on their website www.ecb.europa.eu: "Globalisation is a challenge not only for the EU countries and transport companies but also for multinational companies. If the EU wants to succeed in global competition and respond to the challenges of globalization, it must implement reforms in the areas of tax, labor, energy and transport infrastructure. The reforms reflect the necessary changes to the functioning of the EU and reflects the challenges given to the EU by globalization of the world economy."

TRAFFIC SPEED PREDICTION USING PROBABILISTIC GRAPHICAL MODELS

Lukáš Rapant[1], Tomáš Martinovič[2], Kateřina Slaninová[3], Jan Martinovič[4]

[1,2,3,4] *IT4Innovations National Supercomputing Center, VŠB - Technical University of Ostrava, Ostrava - Poruba, Czech Republic*

Abstract: The importance of traffic state prediction steadily increases together with growing volume of traffic. The ability to predict traffic speed and density in short to medium horizon is one of the main tasks of every Intelligent Transportation System. Many such systems are currently developed to monitor and control the traffic flow in various states. It is also very important for dynamic route planning applications. Basically, there are two possible approaches to this prediction. The first is to utilize physical properties of the traffic flow to construct a numerical model. This approach is, however, very difficult to implement. Due to the problems with traffic sensor density, it is very difficult to gather enough data to accurately describe the starting and boundary conditions of the model. The other option is to use historical traffic data and relate information and patterns they contain to the current traffic state by the application of some form of statistical or machine learning approach. Authors propose a solution to use a probabilistic graphical models (PGM) for this task. These models are naturally able to capture all complexities in the traffic and incorporate uncertainty of the traffic data. This paper presents an algorithm based on dynamic Bayesian networks (DBN), which are one of the most widely used PGMs for modelling of dynamical systems. Our algorithm was tested on real data coming from the Czech Republic motorways.

Keywords: probabilistic graphical models, Bayesian networks, hidden Markov models, traffic speed prediction, ASIM, FCD.

1. Introduction

One of the main tasks of Intelligent Transportation Systems is to predict state of the traffic in short to medium horizon. This prediction can be then utilized in various areas of traffic modelling, analysis, and management. There are two general approaches to this prediction. The first approach requires us to have an exact mathematical description of the traffic flow and its starting and boundary conditions. Examples of this approach is article written by (Tang et al., 2014). This approach is feasible in simple traffic situations but quickly becomes intractable in case of inaccurate or incomplete data regarding both conditions. The second possible approach to traffic state prediction is to use historical data about traffic and relate them to the current state of the traffic by application of some statistical or machine learning approach. Example of this approach is described by (Huang, 2015). This task is, however, also not a simple one. It is complicated by complex nature of the traffic data. They can, depending on type of their source, be inaccurate or not available in required quantity. Despite this fact, this approach is preferable in case of traffic state prediction on Czech Republic motorways due to the unavailability of boundary condition data (i.e. there are not measurements on all ramps leading to and out of motorway).

Important part of any traffic state prediction is traffic data availability. Generally, data sources describing actual traffic situation on Czech motorway can be divided into two groups - stationary data sources (ASIM sensors) and floating car data sources (Floating Car Data).

ASIM sensors are placed on certain toll gates (all these toll gates are placed on the motorways). They comprise of various sensors like passive infrared detectors and radars. They are able to distinguish individual vehicle types, and measure their speed and intensity. Their measurements are aggregated every five minutes and mean speed and intensity are calculated. They have many advantages. Perhaps most important advantage is that there is no need for equipping vehicles with additional electronic devices. Consequently, a sensor measures speed of all vehicles going through it. The second important advantage is a detail of the data. ASIM sensors provide separate information about every lane of the monitored road and can distinguish individual vehicle types. However, these sensors have some serious disadvantages. The ASIM sensor network is very sparse. There are only about 120 toll gates equipped with ASIM sensors; all of these are placed on the motorways. There are also other limitations. Electronic toll gates divide roads into segments of various length, some of them may have length of many kilometres. Thus, data obtained from ASIM sensors exactly describe only traffic situation around the tollgate.

The other available source is Floating Car Data (FCD). The floating car data (FCD) technique is based on the exchange of information between floating cars traveling on a road network and a central data system. The floating cars periodically send their positions and speed, whereas the central data system spatially and temporally aggregates the received data. The frequency of sending/reporting is usually determined by the resolution of data required and the method of communication. FCD have specific discretization. For example, D1 motorway is divided into the sections (TMC segments) with length from several hundred meters to few kilometres. The traffic speed is calculated each minute as a mean of speed of all floating cars that passed through the section in the last minute.

This approach has also several advantages and drawbacks. The number of cars equipped with a GPS unit has doubled over the past five years. It can be expected that the trend will continue. It implies that the number of potential data sources will increase. Moreover, data from GPS receivers is not limited to the predefined places so the coverage is much larger than in the case of the stationary data. Drawbacks come mostly from the use of GNSS technology. GPS

[1] Corresponding author: lukas.rapant@vsb.cz

device can fail to provide precise outputs. This imprecision can have an impact on positioning, ranging from meters to tens of meters and influence the car to segment assignment within the aggregation system. Also it means that it is impossible to identify the lane in which the car is. Because GNSS is based on satellite technology, GPS receiver has to be able to receive signals from several satellites. This can prove to be difficult in some cases (cities, forests).

Both of these data sources are available to us thanks to the viaRODOS[2]. Nature of these data sources limits us in several ways. Given the positioning of the ASIM sensors and properties of FCD, it is impossible for us to use any kind of exact model. Moreover, because FCD contain only information about speed, the predictions are limited only to traffic speed. Therefore, focus of this paper is to find the algorithms that can exploit all the possible information contained in the historical and the current traffic data available for Czech Republic motorways to make a short term traffic speed prediction on motorways. A proposed solution is based on special kind of probabilistic graphical model called dynamic Bayesian network (DBN), because it provides a way to naturally utilize both of the data sources.

A lot of work has already been done in this area. Wang and Kuang (Wang and Kuang, 2015) proposed a traffic prediction method based on complex event processing and Adaptive Bayesian networks. They use synthetic data from the SUMO traffic simulator to evaluate their algorithms. On the other hand, Hoong et al. (Hoong et al., 2012) propose to use Bayesian Network for road condition prediction. They presented a set of evidences that could potentially be utilized for road condition prediction and constructed a Bayesian Network model to predict road conditions. Zhu et al. (Zhu et al., 2016) utilize a linear conditional Gaussian (LCG) Bayesian network model. Advantage of this model is its ability to work with continuous variables rather than discrete. However, learning of such model requires more and better data and therefore authors used data from macroscopic simulation. Paper written by Castillo et al. (Castillo et al., 2008) describes the problem of predicting traffic flows and updating these predictions when information about origin-destination pairs and link flows becomes available. They propose to use Gaussian Bayesian network to deal with this problem. They, however, also work with synthetic data on a small problem. Shiliang et al. (Shiliang et al., 2005) are using combination of Pearson correlation coefficients, Gaussian Mixture Model (GMM) and the Competitive Expectation Maximization (CEM) algorithm to approximate their joint probability distribution of traffic flow in the traffic network. They are utilizing both the spatial and temporal information of the data from the small network in Beijing. Wang et al. (Wang et al., 2015) use model similar to ours, but instead of coupled network built on spatial information, they work with similarity of road segments. They use spectral clustering to find this similarity. The closest to our work is the paper written by Herring et al. (Herring et al., 2010). They also use DBN for the prediction but instead of speed work with travel times. Their DBN, however, has Gaussian observations but much fewer hidden states. They also work with less complex data.

2. Probabilistic graphical models

There are many kinds of probabilistic graphical models but for the purposes of this article, our focus will be pointed to dynamic Bayesian networks, which are a special case of general Bayesian networks.

2.1. Bayesian network

A Bayesian network is a graphical model that represents conditional independences between a set of random variables. Let us consider four random variables A, B, C, and D. The joint probability can be factored as a product of conditional probabilities:

$$P(A,B,C,D) = P(A)P(B \mid A)\,P(C \mid B,A)\,P(D \mid C,B,A). \tag{1}$$

This factorization, however, does not tell us anything useful about the joint probability distribution because each variable can be potentially dependent on every other variable. So let us consider the following factorization:

$$P(A,B,C,D) = P(A)P(B)P(C \mid A)P(D \mid C,B). \tag{2}$$

This factorization implies a set of conditional independence relations. A variable or set of variables X is conditionally independent from Y given Z if $P(X,Y \mid Z) = P(X \mid Z)P(Y \mid Z)$ for all X, Y and Z such that $P(Z) \neq 0$. With this factorization it can be shown that given the values of B and C, A and D are independent:

$$\begin{aligned} P(A,D \mid B,C) &= \frac{P(A,B,C,D)}{P(B,C)} = \frac{P(A)P(B)P(C \mid A)P(D \mid C,B)}{\int P(A)P(B)P(C \mid A)P(D \mid C,B)\,dA\,dD} \\ &= \frac{P(A)P(C \mid A)P(D \mid C,B)}{P(C)} = P(A \mid C)P(D \mid B,C) \end{aligned} \tag{3}$$

[2] http://www.rodos-it4i.cz/defaultEN.aspx

A Bayesian network (BN) is a mean to represent a particular factorization of a joint distribution by a graph. Each variable is represented by a vertex in the graph. A directed edge is drawn from node X to node Y if Y is conditioned on X in the factorization of the joint distribution. To represent the factorization from Eq. 2, edge would be drawn from A to C but not from A to D. The Bayesian network representing this factorization is shown in Fig. 1.

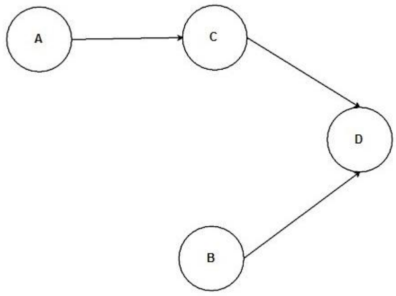

Fig. 1.
Example Bayesian network

Important property of the BN is that its graph can be considered as representation of the joint probability distribution for all variables. The tool to express this joint probability, as the product of the conditional probabilities that need to be specified for each variable, is called the chain rule:

$$P(X_1,\ldots,X_n) = \prod_{i=1}^{n} P(X_i \mid Par(X_i)) \tag{4}$$

Where; $Par(X_i)$: the parent set of a node X_i. Then the conditional probabilities, the structure of the BN, and joint probability distribution can be used to determine the marginal probability or likelihood of each variable holding one of its states. This procedure is called marginalization.
The true power of BN is shown whenever one of these marginal probabilities is changed. The effects of the observation are propagated throughout the network. The probabilities of a various neighbouring node are updated in every propagation step. In case of simple BN, the marginal probabilities or likelihood of each state can be calculated from the knowledge of the joint distribution, using the product rule, and the Bayes' theorem. Therefore, to define a BN it is necessary to specify the Conditional Probability Distribution (CPD) or pdfs of each node that has parents in addition to the prior probability of root vertices.
There are two important actions that can be performed with BN. The first is called inference. One of great strength of BN is that the conditional dependencies between variables can be inferred by visually inspecting the graph. Therefore, set of BN vertices can be divided into non-overlapping subsets of conditionally independent nodes. This decomposition is a basic part of the probability inference, which is the task of computing the probability of each state of a vertex in a Bayesian network when the values of other vertices are known. The second step to perform inference is the belief propagation. Belief propagation is the action of updating the beliefs in each variable when observations of some other variables are given. Inference in BN can be done by 2 classes of methods. The first and the most usual one is the exact probability propagation in a singly connected network. To do this, the network need to be transformed into singly connected structure. In the other class there are some approximate inference techniques (Monte Carlo inference techniques, inference by ancestral simulation, Gibbs sampling, Helmholtz machine inference,..).
The second one is called learning. All of the conditional probabilities in the BN are usually not known. Therefore, some learning techniques that enable us to complete the missing beliefs in the network must be employed. The role of learning is to find and adjust the parameters of the BN so that the pdfs defined by the network sufficiently describe statistical behaviour of the observed data. This procedure is usually realized by some form of EM algorithm.

2.2. Dynamic Bayesian network

Dynamic Bayesian Network (DBN) is a name of a model describing a system that is dynamically changing over time. DBN are usually defined as a special case of singly connected BN specifically designed for modelling the dynamic systems. All the vertices, edges and probabilities that make a static interpretation of a system are identical to a BN. Variables in DBN are called the state of a DBN, because they include a temporal dimension. These states satisfy the Markovian condition, which states that the state of a system at time t depends only on its previous state at time t-1. This property defines the First order Markov property: the future is independent of the past given the present.
The BN model is expanded by this fact. DBN allow not only connections within time slices, but also connections between time slices. These temporal connections introduce condition probabilities between variables from different

time slices. These time dependencies are represented by the transition matrix which is called a Conditional Probability Table (CPT), since it represents the CPD in tabular form. Static CPDs can also be represented by CPTs.
As with static BN, the states of a dynamic one do not need to be directly observable. There might be influencing factors of other variables that can be directly measured or calculated. Moreover, the state of dynamic system does not need to be a unique and simple state. It may by looked at it as a complex structure of interacting states. Each state in a DBN at one time slice may depend on one or more states at the previous time slice and on some states at the same time slice. So, generally speaking, in DBN the states of a system at time t may depend on system's states at time t-1 and possibly on current states of some other nodes in the fragment of DBN structure that represents variables at time t.
DBN can be described by probability distribution function on the sequence of T hidden-state variables $X = \{x_0, \ldots, x_{T-1}\}$ and the sequence of T observable variables $Y = \{y_0, \ldots, y_{T-1}\}$, where T is the time boundary for our model. This can be written as:

$$P(X,Y) = \prod_{t=1}^{T-1} P(x_t \mid x_{t-1}) \prod_{t=1}^{T-1} P(y_t \mid x_t) P(x_0) \tag{5}$$

Where; $P(x_t \mid x_{t-1})$: state transition pdfs, $P(y_t \mid x_t)$: are observation pdfs that specify dependencies of observation nodes regarding to other nodes at time slice t, $P(x_0)$: an initial state distribution. The first two parameters had to be determined for all states in all time slices. Conditional pdfs can be time dependent or time independent. Time independent conditional pdfs can be parametric or nonparametric, when they are described using probability tables. A DBN can be discrete, continuous, or combination of these two depending on the type of the state space of hidden and observable variables. The similar tasks can be performed with DBN as with BN:

1. Inference, estimation of the pdfs of unknown states given some known observations, and initial probability distribution,
2. Learning, estimation of parameters of a DBN such that they best fit to the observed data, and make the best model for the system,
3. Decoding, finding the best-fitting probability values for sequence of hidden states that have generated the known sequence of observations,
4. Pruning, distinguishing which nodes are semantically important for inference in DBN structure, and which are not, and removing them from the network.

In case of our application, the most important tasks are inference and learning.

3. Algorithm

Now let us present you how our algorithm works. As it has already been mentioned, proposed algorithm is based on use of both historical and current traffic data. These data are represented by speed time series coming from the two available sources: ASIM sensor network and FCD. Both of these sources have important roles in our model. ASIM sensors provide reliable information but, as a standalone information source, suffer from the two disadvantages. The first is spatial one, i.e. their network is sparse and is not covering equidistantly the motorway. The second is temporal one as the ASIM sensors have longer aggregation period and therefore are not optimal for online prediction. This problem can be fixed with FCD, which are available for all sections of the Czech Republic motorways and have much shorter aggregation period. However, these data can be quite inaccurate due to the lower penetration of the traffic by floating cars or other technical issues. Therefore, ideal prediction algorithm can utilize both the accurate but localized ASIM sensor data and widely available FCD, which suffer from the fact that they only measure speed of part of the traffic flow.
Solution for this problem was found in the form of dynamic Bayesian network also called coupled hidden Markov model. The example structure of the network can be seen in Fig. 2. Each vertex represents segment of the road. Edges are drawn in such way that future speed value of the segment depends on its last value and last values of its neighbouring segments. Hidden states represent true state of the traffic described by ASIM sensor data and measurements are observed noisy data represented by FCD. Both of these data sources are used during the learning of the network. One of the advantages of this model is that parameters of the model can be learned even when there are no ASIM sensors on some of the segments i.e. some of the hidden states are not observable at all. When properly trained, this network is able to predict the true state of the traffic speed (i.e. hidden state) from the n last values of FCD measurements.

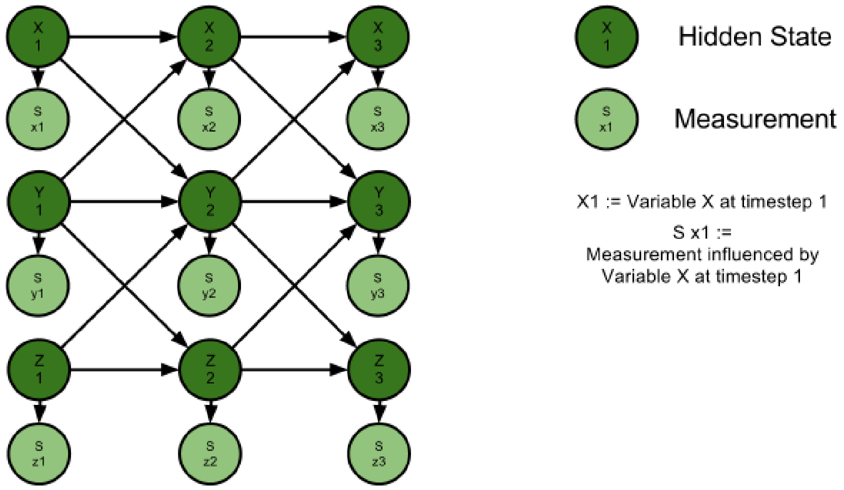

Fig. 2.
Coupled hidden Markov model as DBN
Source: (http://social.microsoft.com/Forums/getfile/103119)

General progress of our algorithm can be summarized into following steps:

1. Learning data pre-processing
2. Learning of the networks
3. Online prediction

Let us go through individual steps of the algorithm more thoroughly. In the first step, ASIM data and FCD are pre-processed for use in our network. This means that both of these continuous variables have to be transformed to discrete ones with m and n values for hidden and measurement nodes respectively. These numbers must not be too high, because the number of parameters in such model rises steeply (model requires $N \cdot m + N \cdot n + N \cdot n \cdot m + (n - 2) \cdot n^4 + 2n^3$ parameters) and it may not be possible to learn all these parameters in reasonable time. Some other works also use continuous observations (measurements) but we have decided to utilize simpler method to ease the learning of the network. The discretization is usually done by rounding the speeds to a certain number (i.e. 5 km/h). However, as it is evident from the Fig. 3, most of the measurements of ASIM sensors are distributed between 80 km/h and 130 km/h. Therefore, such rounding would produce few states with reasonable probability and greater number of improbable states. To address this issue, discretization based on probability density is proposed. State discretization will be smoother in areas with higher probability density and coarser otherwise. For example, if the speed is less than 60 km/h, it would be rounded to nearest multiple of 20 km/h and if the speed is higher than 60 km/h, it would be rounded to nearest multiple of 5 km/h. This procedure should result in states with reasonable probability. The data are also divided into 4 portions (data from 6:00 to 10:00, data from 10:00 to 14:00 and data from 14:00 to 18:00 and the rest, which is not used for prediction). This is done because the traffic speed time series are highly nonstationary and therefore creating only single model for all day would produce remarkably worse results. These periods are also naturally identifiable as morning peak, noon off-peak and afternoon peak.
The next step is the learning procedure of our model. Three separate models are learned, each for different period of the day. The learning procedure is done by EM algorithm and is done offline. EM algorithm is ideal for this problem because it can handle incomplete or unobserved data.
In the last step of our algorithm, special inference task called prediction is performed. In terms of our network, it means finding:

$$P(x(i, t + T) \mid y(:, 1{:}\, t)), \tag{6}$$

Where; $x(i, t + T)$: hidden state of node i at time t+T, $y(:, 1: t)$: represents measurements from the time period foregoing the prediction. Predicted value for each hidden variable is then calculated by maximum a posteriori decision rule (MAP) as:

$$z_i = \underset{k \in \{1,..m\}}{\operatorname{argmax}} P_k(x(i, t+T) \mid y(:, 1{:}\, t)), \tag{7}$$

Where; $P_k(x(i, t+T) \mid y(:, 1: t))$: the probability of hidden variable i at time t+T be at state k. This approximate inference is performed by The Boyen-Koller algorithm (Boyen and Koller, 1998).

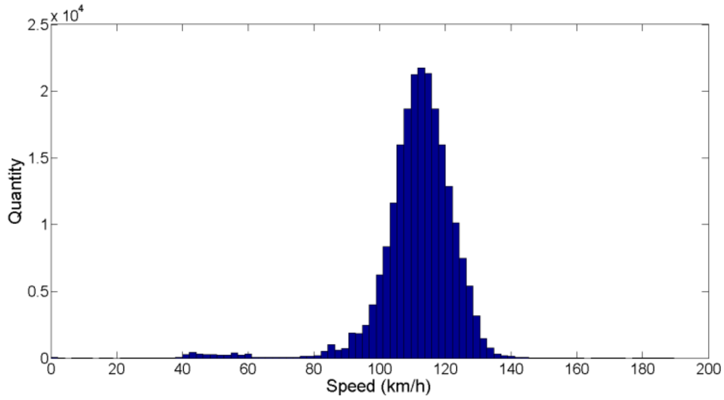

Fig. 3.
Histogram of traffic speed from D1 motorway

4. Experimental results

Our algorithm was implemented in Matlab environment and utilized basic parallelization to accelerate the computation. From the performance perspective, the only problematic part is the learning of parameters which can easily take tens of minutes. However, given enough historical data, it is not necessary to frequently update the model. The computation of prediction with trained model takes only tens of seconds.
The algorithm was tested on data coming from Czech D1 motorway from the period of 1.9.2014 to 30.11.2014. We have chosen 3 consecutive sections from 180th to 195th km in the direction of Brno (i.e. graph structure was the same as in Fig. 2). Traffic speeds from both ASIM data and FCD were discretized according to the scheme presented in the previous part and had 18 and 26 states respectively. Each of these section contained ASIM sensor. Two of these were used for learning and the values from the last one were not included in training set (i.e. remained unobserved). It was, however, used for result verification. We have used data from September to October for training and data from November for evaluation. Root Mean Square Error (RMSE) was chosen as a measure for quality of the prediction. All three learned models were tested and gave similar results. For the sake of space, we only present results from the first one. We have run online prediction predicting the state of the traffic speed in these three segments 5 minutes ahead for the duration of one hour. Results from one of these predictions can be seen in Fig. 4, 5 and 6.

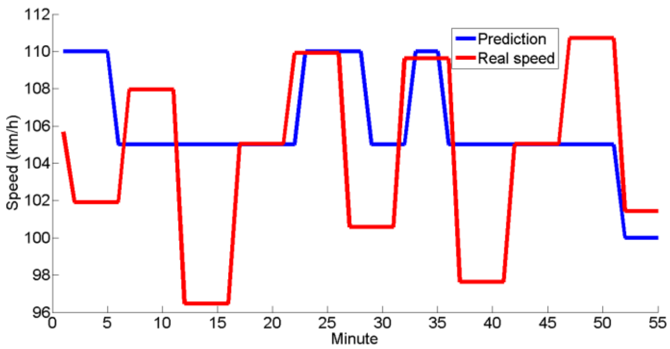

Fig. 4.
Traffic speed prediction for the first segment

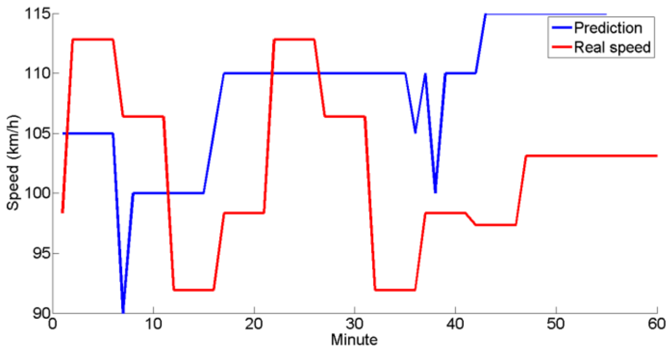

Fig. 5.
Traffic speed prediction for the second segment

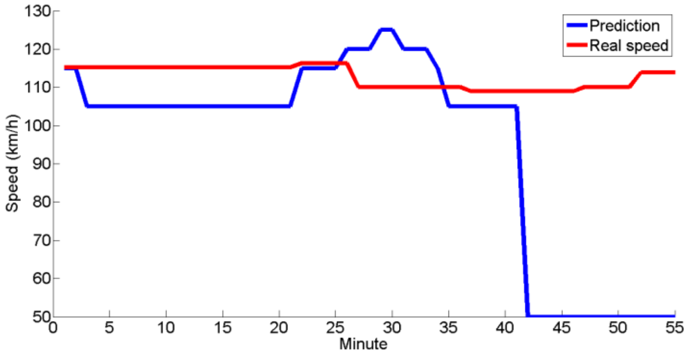

Fig. 6.
Traffic speed prediction for the third segment

The predictions for the first segment (Fig. 4) have RMSE of 5.1258, for the second segment (Fig. 5) RMSE of 10.0327 and for the third which was the one without the ASIM in learning set (Fig. 6) RMSE of 31.5727. In terms of RMSE mean value from all predictions, the confidence interval for the first segment is $< 8.0441, 8.3864 >$, for the second is $< 10.7243, 11.6859 >$ and for the third is $< 14.4149, 15.5572 >$. From these results it is clear, that presence of unobserved variable seriously degrades quality of the results, which is otherwise comparable to results of other contemporary works (Jiang and Fei, 2015). This fact restricts usability of this algorithm to areas with both ASIM and FCD data. However, overcoming of this problem will be main topic of the future research.

5. Conclusion

In this article, an approach to traffic speed prediction on motorways based on dynamic Bayesian network was presented. In proposed algorithm, ASIM sensors and FCD were used as valuable data sources. Both accuracy of the ASIM data and availability of the floating car data were utilized.
In comparison with other approaches like (Jiang and Fei, 2015), our algorithm performed comparably in case of complete data. In case of missing ASIM sensor, quality of results was seriously degraded, but in average stayed within reasonable limits. Main advantage of our algorithm is, that in contrast with many other algorithms, it works with real world traffic data from both FCD and stationary sensors and utilizes advantages of both of them, while, to some extent, overcoming their disadvantages. Results have proven, that our model describes the behaviour of traffic on motorways reasonably well.
This algorithm, however, can still utilize some improvements. The most important improvement will be to resolve the issue of slow and, in case of unobserved data, imperfect learning. This task will be addressed by parallelization of EM algorithm and by experiments with utilization of other optimization algorithms within EM algorithm.

UTILIZATION OF TRAIN ROUTES IN RELATION TO THE IMPLEMENTATION OF PERIODIC TIMETABLE

Přemysl Šrámek[1], Tatiana Molková[2]
[1,2] *University of Pardubice, Jan Perner Transport Faculty, Department of Transport Technology and Control, Pardubice, Czech Republic*

Abstract: This paper deals with the problem of railway line capacity in terms of periodic timetable implementation. Periodic timetable is often required by customers like use friendly variant in passenger transport or due to guaranteed delivery time in freight transport. If it is not possible to construct new lines or tracks and it is not possible to realize any reconstruction measures, it will be appropriate to implement some operational measure, e. g. to improve the utilization of train paths, resp. to determine the influence of periodicity of a timetable to the railway line capacity. Nowadays, according to increase in the number of international freight expresses on corridors, it must be implemented sufficient amount of train routes for these trains into a timetable. Namely, it is chosen an area in the Czech Republic, which is composed of different types of railway lines, among others also of overlapping section of Rail Freight Corridors RFC 7 and 9. It is calculated the capacity consumption by UIC 406 leaflet in relation to the periodicity rate. For calculation is used the simulation tool SimuT, which is also used by Czech Railway Infrastructure Administration for capacity evaluation. By simulation tool there are input random entry delay based on exponential probability distribution. For every simulation screenplay is then counted the average delay increment – this capacity indicator is most important to evaluate the utilization of train routes in terms of quality and quantity. There are created different variants of timetables with variant periodicity rate. Every screenplay consists of 365 simulation runs.

Keywords: line capacity, periodic timetable, SimuT, train routes.

1. Introduction

Nowadays, to be attractive and competitive railway transport must fulfil many requirements. Passengers require comfortable and fast travelling, carriers require modern, fast, reliable and relatively cheap infrastructure with allocable capacity and infrastructure managers require some time for infrastructure repairs. To repair, modernize and maintain the railway infrastructure needs the infrastructure manager a lot of sources, which he can gain by infrastructure operation (or by government subsidies). The more train paths for infrastructure manager, the more sources for repairing and modernizing. Unfortunately for infrastructure manager is not possible to easily increase the quantity of train paths due to carriers and passengers requirements, which emphasizes especially the quality of train operation. To the quality folder it can be included the periodic timetables construction, periodic freight train paths in network or stability of timetables. Therefore is necessary to find the optimal utilization of train routes, related to the implementation of periodic timetable (optimal combination of quality and quantity). The aim is to reach sufficient amount of train routes (in comparison with the timetable 2016) with sufficient timetable stability, without overloading capacity. The goal is to find out the relation between timetable stability and timetable periodicity rate.

2. Data and methods

There are mentioned some information about chosen closed railway network, about European Freight Corridors RFC, about leaflet UIC 406 and about the simulation method (simulation tool SimuT with average delay increment (ADI) calculation).

2.1. Closed railway network

It must be differentiated an open network local stability and closed network total stability. In this case is counted for closed railway network the total stability, it means a system is totally stable in the case of input delay eliminating in the defined time (all processes are running in the frame of closed network) (Hansen, Albrecht, 2008).
It was chosen a closed railway network in the Czech Republic consisting of various lines (different number of tracks, different security equipment e. t. c.), among others of overlapping section of Rail Freight Corridors RFC 7 and RFC 9 (namely section Kolín – Choceň). The whole chosen closed railway network is yellow marked on Figure 1.

[1] Corresponding author: st24539@student.upce.cz

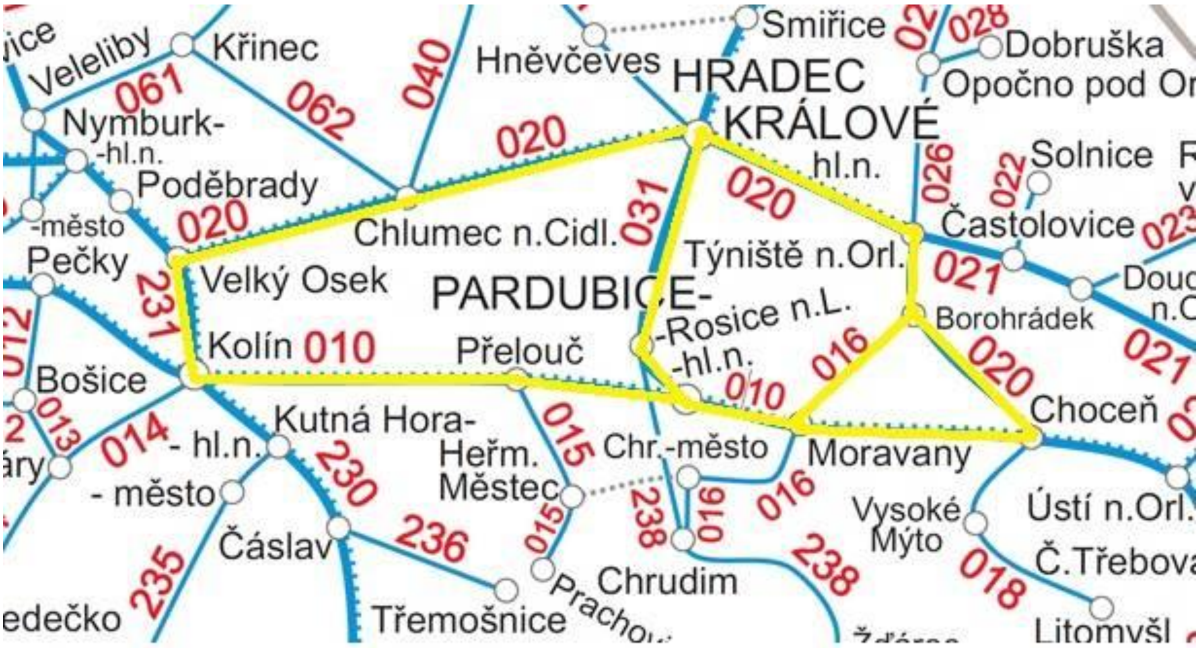

Fig. 1.
The chosen closed railway network
Source: Czech Railway Infrastructure Administration (CRIA)

The line 010 is the overlapping section of RFC 7 and RFC 9, double track, electrified, equipped with ETCS Level 2. The line 020 is single track, electrified and it serves as diversion route for the corridor line 010 in the case of exceptionalities. The line 031 is single track with one double track section with assumption of building double track line in the whole length of the line. It connects 2 county seats Pardubice and Hradec Králové (HK), which have in common 250 000 habitants (with agglomerations). The line 231 is called "Right Bank Line", while it is located on the right bank of the river Elbe. This line is double track, electrified and on this line turns a great amount of freight expresses from the line 010, while the line 231 heads to Germany avoiding Prague. The line 016 is single track, not electrified with operation consisted of stop passenger trains and handling freight trains, only (SŽDC, s. o., 2016).

2.2. Rail Freight Corridors (RFC)

On the basis of the European Parliament and the EU Council no. 913/2010 for competitive freight and no. 1316/2013, which is created the Connecting Europe Facility (CEF), is the gradual establishment of rail freight corridors RFC (Rail Freight Corridors). The main aim of the operation of these corridors is to strengthen the competitiveness of railways synergies between rail systems and harmonization of allocation interstate freight routes by national infrastructure managers (Čech, Šlachtová, 2015).
Czech Republic, respectively Czech Railway Infrastructure Administration (CRIA), as the infrastructure manager and allocator of capacity, is a member of RFC 5 (Baltic - Adriatic), RFC 7 (Orient / East-Mediterranean), RFC 8 (North Sea - Baltic) and RFC 9 (Czechoslovak corridor). Each corridor is operated on the basis of the Corridor information document (CID); each corridor has a single point of contact (C OSS) and allows carriers to apply international prearranged train paths facilitated freight via C-OSS. The request must be filed by information system RNE PCS and must include the cross-border section (Čech, Šlachtová, 2015).
RFC 7 - the Orient corridor runs from Central Europe to Eastern- and Southern-Europe connecting 7 member states - Czech Republic, Austria, Slovak Republic, Hungary, Romania, Bulgaria and Greece. The total length of main lines is approx. 3 900 km and the length of alternative and connecting lines is almost 2 500 km altogether (RFC 7 Orient Corridor, 2015). RFC 9 - the Czech-Slovak Rail Freight Corridor (CS CORRIDOR) runs from Prague to Čierna nad Tisou (Slovak-Ukrainian border) connecting 2 member states - Czech Republic and Slovak Republic. The total length of main lines is 972 km and the length of alternative and connecting lines is 276 km altogether (RFC 9 CS Corridor, 2013).
In capacity analysis, published in Implementation plan of RFC7, there are found lines with capacity utilization higher than 90 %. The longest sections with this high capacity utilization are situated in the Czech Republic, namely sections Poříčany - Pardubice (65 km) and Choceň - Česká Třebová (25 km) (RFC 7 Orient Corridor, 2015).

2.3. The UIC 406 leaflet

The UIC 406 leaflet, completely overhauled in June 2013, is one of the most important documents about the capacity calculation. There is published the approach to calculate capacity consumption by compressing a timetable and to evaluate the number of possible train path to a node, line or corridor. Corridor is in the UIC 406 defined as the main international and national connection and thus usually stretches over several hundred kilometres. Corridors may overlap with one another. On the basis of UIC 406 leaflet there are counted capacity indicators Occupancy Time Rate, Additional Time Rate and Capacity Consumption (UIC, 2013).

2.4. The simulation method

In this part is said something about the simulation method. In the chosen closed railway network there are a total amount of 29 railway stations, in which it is possible overtaking trains (double track line) or crossing trains (single track line). The amount of trains on each line is displayed in the Table 1. It is displayed for the present operation - timetable 2016 (TT 2016), constructed periodic timetable (PTT) and constructed periodic timetable with periodic freight train paths (PFTP, rescheduling of freight expresses). The upper number in the cell is total amount of trains on the line and bottom numbers is the amount of trains of: long distance passenger transport/regional passenger transport/freight transport. The letter X means the train category isn't operated on a line. The shortcut HK means Hradec Králové hl. n., the shortcut VO then Velký Osek station.

Table 1
The amount of trains

Line/Timetable	TT 2016	PTT	PFTP

Total amount of trains (whole network)	956 236/393/327	901 310/241/350	907 310/241/356

Source: Author

For simulation was used simulation tool SimuT, developed by Pavel Krýže, PhD. from CRIA.
The simulation tool SimuT is developed in Visual Basic, therefore it can run on every PC with Microsoft Office. It has to be input the option of a simulation, then railway stations and their shortcuts, station tracks for each railway station, line tracks, connection of station and line tracks, length of interstation departments and amount of line departments, type of train for priority, type of train for each number of a train and the path of each train. The simulation program SimuT can put new paths in a daily timetable with the solution for arisen path conflicts (Šrámek, Molková, 2016).
It was created the daily timetable, the passenger transport trains were concentrated especially from 6 am to 23 pm. Within the simulation program was established the average delay increment (ADI). The average delay increment was calculated by dividing the difference between total output and total input delay and the total number of trains. This indicator was calculated as an ongoing basis for each simulation run, so the total for the entire graph (all simulation runs). The indicator was also calculated for different types of transport, i.e. for long-distance passenger transport, regional passenger transport and freight transport (Šrámek, Molková, 2016). On the basis of occupancy time counted by SimuT were counted by author UIC 406 capacity indicators Occupancy Time Rate (K), Additional Time Rate (R_T) and Capacity Consumption (C).
Three variants were created in SimuT. The first variant covers current railway operation in the Czech Republic. In the second variant there was created a periodic timetable on the basis of keeping up similar amount of trains of each train category, but with periodic routing for each train category. The third variant added to the periodic timetable optimization of freight train paths in network through path rescheduling via bottlenecks (Drábek, 2013). For timetable stability evaluation in relation with periodicity it is counted the periodicity rate – percentage of trains in PTT or PFTP and the whole number of trains.
It must be said the amount of trains in each train category is different for each variant. The whole amount of trains in TT 2016 is higher than in PTT or PFTP, but the heterogeneity is different. For SimuT one train means one train number. In PTT and PFTP there is then less amount of train numbers, but one train number covers on average longer distance in PTT or PFTP because of creating of comprehensive train routes.
As part of the simulation was set for all simulation runs random entry delay based on the exponential probability distribution. There were solved conflicts of station tracks, freight trains were allowed to ride before their schedule time (in the case of free capacity). For each variant was made a total of 365 runs of simulation (for a daily timetable) (Šrámek, Molková, 2016).

3. Results and Discussion

In the simulation there was gained timetable stability indicators – average delay increment for all trains (ADI), average delay increment for long distance passenger transport (ADIL), average delay increment for regional passenger transport (ADIR) and average delay increment for freight transport (ADIF). Total delay for whole network is the dot product of train number matrix and ADI matrix. ADI for whole net is then total delay divided by total amount of trains. These most important timetable stability indicators are in the tables yellow marked. Table 2 is made for timetable 2016, Table 3 for periodic timetable and Table 4 for periodic timetable with periodic freight train paths (rescheduling via bottlenecks).

Table 2
ADI and periodicity rate in timetable 2016

Line/Indicator	ADI (min/train)	ADIL (min/train)	ADIR (min/train)	ADIF (min/train)	Periodicity (%)

ADI for whole net (min/train)	-0.62	1.07	-1.00	-1.83	

Source: Author

With the increasing periodicity are getting the total delay and ADI for whole net lower. In the periodic timetable are in comparison with timetable 2016 all indicators better, in the periodic timetable with periodic freight train paths is much better (lower) ADIF, but a bit worse ADIL and ADIR (in comparison with periodic timetable). It is the price for effective routing of freight expresses, but the effect for whole network is positive (lower total delay and ADI for whole net). Visually are the tables compared on Figure 2 (total delay).

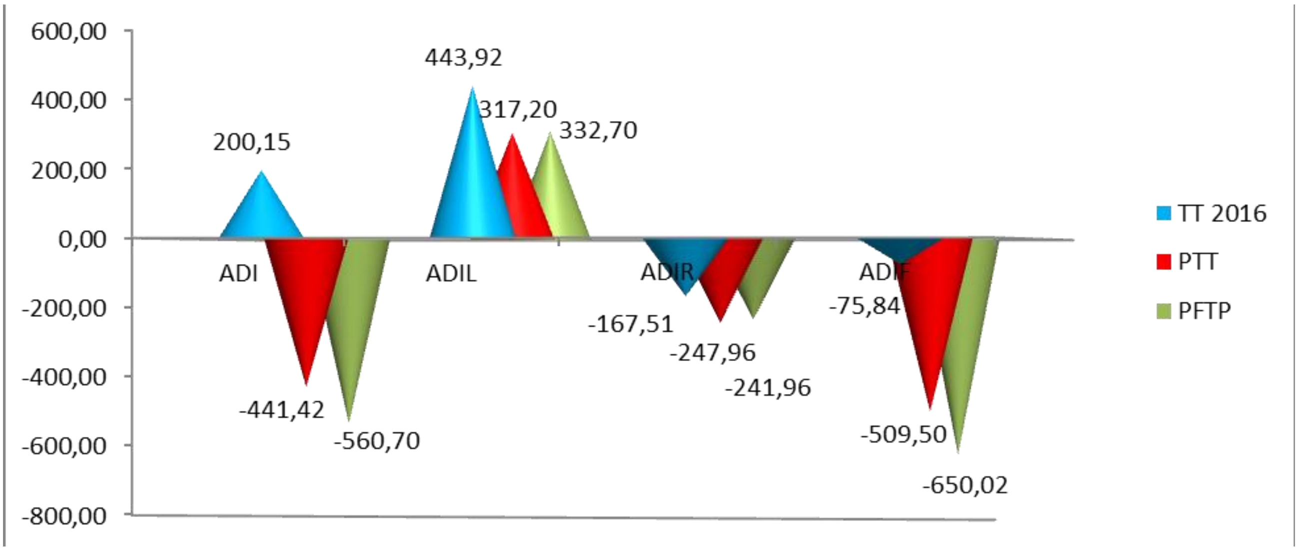

Fig. 2.
Comparison of total delay

With the increasing periodicity are the UIC 406 capacity indicators raising and the infrastructure seems to be more overloaded. It is very interesting with increasing periodicity is timetable on a closed railway network more stable, although some interstation departments are overloaded. It is possible in case of periodic timetable the infrastructure utilization could be in a few sections very high (up to the overloading), but if train routes are effectively made and bundled, it could be reached very high timetable stability. It is true in PTT and PFTP there are less trains than in TT 2016, but indicators ADI, ADIL, ADIR and ADIF are counted for one train, so their predictive value is appropriate.

4. Conclusion

With periodic timetable implementation could be reached very good timetable stability, although some interstation departments could be overloaded. Generally, in PTT and PFTP was routed less amount of trains, but the structure of trains has changed – there were strengthened segments of long distance passenger trains and freight trains, regional passenger trains were realized in less amount, but with preservation of commitment to public service (transfers from long distance passenger trains).

Optimal utilization of train routes is that one with sufficient timetable stability, sufficient quality for customers and sufficient quantity for infrastructure manager. Through PTT implementation is reachable very good timetable stability and high quality (use friendly network connections), the quantity is then lower, unfortunately, but sufficient for generation sources to maintain and modernize the infrastructure. At first, it is the turn of infrastructure manager to modernize interstation departments with overloaded capacity – then could be reached higher quantity in good quality. Through PFTP implementation could be satisfied the needs of freight carriers, optimized the network indicators and fulfilled requirements of prearranged train paths on RFC.

POSSIBILITIES TO EVALUATION RAILWAY TRACKS IN CONDITIONS OF THE SLOVAK RAILWAYS

Juraj Čamaj[1], Jaroslav Mašek[2], Anna Dolinayová[3], Jozef Daniš[4]
[1,2,3,4] *University of Žilina, The Faculty of Operation and Economics of Transport and Communications, Department of Railway Transport, Univerzitna 8215/1, 010 26 Žilina, Slovakia*

Abstract: The railway transport is one of the important sectors of the national economy, which substantially affects the development and growth of the economic level in every region. The European Commission and government of European countries declared in the documents aim to shift part of the volume of freight transport from road to rail. Building and reconstruction of railway network requires the comprehensive view of everyone infrastructure project. The paper is focused to the evaluation railway tracks in the Slovakia by using Multi-Criteria method. Evaluation of railway tracks has important impacts for the assessment of the technical equipment investment, important impact for time discreet train formation and for the allocation of marshalling yards. Transport model for evaluation the railway tracks used the marshalling yards like the centers for the operation assigned catchment area. This model is one of the effective ways to meet the development strategy of the European Community's railways. By applying this model in practice, a transport company can guarantee a higher quality of service and then expect an increase of performance. The model is also applicable to other rail networks. This model supplements a theoretical problem of train formation problem of new ways of looking at evaluation of factors affecting the organization of wagon flows. This transfer should occur in particular in order to decrease the environmental pollution, reducing the number of traffic accidents with fatal consequences and elimination of congestion on the road network in areas of large cities.

Keywords: evaluation model, wagon flow, quality of the services.

1. Introduction

The railway transport is one of the important sectors of the national economy, which substantially affects the development and growth of the economic level in every region. Building and reconstruction of railway network requires the comprehensive view of individual infrastructure projects (Camaj, 2008). The European Commission and government of European countries declared in the documents aim to shift part of the volume of freight transport from road to rail. This transfer should occur in particular in order to lessen environmental pollution, reducing the number of traffic accidents with fatal consequences and elimination of congestion on the road network in areas of large cities.

2. Basic description of the transport network

(From the perspective of modeling the transport network composed of operating control points and sections, which can be interpreted as vertices and edges oriented twice valuation multigraph (Camaj, 2008).
Applying the methods of graph theory is the appropriate mathematical apparatus for description, analysis and synthesis of transport networks (Zitricky, 2015). Formal transport network is determined by a set of peaks (P) and edges (E) with the double-valued (permeability and length):

$$S = (P, E, p, l) \tag{1}$$

The permeability (one-way) is determined by the number of sets that can enter into the section per unit time. Very important is the determination of edge weight. Weight of edges can be expressed not only in units of length (km), as well as e.g. average time (minutes or hours) required for its passage. In connection with the creation of a model railway infrastructure can be very suitable to be difficult formulation the optimality criterion. A number of practical problems are defined as multi-criteria tasks.

3. Methods of multi-criteria analysis

Analytical methods generally constitute a set of rules and procedures applied, which can come to a proper assessment of the subject that is for adopting the best solution. The current mathematical system offers a wide range methods of decisions. Analytical methods can be divided into three groups on empirical, heuristic and exact methods (Dolinayova, 2015).
An empirical methods are based on experience, intuition and subjectivity. These methods can be divided into empirical-intuitive ("trials and errors"), empirical-analytical (analysis replaces intuition), Expert (Delphi method/expert opinions, brainstorming, brain writing, the method of scenarios).
Heuristic methods used the advantages of empirical and statistical methods. They are based on common sense and logic. These methods include the decision table, decision tree, decision analysis and preference theory (if 60% chance that the decision is correct, it should accept the decision maker (Křupka, 2012).
An exact methods are based on scientific analysis and decision-making designed to solve situations that are repeated, and where relationships between elements are expressed quantitatively. This group of methods include (Dolinayova,

[1] Corresponding author: juraj.camaj@fpedas.uniza.sk

2016): methods of Mathematical Statistics (probability theory, correlation analysis, time series analysis), methods of mathematical analysis and linear algebra (differential calculus, extrapolation, matrix), Methods of Operational Analysis (Mathematical Methods in Economics, structural analysis, network analysis, queuing models and so on.

Comprehensive evaluation process is carried out in increasingly complex dynamic conditions. Therefore, it is necessary to choose the appropriate method of their choice, which will take into account several criteria:

- **The point evaluation method** is a system of scoring scale (e.g. 5-point scales). Using the criteria they are often characterized by different terms (one is positive, the other negative), so when evaluating a number of indicators is important in their common core. If this condition is met, it will be according to the degree of importance attached to individual criteria individually and weight of point scores (Fotr, 1988).
- **Evaluative index method** is used when it is necessary to concentrate all the criteria to one decision to one indicator, where:
  - Criteria have different in terms of quantification and randomness.
  - Criteria are from different areas of commercial, production, distribution and so on.
  - Criteria have different importance given the objective analysis (Fotr, 1988)
- **Decision Matrix Method (DMM)** is considered as the basic method of multi-criteria decision making. It may have more variants. One variant consists in the evaluation weight (importance) of the request point scale from 1 to 10 such that the stage 1 is assigned the smallest weight and the maximum weight of 10 degree. The same scale was also assessed the fact as each alternative meet the selected criteria, ie. to "1" - did not match up to "10" - meets perfect. (Křupka, 2012) For the final criterion for the decision is then selects the greatest weighted sum (sum of the product of the extent to evaluation criteria and their weights). Its advantages are simplicity and relatively low process time-consuming, the disadvantages are the high proportion of subjectivity in the valuation criteria and weighting in the assessment of how individual variations meet the selected criteria
- **Forced Decision Matrix Method** – partially eliminates the disadvantages of DMM. Weights of individual criteria and an evaluation of options to meet individual criteria are determined so pairwise comparison. This means that when comparing two criteria is more important (to decide important) criterion marked "1" less important criterion of "0". Similarly, when evaluating how two variants meet the selected criteria of evaluation are satisfactory options better, rated "1" variant and rated worse "0" (Křupka, 2012). The final evaluation of alternatives or weighting of criteria so we get the rating "normal", ie. we demand that the sum of all respectively the balance was equal to 1. FDMM advantage is the relative simplicity of the procedure and the elimination of subjectivity in determining the weights and impact criteria as they are more accurately identified. The disadvantages include relatively large differences in the evaluation of options and criteria, even if they differ only slightly, and in determining the weight criteria or evaluation of alternatives equals "0", not the overall assessment of any impact (Fotr, 1988).
- **The competence index of supplier** is a tool designed to distinguish the weighting of each criteria from the perspective of the customer. The basic formula for the calculation of the relationship:

$$CIS = \sum_{i=1}^{n} HK_i.w_i \tag{2}$$

where:
n – number of criteria,
w_i – weight of each criteria, where $\sum_{i=1}^{n} w_i = 1$
CIS – competence index of supplier
R_i – rating of *i-th* criterion, where is valid: $R_i = f(R_{ir}, R_{iopt})$
R_{ir} – real rating of *i-th* criterion
R_{iopt} – designated optimal rating for *i-th* criterion.

In practice, the evaluation criteria for *Ri* is calculated as the ratio of optimal and fair value of the criteria. It is generally accepted rule is that if the optimum minimum value, expressed, and this is optimum in the calculation of the numerator of each formula. Conversely, if the optimum expressed as a maximum, then in calculating the denominator of the formula. In calculating the optimum values by the extremes (minimum and maximum), then the optimum value of 1. Otherwise the value of CIS is ideal as high as possible value of the index (Fotr, 1988).

• **Analytic Hierarchy Process (AHP**). This method creates DR. Thomas Saaty in the 70s of the last century. It is a decision-making method for determining priority criteria when it must be compared more criteria. Generally, the hierarchy of three levels: the objective criteria and alternatives (Křupka, 2012). This method is still the most valuable and useful in the world. The method allows the best choice based on preference. The advantage of the method lies not only in finding the optimal result, but also allows you to view and clear intermediary elements that contribute most to the outcome (Křupka, 2012). Its disadvantage is the need to make numerous comparisons.

• **Preference Ranking Organisation Method for Enrichment Evaluations** – **PROMETHEE** allows the user to directly use simple multi-criteria table. Instead of having to undertake large number of comparisons, the decision maker defines only its own scale of measurement (without limitation), to determine their priorities and their preferences for each criterion. The advantage of the method **PROMETHEE** that enables fast the sensitivity of the visual form and calculate the robustness of the current classification for each criterion (Křupka, 2012).

4. The individual criteria of railway tracks

The rail network comprises railway lines, which consists of track sections. The assessment parameters tracks can be based on their characteristics divided according to several criteria.

4.1. Infrastructure fee

The fee for the use of the railway infrastructure in the Slovak Republic is paid by the transport operator to the railway for the use of the railway lines. The total amount for access to the railway infrastructure is defined as:

$$U_C = U_{mp} + U_{tp} \tag{3}$$

The calculation of the total payment for a minimal access packet for the train will be determined as the charge summary for capacity ordering and allocation, charge for traffic management and organization and charge for securing transport ability according to the pattern (Dolinayová, 2016):

$$U_{mp} = \sum_{i=1}^{6} U_{1i} * L_i + \sum_{i=1}^{6} U_{2i} * L_i + \frac{1}{1000} * \sum_{i=1}^{6} U_{3i} * Q_i * L_i * k_e \tag{4}$$

where:
Ump - total reimbursement for the use of the railway infrastructure,
U1i - maximum reimbursement for ordering and allocating capacity
U2i - maximum reimbursement for managing and organizing transport
U3i - maximum reimbursement for ensuring the operability of the railway infrastructure
Li - total track length of the competent category between single transport points in kilometers
Qi - total gross weight of the train rounded to the whole ton
ke - coefficient which takes into account the movement of the train with an active driving rail vehicle using diesel traction on electrified tracks, the size of this coefficient being 1.2. The coefficient for the other trains is 1.0.

The calculation for total payment for track access to service devices for freight trains consists of a charge for use of an electric feeding device, a charge for train assignment and it will be determined according to the pattern:

$$U_{tp} = \frac{1}{1000} * Q * L_e * U_e + \sum_{j=A}^{D} P_{Pj} * U_{Nj} \tag{5}$$

where:
Q - total gross weight of train harnessed on electrified track rounded to the whole ton
Le - length of electrified stretch utilized in kilometers
Ue - maximum reimbursement in €/thousands of gross ton kilometers for electrical supply used
PPj - number of train accesses according to the respective category of transport points for freight transport trains
UNj - maximum reimbursement in € for access of freight transport trains. (Dolinayová, 2016)

4.2. The Traction energy

By type of traction we distinguish in Slovakia on track:
- electrified,
- non electrified.

Electrified tracks can be split according to the type of current and frequency to:
- DC electrified lines with the traction voltage of 3 kV,
- AC electrified lines with 50 Hz frequency and voltage 25 kV,
- AC electrified lines with 16.7 Hz frequency and voltage 15 kV.

4.3. The track class

The maximum permissible axle load is dependent on the carrying capacity of the railway infrastructure and bridge. Axle weight is given in tones and is calculated by dividing the gross weight of wagons, i.e. the sum of its own weight and the weight of the wagon load by number of axles. If the data at the axle load is not any indicator that mentioned axle load is part of the maximum allowable (Mašek, 2015). UIC track all sorts of weight per unit length of vehicles in classes A, B1, B2, C2, C3, C4, D2, D3, D4. The markings with capital letters (A, B, C, D) account for the highest permitted axle load indication and the arabic numbers (1, 2, 3, 4) corresponds to the highest permitted gross vehicle weight per unit length. Overview categories of track classes is in Table 1.

Table 1
The track classes and their maximal loading

The track class	The maximum permissible axle load	The maximum permissible weight of the meter wagon
A	16.0 t	5.0 tpm
B 1	18.0 t	5.0 tpm
B 2	18.0 t	6.4 tpm
C 2	20.0 t	6.4 tpm
C 3	20.0 t	7.2 tpm
C 4	20.0 t	8.0 tpm
D 2	22.5 t	6.4 tpm
D 3	22.5 t	7.2 tpm
D 4	22.5 t	8.0 tpm

Source: Masek (2015)

4.4. The track construction

The rail line is composed of the railway substructure, railway superstructure and artificial structures.
The track substructure has a fundamental role to ensure a sufficiently stable connection of the rail body with the ground. The track superstructure is used for roadway rolling stock, leading them and carries. While also transmits power to the track substructure which arise while driving vehicles (Gašparík, 2015). The main task is keeping artificial construction of the railway line in places where they cannot be used alone embankments and indentations or their implementation would be much cost. The group of artificial structures we include retaining walls and restraint walls, tunnels, bridges, viaducts and culverts (Ližbetin, 2016).

4.5. The type of track interlocking system

The track interlocking system has a significant impact on the number of trains running in the interstation sections. Ensuring the movement of trains is carried out in accordance with existing traffic regulations depending on the type of interlocking system.
Track security devices are classified according to the level of security on device:

- 1st. category (train announcing points) the main signaling devices are independent by departures of trains and also by interlocking systems in adjacent operating control points
- 2nd. category (semi-automatic track interlocking system). They provide dependency between adjacent operating control points. Operation of the control unit of section or departures signaling devices is dependent on train movements and requires the cooperation of the operator.
- 3rd. category (full automatic track interlocking system – automatic block). They mediate dependence between adjacent operating control points. Operation of the control unit of section signaling devices is automatic. The control unit is dependent on drive train and does not require action and servicing staff.

Table 2
The track interlocking systems

Automatic block	**Total**	**670 km**
unidirectional automatic block		129 km
bidirectional automatic block		541 km
Automatic signal box		**512** km
Semi-automatic block	**Total**	**762** km
relay semi-automatic block		624 km
signaling semi-automatic block		138 km
Track with telephone communication		**1 556** km

Source: Network statement ŽSR (2015)

4.6. The gradient conditions of track

On the track of the gradient is determined speed limit between the maximum track speed and running speed by:
- size of the slope or climb on the track,
- according to the type of train brake system and drive performance vehicle,
- according to braking distance with respect to prescribed provisions of infrastructure manager.

The biggest gradient is determined for each track individually. The ruling (decisive) gradient is one that can be designed in a straight section of the track (Kendra, 2016).
The track is proposed in the uniform gradient for the longest sections. Where possible, the route is guided as a constant resistance of track (effect of curvature on the track, where applicable, placed in the tunnel route). The longitudinal gradient of the track is proposed in view of smooth start and safe stopping of trains (Kendra, 2013).
The track gradient should be as small as possible. The gradient conditions at operating control points and hump track are designed in accordance with the relevant regulations for the design of railway stations. The length of the horizontal sections should be as far as possible provided that it does not deteriorate the construction and maintenance solutions in traffic routes (Dolinayová, 2016).

4.7. Number of line tracks

The line track, which connects two adjacent operating control points is continuous track of rail. Tracks can be split according to the number of tracks to the single-track lines (allow movement of trains with only one direction) and double-track lines or multi-track lines (allow movement of trains in both directions simultaneously by different track rail) (Zitrický, 2015). The main characteristics of the railway network managed by ŽSR (as of 18.11.2015) is in table 3.

Table 3
The length of track by gauge (in km)

Total construction length of tracks	**3 625.522**
Operated: (km)	3 579.978
• single tracks (km)	2 563.255
• double tracks (km)	1 016.723
• narrow gauge track (km)	46.201
• broad gauge tracks (km)	98.718
• normal gauge tracks (km)	3 435.059

Source: Network statement ŽSR (2015)

4.8. The type of structure gauge

The structure gauge (SG) is defined as the plane perpendicular to the axis of the line, whose axis is perpendicular to the line joining down from the top of the rails, which may not intervene any part of fixed building or any part of the line track. The structure gauge, also called the minimum clearance outline, is the minimum height and width of tunnels and bridges as well as the minimum height and width of the doors that allow a rail siding access into a warehouse. In addition, the term may apply to the minimum distance to railway platforms (passenger or freight), buildings, electrical equipment boxes, railway signal equipment, third rails or to supports for overhead catenaries or overhead lines from the track (Skrucany, 2015).
The loading gauge is to determine of spatial pattern that may interest expense on open wagons. On the Slovak railways are using the following gauge in the following breakdowns (Network statement ŽSR, 2015):
- SG 1 C – SM/ŽSR:.
- SG 1 - SM_E/ŽSR:
- the bridges SG,.
- the tunnel SG,
- on the reconstruction line of Slovak railways– SG B, C,
- the line for multimodal transport SG UIC GC.

4.9. The line speed

The line speed is defined as a permanent maximum speed limit on the particular line, which is indicated in the Route Book. In addition to the line speed we know the set speed, the speed of the train is determined by its timetable. In the professional standards established by the infrastructure manager on Slovak railways (ZSR) is the rail speed defined according to different types of train (Camaj, 2008). All speed levels at the Slovak Railway are in the table 4.

Table 4
The distribution of the various speed zones

The speed level	Track speed
SL 1	to 60 km/h
SL 2	60 – 90 km/h
SL 3	90 – 120 km/h
SL 4	120 – 160 km/h
SL 5	up to 160 km/h

Source: Network statement ŽSR (2015)

When considering the possibilities of railway transport and routes to take into account the following factors:
- vibration of wagons from inequality on the track,
- adhesion, which is a decreasing of speed,
- curvature - Vertical drop of outer belts in curves, the radius of curvature in the track browsing, the radius of curves into turnout,
- deformation of the rails due to the deformation waves
- deformation of the contact wire collector,
- sound barrier.

To satisfy human and social needs appears more and more to the fore the time factor, along with the quality of service becomes a decisive factor in transport (Gašparík, 2015). Modernization of railway transport focusing on the issue of higher speed as one of the fundamental problems of a technical and economic character (Ližbetin, 2016).

5. Methodology for comprehensive evaluation of railway lines

A methodology for rating of lines can serve as support for modeling direction of load in train formation problem. Methodological aspects consist in applying the procedures leading to determine the meaning indicator and also a partial assessment. This requires the determination of:
- weights of individual indicators
- partial evaluation of indicators.

To determine the weight of the indicators needs to be in two steps:
- determine the weight of each group of indicators,
- determine the weight of each indicator in the group.

Weights of individual groups of indicators and weights of individual indicators in the group is based on a numerical scale by 1 to 6 point. The assignment one point represents a group resp. indicator with little importance and assignment of 6 points represents a group of indicators, resp. indicator of crucial importance

5.1. Parameters for evaluation and their indicators

After processing of individual assessment parameters lines is in the next step should be to assign to these parameters of individual indicators. These indicators characterize the individual parameters. The structure of indicators are shown in table 5.

Table 5
Parameters for evaluation and their indicators

Parameters	**Indicators**	points	**Parameters**	**Indicators**	points
1.The infrastructure fee	Train	**6**	7.The gradient conditions	horizontal	**6**
	Transport quantum	**1**		to 5 ‰	**5**
	Distance covered	**4**		to 10‰	**4**
2. Railway gauge	Normal gauge	**6**		to 20‰	**2**
	Narrow gauge	**4**		up to 20‰	**1**
	Broad gauge	**1**	8.Number of line track	Single-line track	**1**
3.The type of traction	Electric traction	**6**		Multi-line track	**6**
	Without electric traction	**1**	9.Character of traffic	Passenger	**1**
4.The track class	A	**1**		Freight	**6**

	Automatic block system	**6**			

Source: Author

The choice of indicators to proceed to the merger of the indicators chosen because of their high countability. The differences of their influence and their subsequent evaluation have the same weight. As an example, we are presenting parameter of track class and their maximal loading where the track class is assigned a score of categories by alphabetic indexing without numerical index.
The model works with 11 groups of parameters, with total 42 indicators. The final evaluation of the track is the sum of the individual evaluation parameters that characterize the railway. Given the number of parameters of tracks allows at most score 66 points and no less than 11 points. In case if any parameter of the track is not in the matrix, it shall be assigned the value by weight closest possible parameters.
As an example parameter maximum line speed in the matrix evaluation, the maximum value of this ratio 160 km / h. If the proposed comprehensive review of lines applied to the track with the track speed higher than 160 km / h, shall be assigned to this indicator weight "6".

5.2. Determination of the conditions for „Ideal Track“

The ideal track is a track where individual factors are assigned the highest rating. This assessment will be a maximum assessment rate in all parameters.
For the evaluation of lines is necessary to establish conditions that would allow the creation of a comprehensive assessment model, relative to the track capacity, technical equipment etc.

6. Solutions

The solution to this design is the use and application of several optimization methods and algorithms. The final evaluation of the track is the sum of individual evaluation parameters that characterize a particular railway line.
Selection can be performed for any lines on the transport network, where is the possibility of building the new lines, ("building from scratch") or to determine directly choice the existing tracks.
The objective of the methods of multi-criteria evaluation is the transformation and synthesis values of different variables to a single summary indicator (the resulting characteristics). This indicator shows the comprehensive level of individual objects in the surveyed lines. It is a summary indicator representation of the overall level (importance) of the line.

$$Kj = \frac{\sum_{i=1}^{n} a_{ji}}{\sum_{i=1}^{n} a_{mi}}.100 \quad ; j \in 1,\ldots,m-1 \tag{6}$$

where:
Kj - coefficient of the j-th line;

$\sum_{i=1}^{n} a_{ji}$ - sum of the evaluation j-th line;

$\sum_{i=1}^{n} a_{mi}$ -sum of the evaluation the “ideal” line.

"Ideal line" is marked the line that all evaluation factors meets in full. Thus, the value x_{m1}, ... , x_{mn} are the maximum. Summary of indicators reflects the importance of the point. The basis of multi-criteria evaluation is processing the initial matrix of objects and their characteristics. The objects represent all railway lines on the network, which in each case meet the criteria for inclusion in a specific choice.

Table 6
Initial matrix for evaluation

Track / Indicator	1	2	...	j	...	m-1	m (the ideal line)
a_1	x_{11}	x_{12}				x_{1n}	x_{m1}
a_2	x_{21}	x_{22}				x_{2n}	x_{m2}
...	...						...
a_i				x_{ij}			
...	...						...
a_n	$x_{m-1,1}$	$x_{m-1,2}$				$x_{m-1,n}$	$x_{m,n}$
$\sum$	$\sum_{i=1}^{n} a_{1i}$	$\sum_{i=1}^{n} a_{2i}$		$\sum_{i=1}^{n} a_{ji}$		$\sum_{i=1}^{n} a_{m-1,i}$	$\sum_{i=1}^{n} a_{mi}$

Source: Author

Legend of the matrix:
$a_{1,\dots,n}$ – evaluation indicators;
x_{ij} – value of i-th indicator in the j-th railway line;
n – number of indicators;
m_{-1} – number of railway lines included to the initial matrix;
m – the ideal line.

7. Conclusion

The result of evaluation of the tracks can be classified into 4 groups, these groups are created by experts. Tracks of the highest final assessment can be classified in the first group of "I". Track with the lowest final assessment can be classified in the last group "IV". The boundaries between groups may be provided directly for the entire infrastructure or the inclusion of the tracks between the two groups will be assessed individually according to the overall complexity the track.
The guaranteed support railway by funding European Union or national governments is necessary that railway undertakings provide competitive transport services like other kinds of transport.
This model for evaluation railway lines represents one of the possible ways to meet the development strategy of the European Community's railways. By applying this model in practice can the infrastructure manager guarantee a higher quality of service and then expect an increase in performance. The model is also applicable for other network transport systems.

IDENTIFICATION OF THE CYCLICAL COMPONENT IN MODELING ROAD ACCIDENTS

Dariusz Grzesica[1]
[1] *Institute of Construction and Transportation Engineering & Management, Transport Section, Cracow University of Technology, Cracow, Poland*

Abstract: The World Health Organization estimates that road traffic accidents are on the 8th place in the ranking of causes of death of the world's population. In addition, from the point of view of the economy, they generate very large external transportation costs. The term, therefore, changes the number of occurrence of road traffic accidents in specific time periods, will allow a better understanding of this phenomenon and counteract their negative effects. The number of road accidents depends on many parameters like infrastructure, or drivers behavior. Many of these factors is cyclical in nature, i.e. is repeated in certain intervals. To identify the cyclical component spectral analysis will be used on data obtained from three time intervals: monthly, weekly and daily. The time series from the point of view of stationarity will be reviewed. On this basis the model will be built as a sum of trigonometric functions that describe the changes of the time series, the result of the influence of the cyclical factor. Individual harmonics of the high level of amplitude will substantially explain the variability of this series.

Keywords: identification of cyclicity, spectral analysis, stationarity of the time series, periodogram.

1. Introduction and background

Modern societies cannot function without transport which, in turn, causes obvious problems such as traffic accidents, pollution, and noise (Stoupel et al., 2009). Road accident data analysis plays an important role in identifying key factors associated with road accidents. Once the road accident factors are identified, the proper actions can be taken to overcome the accident rate. These factors help in taking preventive measures to overcome the road accidents. In work (Ceausu and Desprès, 2006) they presents a system, which explains the method of accidents analysis. The analysis is carried out in order to recognize within accident reports general mechanisms of road accidents that represent prototypes of road accidents. This can be achieved through proper use of the data mining. Data mining techniques do not require certain assumptions between dependent and independent variables which are required in traditional statistical techniques (Chen and Jovanis, 2002; Więcek et al., 2014).
One of the factors that can explain the variability in the number of accidents occurring in time is cyclicity. The cyclical component can be determined using spectral analysis. Spectral analysis is not widely used in the field of transport and logistics, best in events lasting more than one year. However, there are some attempts to use this method in traffic. Due to the fact that phenomena in transport are relatively fast and with high frequency, it is possible to allocate the cyclical changes in it occurring from time to time. Parry with her colleagues worked on traffic periodicity in a short term (Perry et al., 2013). In (Levine et al., 1995), they identified weekly pattern in motor vehicle accidents. In turn, (Zhang et al., 2014) built a hybrid short-term traffic flow forecasting method based on spectral analysis. There is a lack of works that use spectral analysis tool to determine the cyclical component in the field of transport.

2. Data preparation

The main purpose of spectral analysis is to draw attention to the cyclical processes. It involves the wave structure of the waveform variables stochastic processes which allows to analyze the spectrum in frequency domain. This is possible through the use of trigonometric functions sine and cosine, often called harmonics. The magnitude of harmonics for *n* observations is *n*/2. First harmonic has a period equal to *n*, the second *n*/2, one in *n*/3, etc.
Spectral analysis allows to reveal cyclic fluctuations in the data contained in the time series. Thus, there is the ability to determine the cyclical changes that occur in a certain period of time. A necessary condition for using spectral analysis is to have a relatively large amounts of data. The more data, the more likely it is to find a cyclicity in the analyzed time series.
At the initial stage of work it is necessary to check whether a time series is stationary. In order to study the stationarity of the data the advanced Dickey Fuller test was used. It is the other name for unit root test account for possible autocorrelation of the random component (ADF) (Dickey and Fuller, 1979). If the series is nonstationary, it comes down to stationarity by calculating successive differences: $\Delta y_t = y_t - y_{t-1}$. If the time series is still nonstationary, this process is repeated until it reaches stationarity.
Calculations were made using data for the period from 1 January 2012 to 31 December 2015. For the detection of cyclicity in different periods of time, the data recorded for each day was divided into three groups: the monthly period for four years, weekly, in the period from 1 December 2014 to 31 December 2015 and daily from 14 November to 31 December 2015. Each of the studied periods has 44 recorded observation, which will allow to optimize the calculation process. The calculations for weeks and days in the whole research period is not required, as old data affect the explanation of the studied time series in the slightest degree.

[1] Corresponding author: dgrzesica@pk.edu.pl

3. Methodology

3.1. Stationarity of the time series

For data from three time periods was conducted a comprehensive Augmented Dickey Fuller stationarity test to determine the degree of integration of the series. The conclusion was made for a significance level of p=0.05. In this case, the p-value is less than 0.05, evidence of stationarity of time series (Fig. 1).

Fig. 1.
Stationary and nonstationary data in three studied time periods
Source: own elaboration

Monthly and daily time series is close to stationarity, so it’s no need to be differentiate, and the weekly time series is nonstationary. After differentiation it has been brought to stationarity.

3.2. Periodogram in spectral analysis

To detect the occurrence of cyclical component in the studied time series describing the number of road accidents it is possible to use a periodogram. It is used as an estimator with spectral analysis. Effective mainly for the function is clearly periodic. In the periodogram the value of density spectrum increases as the sum of sine and cosine waves. The frequency of these waves is a multiple of the inverse of the length of the analyzed series. Periodogram shows the proportion of the total variance of the sum of harmonic oscillations at the frequencies contained in the interval (ω, $\omega+\Delta\omega$). Periodograms for the individual time intervals is represented in Fig. 2.

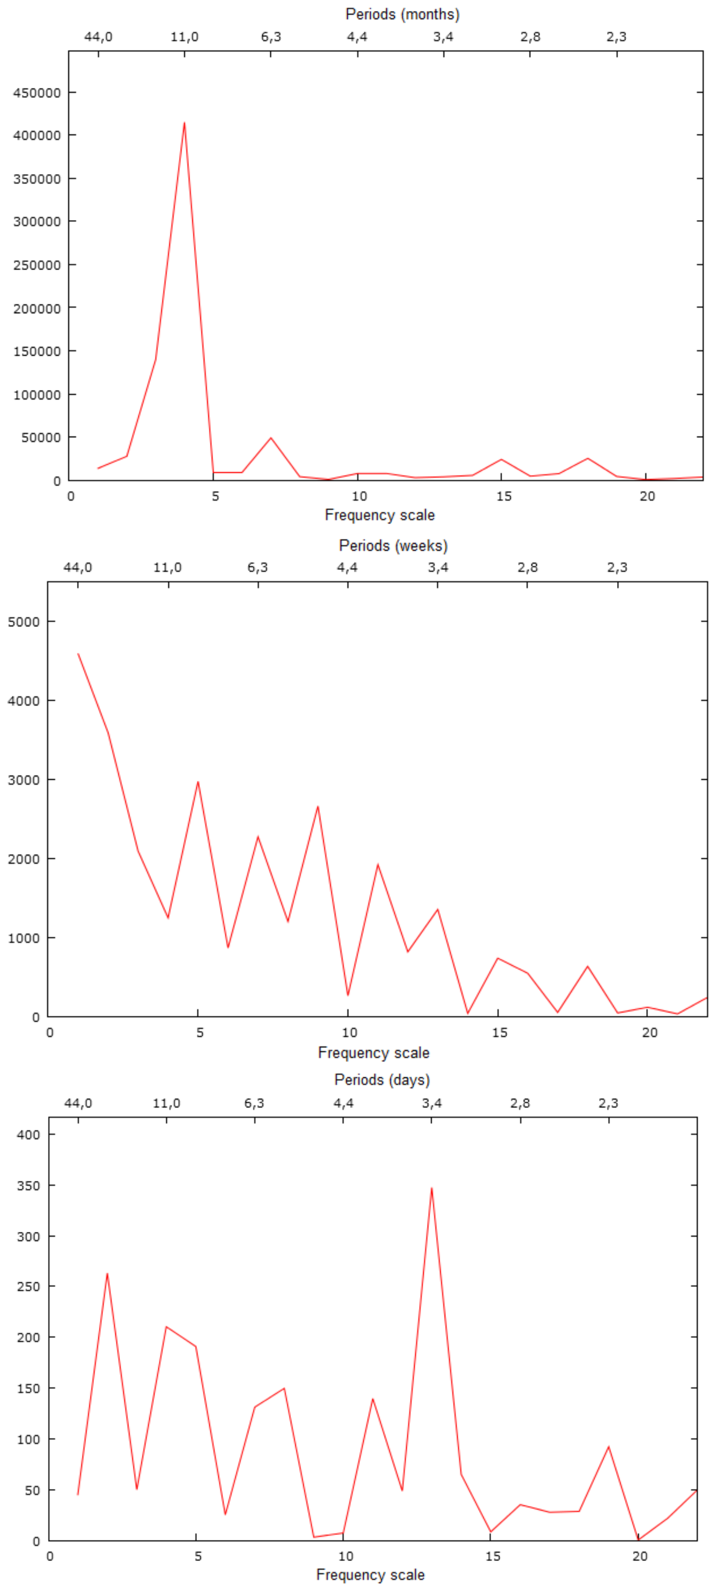

Fig. 2.
Periodograms for three studied periods
Source: own elaboration

As seen on the periodograms in each time period there are large fluctuations, which means that the time series is characterized by frequency variation. During monthly there is one big loop, while in others there are much more of them. In this position we can conclude that the series contain cycles, which appear from time to time.

3.3. Spectral analysis model to identify the cyclical nature of time series

Spectral analysis model is constructed as the sum of harmonics, i.e. the functions sine and the cosine of the specified period. The quantity of all harmonics is *n*/2. After elimination of trend by the differentiation method is required to estimate the model parameters α_0, α_i, and β_i:

$$y_t = \alpha_0 + \sum_{i=1}^{n/2} \left(\alpha_i \sin\left(\frac{2\pi}{n} \cdot i \cdot t\right) + \beta_i \cos\left(\frac{2\pi}{n} \cdot i \cdot t\right) \right) \tag{1}$$

Parameters are estimated by the least squares method using the formulas:

$$a_0 = \frac{1}{n} \sum_{t=1}^{n} y_t \tag{2}$$

$$a_i = \frac{2}{n} \sum_{t=1}^{n} y_t \cdot \sin\left(\frac{2\pi}{n} \cdot i \cdot t\right), \text{for } i = 1, \ldots, \frac{n}{2} - 1, \tag{3}$$

$$b_i = \frac{2}{n} \sum_{t=1}^{n} y_t \cdot \cos\left(\frac{2\pi}{n} \cdot i \cdot t\right), \text{for } i = 1, \ldots, \frac{n}{2} - 1, \tag{4}$$

The longer time series, the greater number of harmonics which can be define. Most often there is no need of considering all possible harmonics. Uses those which are involved in the explanation of the variance of the applicants variable. This contribution can be determined from the formula:

$$\omega_i = \frac{c_i^2}{2s^2} \tag{5}$$

while for the last one:

$$\omega_i = \frac{c_i^2}{s^2} \tag{6}$$

where:

$$c_i^2 = a_i^2 + b_i^2, \tag{7}$$

s^2 – is the estimate of variance considered variable.

4. Results

4.1. Identification of cyclicity in time series

For the adopted assumptions, harmonics were extracted, which most explain the cyclical fluctuations in the studied time series. The number of harmonics and percentage in order from the biggest to the smallest cyclic changes are presented in Table 1.

Table 1
Review of a harmonics in the studied time periods

Time period	No. of selected harmonics [-]	Percentage in explaining cyclicity [%]	Summary percentage [%]	Time period	No. of selected harmonics [-]	Percentage in explaining cyclicity [%]	Summary percentage [%]
Monthly	4	76.55	76.55	**Daily**	13	18.1	74.77
Weekly	1	16.31	71.42		2	13.7	
	2	12.75			4	11	
	5	10.57			5	10	
	9	9.46			8	7.8	
	7	8.08			11	7.3	
	3	7.43			7	6.8	
	11	6.82					

Source: own elaboration

On the basis of the summary percentage of variability explanation of frequency domain shows that the clearest cyclicity dominates on a monthly basis, up to 76.55%. The rest harmonics participate in the explanations below the 3.6%, so they were not included. Another is the variability of the daily cost is equal to total 74.77% (the highest value harmonic is 18.1%) and weekly equal to 71.42% (the highest value harmonic is 16.31%).

From Table 1 it is seen that in the monthly periods, the cyclical occurrence of road accidents has a period of twelve months. This means that the number of accidents each year has a periodic pattern of changes.

4.2. Models based on the cyclical changes in road accidents

For making models the harmonics from table 1 were used. They have the greatest impact on the explanation of the time series. For the monthly period of time the data remain stationary. The model can be created by using the formula:

$$y = 2568{,}16 - 495{,}636 * sin(2 * \pi/44 * 4 * t) - 246{,}223 * cos(2 * \pi/44 * 4 * t) \quad (8)$$

The model is quite simple as it contains only one harmonic, which explains the changes recurring in more than 76 %. On the basis of the formula (8) you can create a course explaining changes in the number of accidents on a monthly cyclicity (Fig. 3).

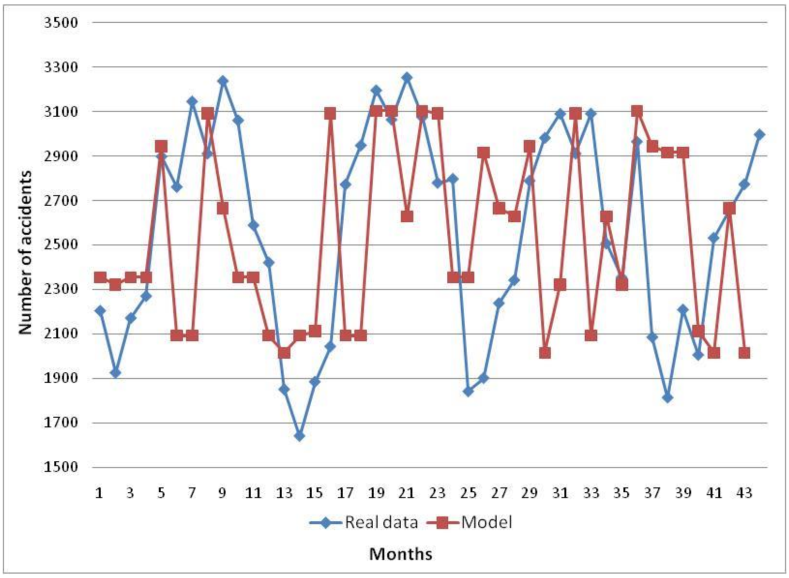

Fig. 3.
Model based on monthly cyclicity
Source: own elaboration

The correctness of the developed model is confirmed by measuring compliance, called the coefficient of determination. For the presented model it is 0.72. This indicates the strong adjustment of the linear regression model for real data.
The model takes into account the trend for weekly cyclicity will be created on the basis of the formula:

$$y_t = f(x) + \sum_{i=1}^{n/2} \left(\alpha_i \sin\left(\frac{2\pi}{n} \cdot i \cdot t\right) + \beta_i \cos\left(\frac{2\pi}{n} \cdot i \cdot t\right) \right) \quad (9)$$

where:
f(x) –trend function.

The obtained model can be formulated as follow:

$$y = 2{,}5484 * t + 517{,}21 - 36{,}33 * sin(2 * \pi/44 * t) + 36{,}02 * cos(2 * \pi/44 * t) + 27{,}12 * sin(2 * \pi/44 * 2 * t) + 36{,}22 * cos(2 * \pi/44 * 2 * t) + 32{,}96 * sin(2 * \pi/44 * 3 * t) + 10{,}33 * cos(2 * \pi/44 * 3 * t) + 37{,}34 * sin(2 * \pi/44 * 5 * t) - 17{,}38 * cos(2 * \pi/44 * 5 * t) + 0{,}6 * sin(2 * \pi/44 * 7 * t) - 36 * cos(2 * \pi/44 * 7 * t) - 7{,}2 * sin(2 * \pi/44 * 9 * t) - 38{,}3 * cos(2 * \pi/44 * 9 * t) - 33{,}07 * sin(2 * \pi/44 * 11 * t) + 1{,}21 * cos(2 * \pi/44 * 11 * t) \quad (10)$$

The model together with the actual data is shown in Fig. 4

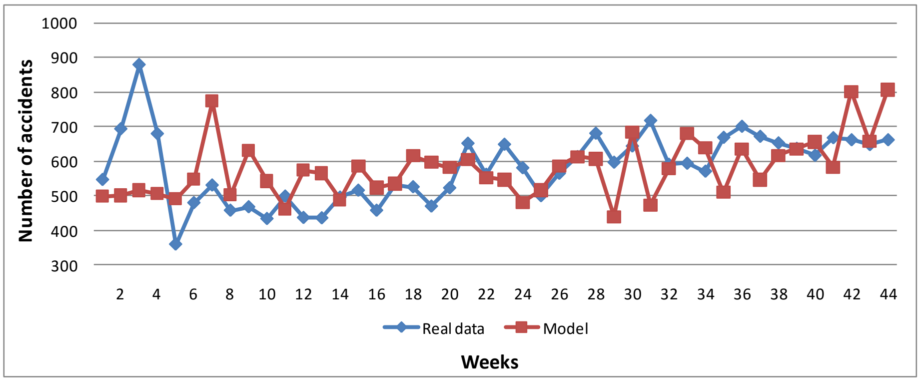

Fig. 4.
Model based on weekly cyclicity
Source: own elaboration

Measuring compliance for this model is 0.71.
For daily cyclicity model can be formulated as follow:

$$y = 91{,}522 - 12{,}2525 * sin(2 * \pi/44t) - 0{,}3824 * cos(2 * \pi/44 * t) - 10{,}033 * sin(2 * \pi/44 * 4 * t) + 26{,}6 * cos(2 * \pi/44 * 4 * t) + 0{,}0435 * sin(2 * \pi/44 * 5 * t) + 10{,}44 * cos(2 * \pi/44 * 5 * t) - 6{,}01 * sin(2 * \pi/44 * 7 * t) + 6{,}227 * cos(2 * \pi/44 * 7 * t) - 9{,}118 * sin(2 * \pi/44 * 8 * t) + 1{,}532 * cos(2 * \pi/44 * 8 * t) - 2{,}591 * sin(2 * \pi/44 * 11 * t) + 8{,}5455 * cos(2 * \pi/44 * 11 * t) - 8{,}025 * sin(2 * \pi/44 * 13 * t) + 11{,}577 * cos(2 * \pi/44 * 13 * t) \quad (11)$$

The model together with the real data shown in Fig. 5.

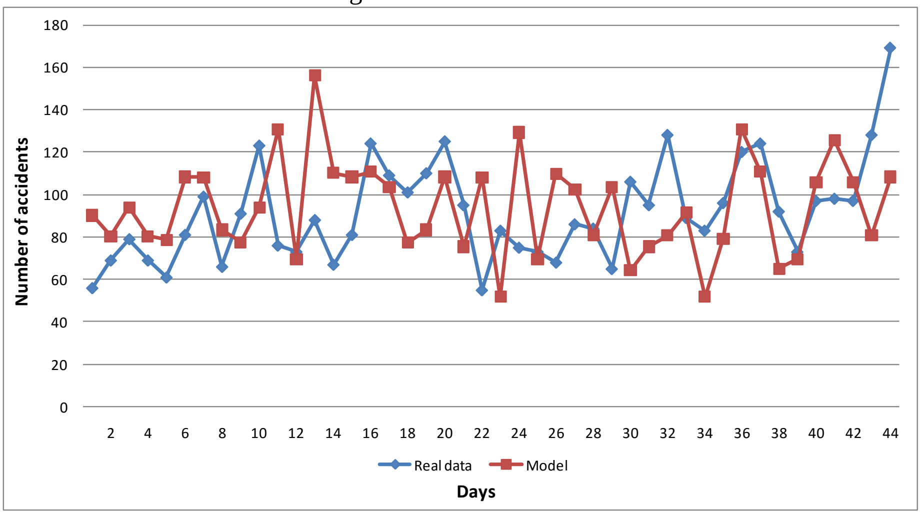

Fig. 5.
Model based on daily cyclicity
Source: own elaboration

Measuring compliance for this model is 0,89.
From the three investigated types of cyclicity, the model is best suited for daily data. This implies that diurnal cyclicity is the most powerful. The rest, monthly and weekly, have similar measuring compliance at the level of 0.71.

5. Conclusions

Method of spectral analysis was used to study cyclicity of the occurrence of road accidents. Using this technique, you can easily determine the amplitude of the time series, i.e. the harmonics. Investigated were three periods of time: monthly, weekly and daily. From the conducted research it follows that one harmonic in 76.55 % explains the cyclical changes in the series. In other cases, the level of explanation cyclicity is slightly less, but for its explanation it is necessary to use 7 and 6 harmonics. Based on them models were built to determine changes in the number of road accidents. Comparing the cumulative percentage of explanation of the existence of cyclicity with the measure of association shows that it is biggest for daily periods.
Spectral analysis is used for long periods, longer than a year, however, finds application in the study of daily variables. It can help to identify the cyclical changes in the magnitude of road accidents and, consequently, respond accordingly in order to reduce the number of their occurrence.

MODELLING OF INTRA PLANT TRANSPORTATION SYSTEM USING AGV

Hana Neradilova[1], Gabriel Fedorko[2], Viktoria Borsosova[3]
[1] College of Logistics Prerov, Palackeho 25, 750 02 Prerov, Czech Republic
[2,3] Technical University of Kosice, Letna 9, 040 01 Kosice, Slovakia

Abstract: AGV are currently being used in important industrial companies to ensure supplying and to ensure the functioning of interoperable transport and shipping finished products. Increasingly they replace conventional transportation technologies. In the contribution it will be described a creation of a simulation model of supplying assembly lines using AGV in Tecnomatix Plant Simulation software. For very accurate approximation to reality the method of complementary programming in language SimTalk was used within the model creation. The presented model allows to analyse the utilization of individual workplaces and to verify the process of material supply. The simulation model was created for the purpose of analyzing logistic processes in a company.

Keywords: AGV, simulation, analysis, transport, supply.

1. Introduction

Automated logistics systems represent a comprehensive solution of automation within the enterprise logistics in different industrial sectors. The objective of deploying automated logistics systems is to increase the efficiency of individual logistic operations (Tomkova et al., 2015). Onset of automation is visible already for a longer time especially in the automotive industry for assembly lines, but also in warehouses and distribution centres. Currently harder and harder market environment and constantly resurgent competition are a challenge for designing and modelling of reliable, safe and flexible manufacturing processes, operations and workplaces. Industrial automation and robotization are no longer only fancy trend but a necessity with a view to increasing the efficiency of establishments, departments, technologies and processes. Designing and projecting of AGV systems is not easy task. Mastering this task requires a wide range of knowledge. Fazlollahtabar (Fazlollahtabar, 2016) dealt with the draft of parallel automated line for the production of different products. He considered AGV system with auto-guided for their supplying. When planning a travel route the main problem was the time schedule of each operation. AGV systems are used for carrying loads of different sizes. Use AGV system within the container terminal is described in the paper Research on scheduling problem of multi-load AGV at automated container terminal (Huo et al, 2016). In the paper he describes the use of genetic algorithm method. The issue of time planning of freight distribution is another from problem areas, which is currently the object of research in connection with the AGV. Wang and Zhou devoted themselves to these issues. They dealt with issues of AGV operation planning in flexible manufacturing systems (Wang and Zhou, 2016). Further work dedicated to AGV operation planning is Multi AGV scheduling problem in automated container terminal by authors and Jin and Zhang (Jin and Zhang, 2016). At present, each AGV systems have various methods of guidance on transport routes. One possibility is e.g. usage of a camera for motion control as it is presented in the work of Ishizuka and Hidaka. AGV is currently one of the leading areas of research in the field of logistics. Kumar further discusses this fact at all. As part of their contribution there is more detailed description of computer simulation method as the main comparative tool for research on the properties of different variants of AGV systems (Kumar et al, 2015).

2. Characteristics of automated logistics systems

Automated logistics systems resulting from long-term pressure to improve and accelerate the services provided in the field of logistics. The manufacturing process of the products and their distribution to the ultimate consumer, it is constantly improving, accelerating and automation is one of the tools to achieve the specific requirements. Automation process touches directly or marginally e.g. material handling, supplying, and consequently it affects the quality, continuity and efficiency of the entire logistics process. In general, automated transport logistics systems can be divided into two basic groups:

- Conveyor systems,
- Automated control systems of transport vehicles and material handling vehicles.

2.1. Conveyor systems

Conveyor systems are widely used within logistics (Ficzere et al., 2014). They can be used e.g. for handling and transport of pallets between automated warehouse stacker and off-load places. The system may comprise conveyors, either the roller or chain and the other additional equipment such as a hoist, rotary drives, transfer stations, automatic tractors and warehouse pallet stackers (Szendrő and Török, 2014). All operations are automated and software controlled to minimize time and maximize operational efficiency of the storage process (http://www.mecalux.sk/automaticky-sklad-palety/zakladac).

[1] Corresponding author: hana.neradilova@vslg.cz

Conveyor systems for boxes (Fig. 1) provide automated transport within individual work places thereby increasing the efficiency of handling crates or boxes during storing and delivering from warehouse.

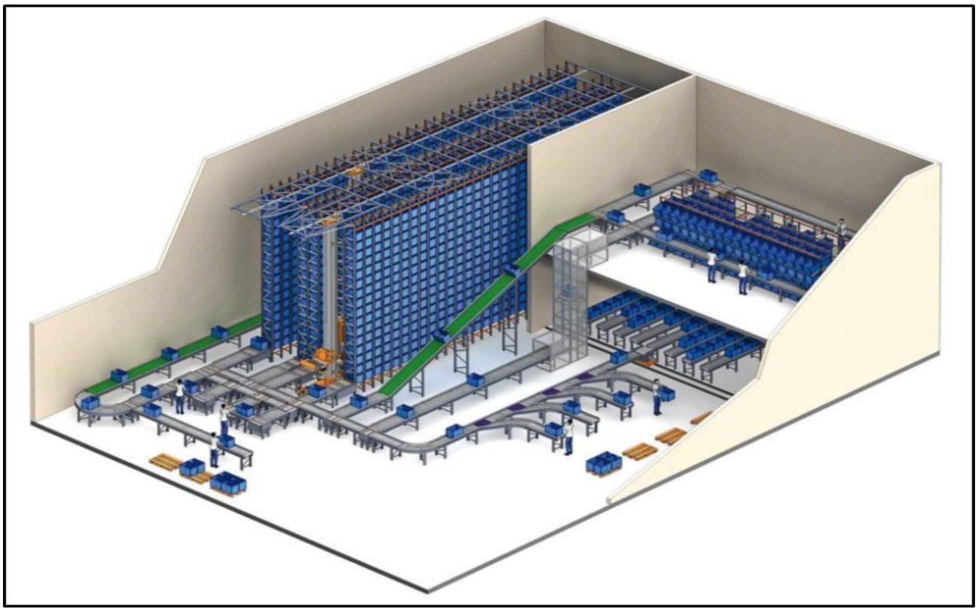

Fig. 1.
Conveyor system for boxes
Source:https://encryptedtbn2.gstatic.com/images?q=tbn:ANd9GcRI7qlwXTn_6tgdPcVsEKhwW8Lj-WKBgLDdlCer1Br541UMhdTvVA

2.2. Automated control systems of transport vehicles and material handling vehicles

Automated guided systems for vehicles can be classified as a developed and dynamic sphere within the handling of goods. Years of development have enabled the progress in guiding vehicles by laser or other principles. Technological development has increased flexibility, application diversity and the ability of automated guided systems of vehicles.
System AGV **-** automated guided vehicle (AGV) **-** the unmanned autonomous device, which moves for example on the predetermined path. The movement is controlled by a combination of software and guidance systems, and it follows that the devices do not require human intervention. The most common use of AGV system is in companies where handling the large amount of materials in production halls or warehouses. Cargo is usually transported in trailers that are in the coupling (Fig. 2), (Ullrich, 2015).

Fig. 2.
A sample of AGV system with coupled trailers
Source: http://ceittechinnovation.eu/index.php/sk/agv-system

Currently AGV systems are popular and recorded a significant rise, as not only simplify and facilitate material handling, but its independence improve efficiency and reduce the cost of human operators in logistics. AGV are vehicles designed for handling materials and products inside a company, they save time, energy and space within the enterprise logistics. Vehicles can communicate with other robots or with other automation systems to ensure smooth handling of material (Štusek, 2007).

2.2.1. Basic parts of AGV system

Basic parts of AGV system are shown in the following diagram (Fig. 3).

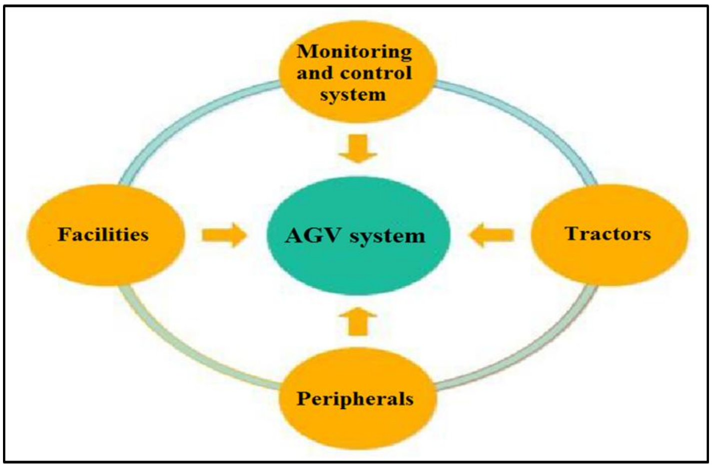

Fig. 3.
Basic parts of AGV system
Source: Authors

AGV tractors
Automatic tractors are ranked among the standard equipment for AGV systems, which are used to transport material. The devices are usable in every sector of industry and the only condition for their use is an existence of industrial poured floors on which surface the AGV move. Tractor allows distribution of goods in the logistic flow through various peripherals on basis of connection method (http://ceittechinnovation.eu/index.php/sk/agv-system).

AGV peripherals
AGV peripherals represent drawn transport equipment behind a tow bar of automatic tractors that enhance flexible logistics system complexity. Among AGV peripherals is possible to include conventional models of wagons, assemblers, conveyors and their modified versions. Selection of peripherals is influenced by the type of transported material or transported unit (http://ceittechinnovation.eu/index.php/sk/agv-system).

Facilities - Navigation systems
For solving navigation systems can be used the following options (Ullrich, 2015):

- Inertial or gyroscopic navigation - allows a computer to determine the direction and give orders to vehicles,
- Guidance tapes - for determining guide path are used tapes, which can be of two types - coloured or magnetic,
- Guideline in the floor - the wires are located several centimetres below the floor surface and conduct a full length of the route along which a tractor is moving,
- Laser navigation - a form of wireless navigation using reflective materials placed on poles, shelves, walls and equipment,
- GPS navigation – the global positioning system is ideal for outdoor use vehicles. One condition for the correct GPS is line of sight between the satellite antenna and antenna receiver on the vehicle to capture the radio signal.

Monitoring and control system
Monitoring and control system plays a key role in integrating the AGV system with its surroundings. This involves advanced hardware-software product that is used for tracking, managing, monitoring automatically guided vehicles and their peripherals and the continuous collection and evaluation of information about the system (Molnar, 2012). Mutual communication between logistics equipment and the system is provided by radio or Wi-Fi signal. Obtained information about the system are processed and transferred into a user-friendly form, usually into a graphic form. The user has the ability to change system elements through this system (http://ceittechinnovation.eu/index.php/sk/agv-system)

2.2.2. AGV categories

AGV systems categorization and division is not easy to implement, because their development constantly follows current trends in logistics. Nevertheless, one option AGV categorization is by Ullrich (Ullrich, 2015).

- Forklift AGVs – their range of use is very wide. Logistical tasks performed by this type of AGV can be simple or very complex. They are designed for handling with standard pallets, special pallets or compatible containers,

- Piggyback AGVs – vehicles allow manipulation of conventional transport units such as pallets, containers or cages, but they are not able to pick up the units directly from the floor. Transport units are required to be lifted and loaded by other device typically to the height of 60 cm,
- Towing vehicle – it allows perform simple movements there and back. When it comes to destination, it will stop and wait for employees to exchange trailers. The vehicle itself serves only to towing,
- Underride AGVs – are specialized in transporting roller carts and roller containers by lifting them up and moving. This type is widely used in hospitals,
- Assembly AGVs – are applied in serial assembly, supporting structure carries the assembly object and assembly process is done directly on the AGV system. Driving speed is extremely low,
- Heavy load AGVs – are used either in the production or processing of paper, steel and in automotive industry and they are used for the transport of steel coils, large paper roll, etc,
- Mini AGVs – small, smart and flexible vehicle that is capable of performing tasks quickly. Vehicles should be able to mutually cooperate and execute an intended task. They have greatest use in assembling shipments to customers, finding and collecting goods in storage areas,
- PeopleMover AGVs – are used to transport passengers, they are mostly used in outdoor areas, or in public areas,
- Diesel AGVs – this category includes vehicles used in outdoor areas to transport materials in larger masses. The outdoor use allows utilization of the drive,
- Special design AGVs – are vehicles designed for special projects and vehicles, which cannot be classified in the previous categories.

3. Creation of a simulation model of automated transportation system

As it was mentioned in the introduction, one of the effective methods for analysis and research of AGV systems is a computer simulation method (Strohmandl, 2014). Its use will be presented with a simple example. To create a simulation model of automated transportation system was chosen simulation program for creating models of production processes and management strategies Tecnomatix Plant Simulation.
Primary in creating a simulation model was the placement of individual workplaces and warehouse and determining the route on which logistic trains will run (Fig. 4, Fig. 5). The analyzed company is focused on production and assembly of small parts, which has its own warehouse of input material with regular orders from external suppliers. Production and assembly take place in the same hall in which five automated workplaces are stationed. Material flow within the manufacturing and assembly hall is provided by set of vehicles on circular route that connect all departments. Basic components are sequentially processed in various manufacturing or assembly processes such as shaping, stamping, trimming, varnish and so on. Conveyor belts are used in the three workplaces to ensure automated component handling for assembly machines. After a one-way circular route there are 11 stations, which provides the necessary loading or unloading of the various components transported in transportation units.

3.1. Creation of moveable units

The moveable units are active logistic elements, which are getting into motion within the simulation model. Therefore, an important step in creating the model is to define all moveable units including all trailers and tractor units, transportation units and transported material itself. Moveable units differ in the name as well as in their predefined attributes that are set individually by double-clicking on the item. In addition to size of units, also capacity of trailers and transportation units are set.

3.2. Creation of workplaces

Each workstation represents a new and hierarchically arranged unit within the simulation model. Warehouse of components is the first stop for set of vehicles. Based on the assumption that the firm receives necessary components to the store at regular intervals, warehouse of components by using blocks "Source" generates all the necessary materials, components for the production of finished product at regular intervals, this means that during the simulation is never any shortage of these components.
Block "Assembly" allows to load into the transport unit as many components as many is defined in it. Also the information is needed about which connector goes the main movable unit through and the material should be loaded on. "Transfer Station" is the key block for loading and unloading. It determines place from where to where the material is transported, what type of material, and which tractor will perform the activity. Empty transport units removed from some workplaces on trucks are unloaded in the warehouse where they exit the simulation model over the block "Drain" (Fig. 6).

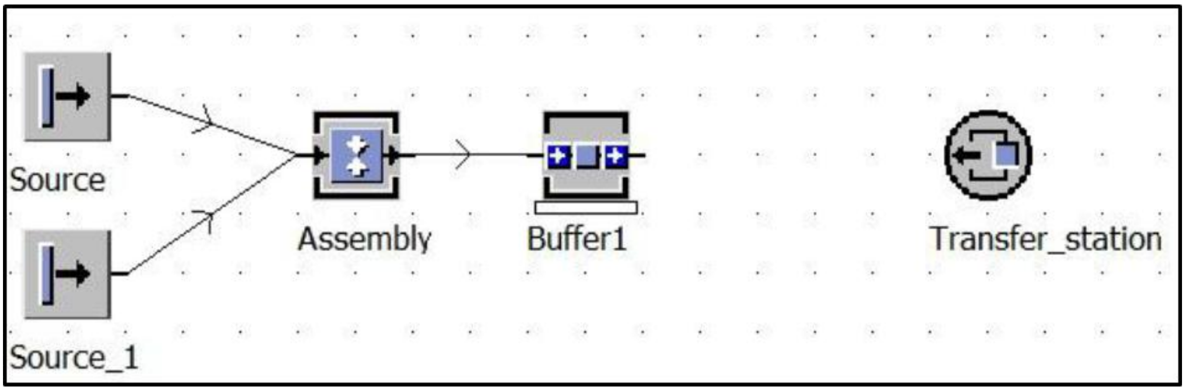

Fig. 6.
The basic model structure of component storage
Source: Authors

Warehouse of components generates 6 kinds of components representing 6 blocks "Source" for components and also 6 transport units so it means further 6 blocks "Source" for generating transport units. As it was mentioned, the production and assembly include 5 automated workstations (Table 1).

Workstation 1 follows immediately after the warehouse on the circular route and there are unloaded two different types of components in the transportation units. After unloading the components are discharged from transport units into the containers. At the workplace no.1 the components are assembled in two assembly machines. Semi-finished products made by connecting are gathered in the stock bin "Buffer", re-loaded into the transport units and waiting for loading due to relocation to the place of further processing it means to the Workstation 3. Empty transport units are transported back to the store.
Workstation 2 is identical to the Workstation 1 in the composition and operation of the processes. The difference is in using another kind of components from the warehouse and installation of components is carried out by only one assembly machine. The outputs from the Workstation 2 are semi-finished products intended for further processing at the Workstation 6 (the finishing workstation).
Workstation 3 - the first step is again unloading the material by using "Transfer Station". Along the Workstation are three stops, at the first stop one type of components is put out in transport units, the components after unloaded from crates moving on a conveyor belt. In the Workstation 3 there are three conveyor belts 7 metres long that connect the place of unloading material with two machines, in the simulation model these are blocks "SingleProc“ that carry out the necessary adjustment of input components. At the end of the last conveyor belt adjusted component joins the semi-finished product from Workstation 1, which is unloaded at the second stop. Transport units, in which the components were brought, are moved by transport truck to the endpoint of Workstation 3, where adjusted components waiting for loading and displacement at the Workstation 4.
Workstation 4 is identical to the Workstation 3 in the composition and operation of the processes, unlike workstation 3 it has four conveyor belts that connect all processes at workstation as well together with the loading. The workstation is supplied with input material from the warehouse and after adjustment is connected with an output semi-manufacture from Workstation 3. From the loading place the products are moved to Workstation 6.
Workstation 5 is the last workplace where the semi-manufactures sequentially formed on the previous workstations are joined and at the end a finished product is produced. After the last process which is the varnishing, the products are loaded into the transport units and exiting the simulation model.
The aim of creating workstations was to create the necessary links for the proper functioning of the manufacturing and assembly processes. Also the parameters were set for the simulation experiments, which remained constant during the simulation experiments.

Table 1
Summary of workstations

Workstation	Process	Duration (sec)	Machines (number)	Loading/Discharge (sec)
Workstation 1	assembly	30	2	5
Workstation 2	assembly	18	1	5
Workstation 3	trimming	15	1	5
	shaping	15	1	5
	assembly	10	1	5
Workstation 4	cut-out	15	1	5
	stamping	15	1	5
	assembly	10	1	5
Workstation 5	assembly	15	1	5
	varnish	10	1	5

Source: Authors

The aim of creating the simulation model was to define all necessary moveable units and set their attributes, to allocate workplaces in which were created the necessary relations for the proper functioning of the production process, to define circular route and to form set of trailers. The outcome is a functional simulation model that simulates a work shift for the time of 8 hours.

4. The use of a simulation model of automated transportation system

One of the main efforts of the company is to achieve maximal smoothness and synchronization of logistics and production processes. The automatic transport system is one way to do this. For monitoring and improvements of the simulation model was carried out several simulation experiments. After setting the amount of stocks and storage capacity has been launched and pursued a simulation model that after 8 hours of work produced 1,360 pieces of finished products. The monitored model showed no errors during the simulation time and after simulating 8-hour work shift was successfully completed. The effort in creating the model was to determine the optimal amount of inventory for all departments in order not to create unnecessary untapped stocks in the workplaces and at the same time ensure the continuity of production processes. The result of running the simulation model has been the finding that the amount of inventory that was defined when creating the simulation model is too large. The following figure (Fig. 7) shows the state at the Workstation 1 after 8-hour work shift.

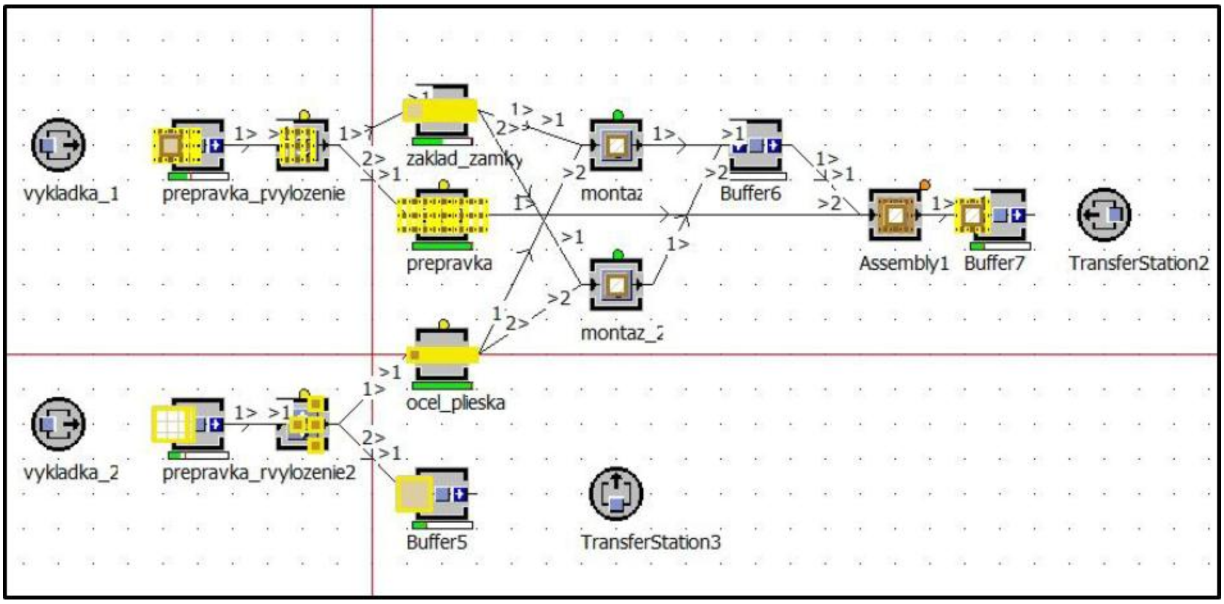

Fig. 7.
State at the Workstation 1 after 8-hour work shift
Source: Authors

The Workstation 1 is an important link throughout the manufacturing process, which affects the proper and smooth functioning of other departments. Sankey diagram (Fig. 8) shows the process of material flow of output components from Workstation 1 to other departments. The thickness of the line represents the volume of material for each time point and the length of line represents the distance of transport.

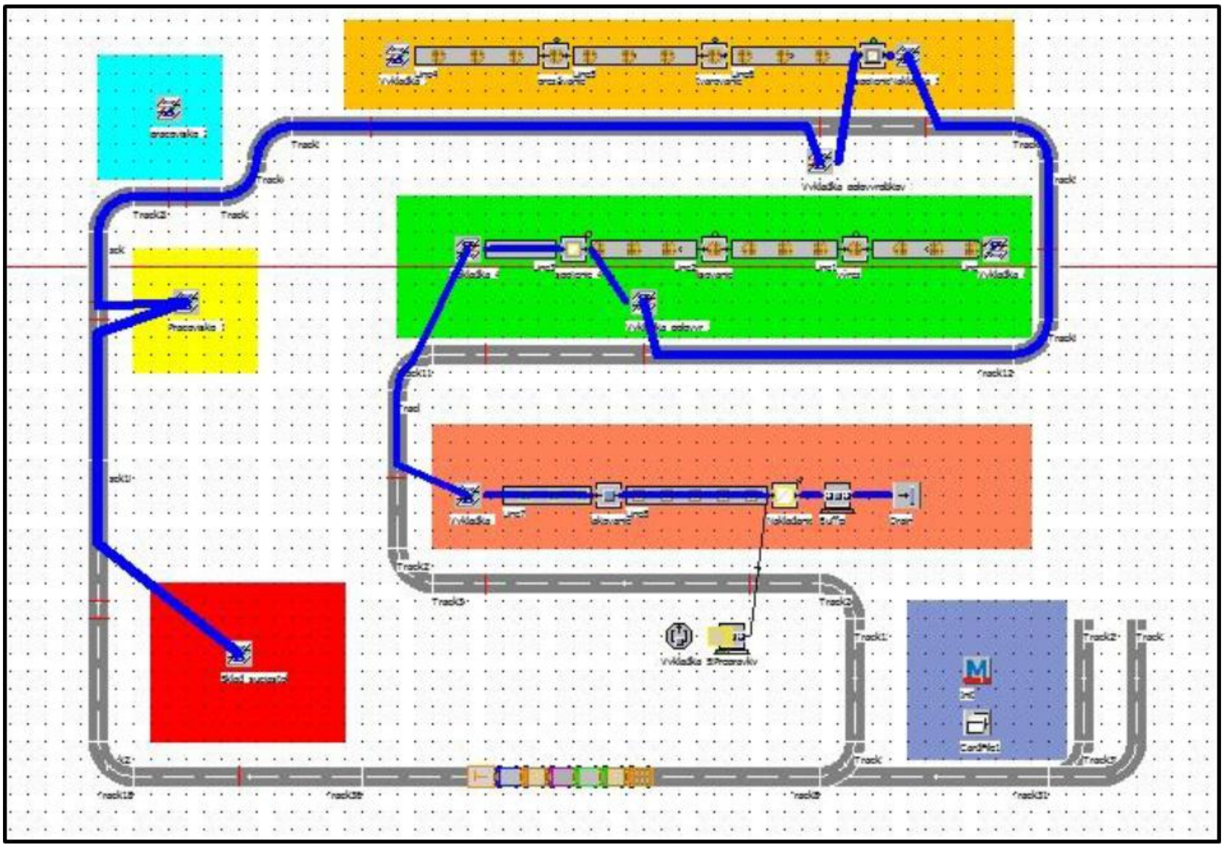

Fig. 8.
Sankey diagram of the material flow of output components from Workstation 1
Source: Authors

Four simulation experiments were carried out, which should serve to improve the simulation model and to improve processes within the monitored workplaces.

The simulation experiment no. 1 concerned the changes in the volume of input stocks in the Workstation 1. The monitored simulation model showed a large amount of unnecessary supplies at Workstation 1. The aim of the experiment no. 1 was to reduce these stocks by adjusting the imported quantity and also the capacities of respective storage containers were adapted. These changes contributed to increasing regularity in delivery of output components from Workstation 1, which affect the continuity of the functioning of other workplaces. The simulation experiment no. 1 was considered successful, it means, the changes were applied to the simulation model.
The simulation experiment no. 2 was aimed to reduce the speed of the conveyor belts at Workstation 3. The experiment no. 2 was focused on monitoring the performance of the model at a reduced speed of conveyor belts at the Workplace 3, as the performance graphs showed blocking the belts. Prerequisite for changes in the speed of conveyor belts was to harmonize interrelated processes at the workplace. Experiment no. 2 had no affect at the movement of material flow between workplaces and despite of this performed change increased a coherence of activities at Workplace 3. Therefore, the changes were applied to the simulation model.
The simulation experiment no. 3 detected changes at speeds of conveyor belts at the workplace 4. The low performance of the machine at the Workplace 4 was causing excessive accumulation of parts in the container, which weakened the performance of the whole production process. Therefore, another experiment no. 3 was carried out, in order to increase the production of the entire production process by increasing the speed of the conveyor belts at the Workplace 4.
The simulation experiment no. 4 examined the state for the situation when two sets of carriages were created. By creating two sets was shorten the duration of one circular route because one set of trailers did not stop at all workplaces along the circular route, just on those which it supplies. The shortened duration of circular route had affected the continuity of production processes, which has been achieved by improving the simulation model according to the previous simulation experiments no. 1, 2 and 3.

5. Conclusion

The importance of AGV systems within logistics will continue to grow. Their role in maintaining of supply, transport and various service activities will become more and more dominant and irreplaceable. Currently the method of computer simulation has major importance for research and operation of AGV systems. For its successful application, it is needed to create a suitable simulation model and to use the appropriate simulation software. AGV systems operators should however be aware that the importance of computer simulation does not end by launching of the whole system. On the contrary, they should try to use simulation model not only during the regular operation of the entire transport system. This is particularly the verification of various changes in the process of transport, the development of dispatching plans and the performance analysis and capacity utilization of the transport system. In consequence of above-mentioned facts, the computer simulation becomes routine work tool and decision-making tool.

Abstract: This paper presents the possibilities of tracking technologies application in the postal systems. There could be the postal items, vehicles, production tools and employees tracked in the postal system. Based on the tracking object and the way the collected data are used, these technologies could lead to a corresponding efficiency control of the business process and higher quality achievements in the postal company. For the tracking purposes it is possible to use various technologies. In this paper the implementation of Radio Frequency Identification (RFID) is illustrated.

Keywords: tracking, postal technology, efficiency control, RFID.

1. Introduction

The postal network makes a biggest logistic system globally. The traditional postal services have a significant role in the global economy even in the modern society characterized by information technologies. For example, when people communicate and buy through the Internet, goods must be delivered to the purchaser in physical form where a corresponding postal infrastructure is certainly necessary. In this case postal service could be seen as a connection between virtual and physical world.

For decades, national postal operators were the only providers of postal services by keeping a monopoly in this area. However, today's postal market is rapidly transforming to adapt to the modern world market characterized by liberalization, deregulation, globalization and technological progress. In the postal industry, these developments bring increased competition, changed customer behavior as well as a possible reduction in the volumes of shipments. In parallel with these market changes, a substitution by other communication media should be mentioned, as well as increased efficiency standards and requirements for improved performance at all stages of the postal process.

A possible solutions for these challenges is the use of modern technologies in the postal process. One of the mentioned is RFID (Radio Frequency Identification). The introduction of RFID systems in the postal sector can bring significant savings and competitive advantages while enhancing the quality of operations. It is very important to notice that while the costs of prevention and measurements grow then the costs of failure in business or the payment of fees for exceeding the time limits or shipment losses decrease.

Harrop and Holland (2008) in their report estimate that the global market for RFID systems, including tags, in the postal sector will be $2.5 billion in 2018. It could be much bigger if current efforts to tag individual items gain widespread acceptance. In due course, over one trillion postal items will be tagged yearly, making this the second largest application of RFID in the world after the retail supply chain.

In this paper we analyze the possible points in the postal process where RFID technology could bring the higher efficiency and quality. In the second section we first explain the basic concept of RFID technology. Then in the third section we scrutinize the possibilities of RFID implementation in the postal system. These possibilities could be divided in groups depending on what is tracked. In this paper we make the following groups: tracking of postal vehicles, production tools, employees and postal items. Finally, we conclude with the benefits expected by the implementation of RFID technology.

2. RFID technology

Automatic identification, or auto ID for short, is the broad term given to a host of technologies that are used to help machines identify objects. Auto identification is often coupled with automatic data capture. That is, companies want to identify items, capture information about them and somehow get the data into a computer without having employees type it in. The aim of most auto-ID systems is to increase efficiency, reduce data entry errors and free up staff to perform more value-added functions, such as providing customer service. There are a host of technologies that fall under the auto-ID umbrella. These include bar codes, smart cards, voice recognition, some biometric technologies, optical character recognition and radio frequency identification (RFID).

Radio Frequency Identification (RFID) is a generic term for technologies that use radio waves to automatically identify people or objects. There are several methods of identification, but the most common is to store a serial number that identifies a person or object, and perhaps other information, on a microchip that is attached to an antenna (the chip and the antenna together are called an RFID transponder or an RFID tag). The antenna enables the chip to transmit the identification information to a reader. The reader converts the radio waves reflected back from the RFID tag into digital information that can then be passed on to computers that can make use of it.

[1] Corresponding author: libor.svadlenka@upce.cz

RFID system consists of a tag, which is made up of a microchip with an antenna and an interrogator or reader with an antenna. The reader sends out electromagnetic waves. The tag antenna is tuned to receive these waves. A passive RFID tag draws power from field created by the reader and uses it to power the microchip's circuits. The chip then modulates the waves that the tag sends back to the reader and the reader converts the new waves into digital data.
The most common applications of RFID technology are tracking goods in the supply chain, reusable containers, high value tools and other assets and parts moving to a manufacturing production line. RFID is also used for security (including controlling access to buildings and networks) and payment systems that let customers pay for items without using cash. The application in the postal industry is significant as well.
According to research conducted in 2015, the total RFID market is worth $10.1 billion, up from $9.5 billion in 2014 and $8.8 billion in 2013. This includes tags, readers and software/services for RFID cards, labels, fobs and all other form factors, for both passive and active RFID. Forecast predicts rise to $13.2 billion in 2020.

3. RFID in the Postal Sector

It all started with active tags being put in a random sample of postal packages, including letters, from many countries to assess the level of service so cross charges between the postal services of different countries could be equitable. This is still done to this day. However, RFID is now used by postal and courier services for many other purposes.
The potential market for RFID in the postal and courier service is second only to that for the retail supply chain as shown below (Figure 1).

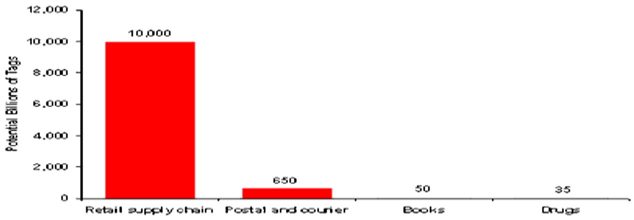

Fig. 1.
Potential global market in billions of RFID tags yearly
(Source: Das and Harrop, 2015)

RFID can facilitate the perfect product recall and postal companies are fitting RFID labels on cases and pallets of consumer packaged goods at retailers, because it increases availability and thus sales and reduces costs, valued at billions of dollars yearly for that industry. RFID is so crucial to the future of courier and postal services that UPS (United Parcel Service) has invested in four RFID companies just to be first to see the future.
The global market for RFID systems, including tags, in this sector will grow extremely rapidly to be $3 billion in 2016 (Figure 2).

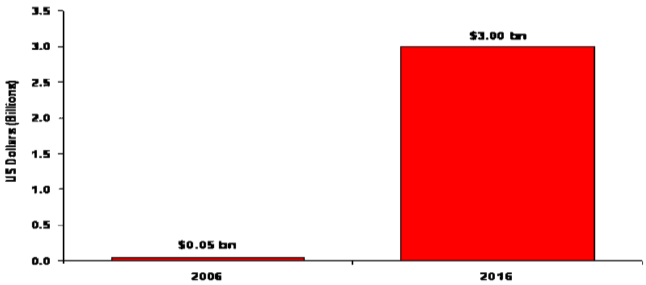

Fig. 2. *The global market for RFID systems*
(Source: Das and Harrop, 2015)

Today, the percentage of tags by value that are active (i.e. with a battery to increase range or manage sensors or encryption) is around 20%. In the postal and courier service the percentage by value is higher because most of the initial work is done on vehicles, trailers and conveyances but that will change. As the really high volume tagging of postal items commences, the percentage of spend on active tags in the postal and courier service will drop to a figure below the average for all RFID. Indeed, the new passive tags with enhanced performance, notably improved range, will take market share from active tags in existing applications. Nonetheless, the market for active tags in the postal and courier service will continue to rise. It will remain a worthwhile and profitable activity for suppliers (Das and Harrop, 2015).
The global market for RFID systems, including tags, in this sector will grow extremely rapidly to be $2.5 billion in 2021. It could be much bigger if current efforts to tag individual items gain widespread acceptance. In due course, over one trillion postal items will be tagged yearly, making this the second largest application of RFID in the world after the retail supply chain. Detailed ten year forecasts are given plus a full explanation of the technologies. In detail, there are over 40 new case studies of RFID in action in the postal and courier service in North America, Europe, the Middle East

and East Asia. The major breakthroughs that will provide future success are discussed. Postal services ignoring this accelerating change will become uncompetitive and suppliers missing out will regret it. RFID is an idea whose time has come in postal, courier and high volume light logistics. In the past, RFID has been used for little more than the evaluation of postal performance, using tags in a small percentage of letters, and the tracking of a small number of conveyances and vehicles. From the International Postal Corporation now monitoring mail flow with RFID in over 50 countries to Saudi Post tagging postal boxes, the big innovations are now happening. Saudi Post and the electronics giants in Korea are among the great innovators in this area. Within Deutsche Post, another RFID innovator, DHL has done successful trials of RFID labelling individual items to improve service and reduce cost and has tested market prices against the possibility of tagging all its one billion items yearly. This is the stuff of competitive advantage.

3.1. Vehicle tracking system

As we mentioned, postal vehicles, as a part of the postal infrastructure, can be covered by tracking technologies. In that sense, an efficient vehicle tracking system is designed and implemented for tracking the movement of any equipped postal vehicle from any location at any time. Purpose of the vehicle tracking system is multiple. The emphasis is on monitoring the characteristics of vehicles which are important for the smooth running of postal flows. Some of these features are vehicle tracking, vehicle's access control and inventory.

Vehicle tracking **-** in the case of vehicles movement between predetermined and fixed destinations it is possible to automate the monitoring of vehicle's movement without human influence. On each vehicle is fixed tag. In the moment of arrival and departure on the destination the reader on a given point writing to tag data of arrival and departure time. When the vehicle is returned to the destination point these data is automatically removed during the passing of the vehicle through the entrance of the building, through the antenna and the reader.

Vehicle's access control **-** means control such as access to a reloading point, access to parking, vehicle identification in the process of refueling, vehicle identification during transport and so on. In the case of controlling parking, RFID tag is placed on the vehicle or on the driver and reader is located at the entrance of the parking space. Arrival of the vehicle causes reading information located in the transponder, processing this information and providing of appropriate command.

Inventory **-** reliable and accurate data on the status, condition and tire positions are one of the most important factors for successful management of operational fleet costs at post offices. The usual situation is that the tires indicate by incision or marks with waterproof markers. Keeping records of each tire, including the place where it is set, date of purchase, date of retreading, amortized cost, etc., is done by manually collecting, typing in the document and the manual data processing. This process is susceptible to errors and possible manipulations. A system for keeping records of tires based on RFID technology consists of the following components:

- Miniature radio frequency tag that has pre-registered the unique ID code of twenty characters. There is no possibility to find the two tags with the same ID code. The tag is fixed to the outer tire, on the side of the tire. Fixing is done by simply pasting flakes over the tag. In this way, each tire is uniquely defined by the ID code. Basic characteristics of the tag is light weight, work in extreme conditions and communication wirelessly with the handheld reader for updating data,
- Handheld reader for automatic collection and storage of data on each tire. ID code from the tag is wirelessly transmitted to a database that is in the handheld reader. For all the tires on one vehicle process takes a few minutes. In addition to the tire's ID codes, there are entered and vehicle's information, driver's information and so on. In the same way collects data of the tires in the warehouse and workshop. Data from the handheld reader is transmitted via the communication to a computer for further processing,
- A computer that enables further processing of data on tires obtained from the handheld reader,
- Software that is installed on computer and uses for the collection, analysis and reporting.

3.2. Production tools monitoring

Controlled delivery and collection of postal items from post boxes **-** using the RFID system it is possible to automate the process of monitoring collection of items from post boxes. On each mailbox a tag with clearly inscribed ID code is placed. Bags for collection are equipped with micro-reader with a memory sufficient for registration and storage of alleged ID codes from tags on the post boxes. A reading of contents from the micro-reader is performed at the place where the items are collected. In this way, automatically is recorded the ID of each post box which was read during the collection of items.

The Wasel project, implemented by the Saudi Post, in an attempt to transform and improve business before privatization and provides the use of smart mailboxes equipped with RFID chip. The role of the chip is to report to the courier equipped with handheld reader whether address is appropriate. Also, the idea of this project is the possibility of elimination of users need to go to the post office when sending items. Instead of that, aim is to perform dispatch through electronic (smart) mailboxes.

After participating in the first phases of an ongoing project using active RFID tags to monitor the performance of Saudi Arabia's postal service, Saudi Post is rolling out RFID based mailboxes for citizens across the kingdom. This rollout is part of an overall IT and service upgrade that includes an active RFID based system to monitor quality at the nation's mail sorting centers.

Each of the 10 million mailboxes that will be installed at homes in Saudi Arabia is fitted with a passive ultrahigh frequency (UHF) EPC Gen 2 RFID tag that uniquely identifies it. Postal carriers employ handheld reader to identify the mailboxes before slipping letters into them (Figure 3). After a letter is inserted into a mailbox, the tag is read once more so that Saudi Post's system can verify when mail was delivered to that particular home. The handhelds, containing GPS and wireless data communication modules, are used to provide real time updates to managers regarding postal carriers' locations and activities.

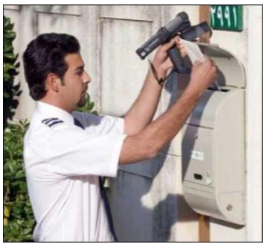

Fig. 3.
Saudi postal carriers with handheld reader

Before the RFID based mailboxes were installed, Saudi citizens picked up their mail at post offices, where they could also take care of banking, the payment of utility bills and other tasks. Homes did not have mailboxes at all, and the country lacked a single, unified addressing system. That limitation has resulted in various entities, such as electric companies or private logistics firms, creating their own grids and zones and utilizing different addressing systems for the same location and, thus, causing confusion and delays for the delivery of packages and mail. To rectify this problem, the government run Saudi Post implemented uniform addresses simultaneous with the planning of the RFID based mailbox project.
To date, millions of steel government owned mailboxes bearing RFID tags have been installed across multiple cities, as part of the so called Wasel project (*wasel* is the Arabic word for "reachable"). The mailboxes, which resemble those widely used in Europe, are attached to the exterior walls of homes and buildings (Figure 4).

Fig. 4.
Saudi Post mailbox with an embedded EPC Gen 2RFID tag

The tags which have 96 bits of programmable memory and function at 915 MHz are embedded in a plastic housing attached to the steel mailbox, manufactured by a local company. The housing keeps the metal from interfering with the tag, and also protects the tags from Saudi Arabia's sand, as well as windstorms and other harsh weather. In addition to providing the intelligent mailboxes at homes, Saudi Post is continuing to offer post office boxes to its citizens. The postal carrier is leaving it up to each individual to decide if he or she wants to use both systems, or to switch completely to home based delivery.
Saudi Post is planning a pilot to use the RFID mailboxes together with bar coded ID numbers printed on mailed items, in order to monitor the performance of the country's mail sorting centers. The monitoring system currently features semi-active RFID tags attached to regular mail test letters.
The letters are mailed from random locations and are tracked at key postal sorting centers. Saudi Post also has three mobile reading systems that can be set up in any facility in which it wants to track mail for quality measurement. Each mobile system contains a special computer that operates as a controller, as well as an interrogator and two units for exciting the tags. The units connect to Saudi Post's main servers via a GSM connection and the carrier moves them around as needed to conduct quality tests.
In the new pilot Saudi Post is utilizing the infrastructure already set up to track a total of 500 bags of secure government mail carrying semi-active tags. The entire system and the tags are provided by Lyngsoe Systems. Each piece of government mail in the sack is printed with a unique ID number in bar code form, enabling Saudi Post to know which items are in a particular bag. As part of the pilot, the mail carrier plans to expand the reader infrastructure to three additional postal sorting centers.
Once the government mail is delivered to the RFID based mailboxes, and after a letter carrier has scanned the mailbox tag, the information will serve as an electronic proof of delivery receipt.

The system's main benefits are its ability to ensure that the correct mail is delivered to the proper mailbox, and to serve as proof of delivery for registered and official government mail. If the test of semi-active tags on sacks of mail becomes an ongoing project and is used together with the RFID based mailbox system, Saudi Post will also be able to track the time required for express home deliveries.

RFID control over roll containers **-** more than 600 RFID portals have been mounted in Swiss Post's postal and logistic centers to give the post complete control over their 70,000 roll container assets and their flow.

Fig. 5.
RFID tag for roll containers

Apart from the RFID tags on the containers, the fully integrated solution also utilizes barcodes and interfaces to other IT systems to provide end-to-end, track-and-trace of containers as well as onboard mail trays. Destination barcodes on mail trays are registered as consignments within individual containers using a unique automated nesting solution.

Swiss Post has a strategic goal of consistently meeting its own ambitious targets for customer satisfaction. Efficiency is the key, making heavy use of container and tray-based automated logistics, to handle:

- 2.4 billion letters,
- 100 million parcels,
- 70,000 roll containers.

Swiss Post has defined its own core values as "reliable", "value-enhancing" and "sustainable." To minimize operational costs, eliminate manual process, improve quality and logistics, it wanted to be able to identify and track all its containers and the items they contain.

Lyngsoe Systems won a tender to provide a new material management solution to provide Swiss Post with a complete inventory and flow overview system. The solution installed is advanced, fully automated and RFID-based comprising over 600 Quick Mount RFID portals at 47 sorting centers around the country, able to read passive EPC global Gen2 RFID tags attached to roll containers. The system also uses barcodes on mail trays that interface with other IT systems to provide end-to-end track and trace. Swiss Post achieved the following benefits:

- 100% visibility for roll container flow,
- Real-time track and trace data,
- Substantially reduced costs.

Tote boxes **-** UPS is a follower in RFID. The company began a series of pilot tests in 2004 on both its package delivery business and its supply chain solutions business, which serve many customers who must comply with upcoming RFID mandates. In one trial passive RFID tags are replacing bar codes on reusable fibreboard tote boxes used to shuttle packages through UPS's automated facilities. The objective is to extend the life of the tote boxes and to reduce the read-failure rates of the barcodes, which tend to wear off over time. In another pilot, RFID tags have been attached to UPS trucks in an effort to monitor cost-effectively vehicle activity moving on and off the property at three different locations.

Locking valuable bag **-** postal bags are often tagged with active or passive RFID tags to keep track of them. The Italian Postal Service has been a leader in this and other uses of RFID in the postal service. The problem of insurance of valuable bags can be enhanced by using the RFID system. On the inside of the bag is placed mechanical lock. Since such a mechanical lock can be easily robbed, RFID system provides complete mechanical and electronic coded protection of the possible ways of unauthorized unlocking. Unlocking is performed by mechanical key with a miniature radio frequency tag. The device inside the bag recognize ID code and unblock the mechanical lock and allows unlocking. Tag can include numerous combinations which the reader recognizes and on the basis of which allows the unblocking or blocking of a mechanical lock. One of the most important feature of this system, thanks to the technology of encryption, is that code in the tag changes dynamically every time when the key with tag brings closer to lock. At the same time provides a method of blocking and unblocking (Harrop, 2005).

Also, money transfer and insurance of deposit transactions can be raised to a higher level using the RFID system. Each bag of money contains a fixed tag, which reads on the depository machine. When the ID code from the tag is authorized, unlocks the space for the money. The client puts a bag with money in the slot and again starts ID code reading. If the ID code is correct client gets printed receipt.

3.3. RFID personnel and people monitoring

People access control, monitoring and attendance tracking belong to most demanded RFID applications. RFID based access control and monitoring systems are typically used for granting access or control the people attendance to office, enterprise, work place, car park, school, library, hotels, events and exhibition areas as well as for tracking employee time for payroll, safety, production and maintenance needs.
RFID based access control system can provide an easy and efficient solution for enabling access to only authorized employees. RFID embedded cards are being used for identification of authorized person to allow or deny access to restricted area.
Access control points can be doors, turnstiles, parking gates, elevator or other physical barriers with embedded RFID readers and antennas. The typical RFID tag can be a contactless smartcard, key fob, wristband or smart phone with NFC UHF sticker. The ID of a tag is verified against the access control list and the IDs access rights.
RFID solution at work places is ideal for a wide range of industries and businesses where hourly and salaried employee time is tracked, including manufacturing, warehouse and distribution, healthcare, retail, professional and medical offices, government, and educational agencies. RFID could be very useful in control over lost time and productivity, which can have a significant impact on the company’s profitability.
Data collected can be further used for work efficiency improvements and work flow optimization. The workers performance can be evaluated and compared, e.g. how many products a worker created within given time. This information can be used for work flow and methods optimization, evaluation, experience sharing and staff motivation.
RFID time and attendance systems automate employee time and attendance tracking improve productivity and eliminate costly payroll errors and thus reduce the time required to process employee time and attendance. Tracking employee time and attendance can be fast and simple with the RFID. Each employee is provided with a unique RFID badge. As the employee passes the RFID badge near the RFID reader/RFID gate, the RFID reader records the time of entry or exit. Data is downloaded on a scheduled or periodic basis, automatically delivering accurate time and attendance records (Roth, 2006).
Working hours recording terminal device provides accurate records of employees arrivals and departures from the company. Abuse by the employees can be reduced to the minimum by placing the network video camera to surrvey the spot arround the RFID readers. Video camera provides snap-shot of employees checking in or out. Employees check in when arriving to the work and check out when departuring by placing their ID card in front of the appropriate terminal device reader (CHECK IN or CHECK OUT). While checking in or out, employee can hold his/her card in protective foil or wallet. The card doesn't have to be taken out in order to be detected by the RFID reader.

Fig. 6.
Terminal device reader (CHECK IN or CHECK OUT)

ID card usually contains printed company's trade mark, owner's basic data and his/her photo, so the card provides not only electronic but also visual identification of the employee. ID card is equipped with re-writable memory which can be used for additional functions system provides (for example paying in company's restaurant). Employee's departure from the company during working hours can be managed in different ways. We suggest that employee reports to his/her superior which then decides whether employee can leave the company. Depending on the decision, superior then issues electronic approval, using his/her PC. Employee checks out when leaving and checks in on the return.
Turnstiles are placed on the gates for access control and passage records. They allow single person passage only. They can be equipped with RFID card readers, bar code readers, or both, as well as the coins and tokens acceptor. The turnstiles can be managed by external controller. Existence of separate reading devices for arrival and departure recording and turnstiles on the entering gate enables anti-pass back protection.

Fig. 7.
Turnstil

There are several different technologies used for card-based access control systems. Magnetic stripe cards store secure information encoded on a magnetic strip. By sliding the card through a special reader, an employee can gain entry to specific buildings and designated areas. Another highly popular method utilizes proximity (or RFID) card technology. With proximity cards, the information is embedded in the card, and the cardholder must simply waive the card within range of a card reader. The system can be designed so that specific workers are able to gain access to certain buildings and areas that require authorization. When it comes to controlling access to computers and networks, smart cards are an excellent option. Typically, these cards contain information on a smart chip embedded into the card. The employee inserts the card into the computer in order to log in and gain access to the company network. Such technology is often used for companies and corporations where workers must log in remotely. This allows employees from various locations to access the same network (FlexiRay, 2016).
Besides cards, very interesting solution is RFID chip implanted under one's skin (Fig. 8). The first reported experiments with an RFID implant were carried out in 1998 by the British scientist Kevin Warwick. His implant was used to open doors, switch on lights, and cause verbal output within a building. After nine days the implant was removed and has since been held in the Science Museum (London). This kind of human identification is further developing even today, despite a possible moral dilemmas about this process.

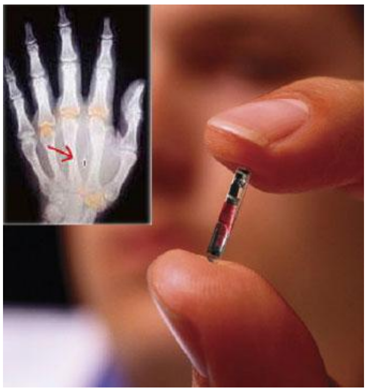

Fig. 8.

3.4. Shipment tracking

Shipment tracking is the process of localizing shipping containers, letters and parcels at different points of time during sorting, warehousing and delivery to verify their provenance and to predict and aid delivery.
Shipment tracking developed historically because it provided customers information about the route of a shipment and the anticipated date and time of delivery. Mail tracking is made possible through certified mail and registered mail, additional postal services which require the identification of a piece of mail to be recorded during various points of delivery, so that the sender can obtain a proof of delivery and the receiver can predict the time of delivery.
By using the service of tracking the item, a customer may get the information on date, time, place and status of their item from the moment of its entering the system. Each item in the system has its own identification (reception) number received upon posting.

3.4.1. RFID Postage Stamp

RFID technology is the future in improving the mail delivery. It is obvious that this technology will be the standard in marking parcels, especially as this technology has an increasing decline in the cost price tags (chips) and accompanying infrastructure equipment for RFID recording. The model of RFID Postage Stamp aims to initiate the implementation of the RFID technology on the basis of the symbiosis of traditional postage stamp and RFID tag which should mark the shipment and provide its complete Trace&Track service.

High-tech stamps containing radio frequency identification (RFID) chips are likely to replace the barcodes printed on letters and packages to sort and process mail. In due course, over one trillion postal items will be tagged yearly, making this the second largest application of RFID in the world after the retail supply chain. That may occur already around the year 2020. Postal services and shipping companies are already using RFID to grant access to secure areas, measure mail delivery performance and track vehicles.

In terms of programmable RFID postage stamps user can attach a stamp without a predetermined postage to an article to be mailed. The stamp has a top layer having a visual display, middle layer having an electronics layer, and a bottom layer having an adhesive layer. The stamp is encoded such that the visual display of the stamp is altered to indicate a state of the stamp. Postage of the item is determined by a postal authority worker and payment is authorized using the unique identifier. This eliminates the need for the sender to have any personal interaction with a postal worker to ship an article and eliminating the need for the sender to estimate postal cost prior to the article being received at the postal office. Altering the adhesive layer provides safe removal of the affixed stamp which can then be reused.

A system and method for postage payment utilizes passive RFID tags as postage “stamps”, with the amount of the postage automatically billed to a previously established customer account. The tags are stored in a separate stamp database and are “enabled” by linking the individual tag to a customer account. The use of the RFID stamps eliminates the need for the customer to know the proper postage beforehand. The existence of a customer account with a proper return address reduces the likelihood of a dead letter. Also, a special category of stamps may be used for automatic reply mail. By virtue of using an RFID tag, the mailed item's progress through the postal delivery system may be tracked from dispatch to delivery.

3.4.2. Measuring letter performance with RFID tags

RFID (Radio Frequency Identification) is an alternative technology to barcodes for the identification of items. The main difference is that barcode information is captured by optical means (a barcode scanner) whereas the RFID information is captured via a radio signal. The captured information for the purpose of letter performance measurement is the same but the means are different. The main advantage of RFID technology is that it is easy to automate the data capture process compared to barcodes. Scanning barcodes is typically a manual process which makes it more labor intensive.

The absence of unique identifiers requires the implementation of a sampling methodology, where test letters are mailed according to a statistical model. The posting and delivery dates are recorded by trained people. This data only provides information about the time the test letter takes to complete its journey.

The inclusion of an RFID transponder or tag in the test letter makes it possible to track the item at specific locations, typically where mail changes responsibility from the sending post to the receiving post. RFID equipment at specific entrance or exit doors records the passage of these tags without interfering with the operational process. The time and location is associated with the item details. This information undisputedly marks the ownership of the mail item that is necessary for measuring the letter performance of the postal operator responsible for processing the mail.

Posts have extended the technology in their facilities to gain a better understanding of their processes and make performance improvements where necessary. RFID is the enabling technology for measuring the performance of items that do not have a barcode such as letter mail. It largely avoids the problems of human error and cost of disorientation, obscuration and needing to read many barcodes at a time, phosphor dots, print issues, etc. This is why RFID is already used in the postal and courier service for secure access by people to vehicles and secure areas, secure access of vehicles to yards, location of parcels, conveyances, trailers and much more besides. RFID monitors the performance of the letter post, matches letters to postal boxes to prevent errors and records when and how much a sensitive package has been overheated in transit. In Sweden it is the basis of smart packages that record time of tampering and theft and leads to arrests.

The Universal Postal Union has been using passive ultrahigh-frequency (UHF) RFID tags based on the EPC Gen 2 air-interface protocol standard for monitoring the delivery times of letters in member countries, but there are no official standards for the use of RFID in the postal service. In general, most national postal agencies are utilizing passive UHF transponders to track parcels, bins, sacks and other assets used in their operations. For example, Correos, Spain's postal service, employs passive UHF RFID technology to pinpoint inefficiencies in its mail-handling processes. When it was installed in 2006, the system utilized 340 readers and 2,000 antennas installed across its 16 automated processing centers throughout the country, as well as four bulk mail-handling centers. Correos worked with a third party that uses a pool of 5,000 passive Gen 2 RFID labels to monitor the movements of letters through the mail delivery systems. By tracking the tagged mail's movements, the agency identified mail-handling procedures that it must improve to make speedy deliveries more consistent.

Radio Frequency Identification chips have been already deployed by postal companies in around 50 countries across the world to measure the quality of their services. The tags are attached to sample items. Their delivery process is monitored and is used to assess the efficiency of a postal service. But as costs drop and tags become smaller, RFID could be used for item-level tracking. Item-level tracking implies a massive deployment of RFID, potentially involving all the items sent. This would result in a close-to-zero risk of failed delivery. To make this possible, RFID chips would have to be cheap, tiny, easily available and based on common standards. High tech companies, like Hitachi or Motorola,

are currently working to make chips more affordable and functional. The size has already decreased so much that now experts do not talk of chips, but of “smart dust”. But interoperability remains a key concern. The European Commission launched a two-year project called GRIFS to build a global RFID standards forum. All stakeholders agree on the need of talking and finding common grounds.
There is even a postal RFID system that completely automates the whole process of mail delivery from accepting the package to classification and dispatching. It has been successfully tested in Korea. The new RFID system, developed by ETRI of Korea, aims to reduce costs, errors and tedious human intervention. It will provide a comprehensive electronic postal system with the potential to maximize mail package process capabilities while minimizing logistics cost.
It is difficult to estimate when RFID tagging of most of the courier and letter post will occur; however RFID labeled parcels, conveyances, vehicles and trailers are now very usual, with multiple benefits often being enjoyed. RFID is enhancing security and safety and removing tedious operations. Swedish Post has a parcel that detects and records tampering using RFID and other innovations abound, including RFID cards controlling driver access to postal vehicles and RFID enabled postal sorting equipment.

3.4.3. AMQM system for postal service quality measurement

The Universal Postal Union has paid special attention to traffic measurements and stimulates the postal operators by various measures to introduce advanced systems of measuring quality in providing postal services. Many postal operators have undertaken significant steps to increase the percentage of postal item delivery within a defined period of time, to reduce the terminal costs and to respond to the increased users' requirements. These authorities were the first to introduce the quality measurement system - AMQM (Automatic Mail Quality Measurement).
This system allows tracking of postal items "from start to end", i. e. from sender to receiver, and provide the postal authorities with the necessary activity with the aim of identifying and then also of eliminating bottlenecks in the phases of transfer and processing. The AMQM system records the difference between the actual and expected transfer speed of postal items in particular parts of the transfer process. This information is the basis for constant process of increasing the quality of providing postal services (Spajić and Sapina, 2007).
The basic elements of the AMQM system for quality measurement include:

1. Transponders,
2. Stations for reading/low-frequency antennas, uhf antenna grid and reading unit,
3. Local system for collecting data ldsc,
4. Central control system.

Post Norway is Norway’s national postal service, covering the entire country and its islands. Norway’s postal service needed to ramp up its technology-based systems to meet the need for visibility and real-time information on shipments. Its forward-looking policy has meant constant investment in an RFID based hardware and software infrastructure over the last 20 years, designed to support the best in customer services. Investment in an advanced RFID data capture infrastructure achieved the following:

- Real-time data on location and expected delivery of shipments,
- Full track and trace,
- Competitive advantage over other carriers,
- An increase in business measurable on the top line.

The geography and demographics of Norway pose special problems in terms of logistics. Recognizing the need to arrest falling revenues whilst increasing value, Post Norway began to implement an advanced portal infrastructure to generate data on the movements of items at a very early stage. Lyngsoe Systems has supported the carrier every step of the way to measure its domestic and international Quality of Service levels. The most recent significant investment was the installation of active/passive RFID portals across the country at no less than 340 locations (Lyngose Systems, 2016). Post Norway’s policy is to utilize Lyngsoe Systems' Automatic Mail Quality Measurements (AMQM) RFID hardware and Quality of Service Monitor (QSM™) software to take the provision of customer data to the next level. Benefits include:

- Top line business growth,
- Cost reductions,
- High quality of service,
- Improved logistics,
- Real-time data and visibility for customer shipments.

Post Norway is able to offer complete Track and Trace to B2B, B2C and private customers thanks to Lyngsoe Systems’ RFID portal infrastructure, track large load containers for carrying parcels and measure Quality of Service for domestic and international services. Lyngsoe Systems has provided a complete range of services from planning and design, through consultancy to installation over more than 20 years.

Post of Serbia is the winner of the award for AMQM – Enlargement of the system for automatic quality measurement as the best implemented project financed by the Fund for the quality of the Universal Postal Union since 2007. Transit time of the test-letter which included the transponder, is recorded through RFID equipment and Post of Serbia in an absolute leader of this segment in the region. The following chart presents the results of AMQM measurement system in the Post of Serbia for the year 2012 (Fig. 9).

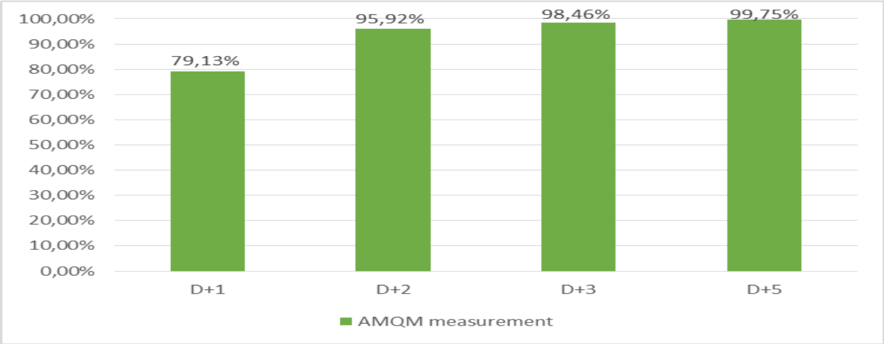

Fig. 9.
Quality level measured by AMQM system in 2012

The following graph shows a relationship between the level of quality specified by the regulatory body of Republic of Serbia (RATEL) and quality level measured by AMQM system (Fig. 10).

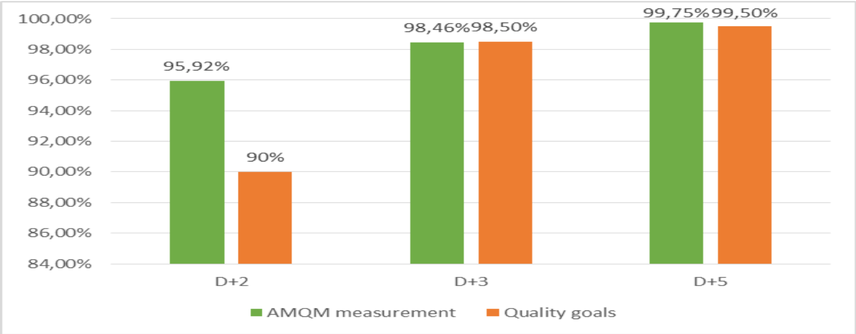

Fig. 10.
The relationship between required minimum level of quality and quality level measured by AMQM system for 2012

Looking at the results in the previous chart it is noted that the achieved results have exceeded goals set by RATEL, except for D+3 transit time.

4. Conclusion

The new material management system allows to always know where a mail is located, its destination and to identify bottlenecks in production or transport. It helps improve the level of quality of service and meet strategic targets including customer satisfaction.

Due to its diversity and flexibility RFID technology provides opportunities for improvement in all areas of human activity. It brings to accelerating and increasing of production efficiency, facilitating of monitoring in transport, eliminating the need for manual inventorying of warehouses and shops, control of pets and patients in hospitals and many other benefits in all fields where the identification and sharing of data is required.

The possibilities of using RFID technology are practically limitless. The information gathered by RFID technology provides making correct and timely decisions, and also, it can be expected that the application of RFID improve and optimize the engagement of the workforce, increase the efficiency of the supply system and reduce human errors and frauds and finally what is most important, it could bring to significant savings.

The development of new technologies many analysts saw as a threat to the postal sector; however, in practice it shows just the opposite. They create a fertile ground for the development of new postal services, quality and efficiency improvements. In this paper we precisely address these issues by illustrating the possibilities of RFID implementation in the postal company. We pointed out these possibilities in the following segments: vehicle tracking, production tools monitoring, personnel monitoring and shipment tracking.

MODELING AND INVESTIGATING FREEWAYS AS SYSTEMS WITH VARIABLE CHARACTERISTICS: APPROACHES IN RUSSIA AND GERMANY

Anton Sysoev[1], Justin Geistefeldt[2], Semen Blyumin[3], Alexander Galkin[4], Pavel Saraev[5]
[1,3,4,5] Lipetsk State Technical University, Department of Applied Mathematics, Lipetsk, Russia
[2] Ruhr University Bochum, Institute for Traffic Engineering and Management, Bochum, Germany

Abstract: The increasing number of vehicles requires a more detailed investigation of road traffic systems on different layers – from city intersections on the microscopic level to transportation networks within a city, region or state on the macroscopic level. In this context, the analysis of freeway characteristics is of particular importance. A crutial component in this field is the capacity, which be calculated by using different approaches. The paper presents a comparative analysis to determine the capacities for freeways both in Germany and Russia. Usually, the capacity is defined as the maximum number of vehicleswhich can traverse a stretch of road per time unit in one or two directions under the prevailing road, traffic, and weather conditionsRecently, new stochastic concepts to estimate the capacity of a freeway were developed and applied in different studies. In this case, the capacity is regarded as a random variable whose features can be determined by analyzing the transition of traffic flow from fluid traffic conditions into congested flow. This event is usually referred to as a traffic breakdown. As every random process, the capacity here can be described by a distribution function. Anonparametric method to find parameters of this distribution is the Kaplan-Meier approach. It was found out that Weibull distribution best approximates empirical data. To model Weibull-distributed values correctly, it is necessary to construct bounds for the distribution function. Another problem highlighted in the paper is the interval characteristics for distribution parameters estimated using the Kaplan-Meier approach.

Keywords: mathematical modeling, variable structure systems, Weibull distribution, freeways.

1. Introduction

The comparison of classic and alternative approaches to model and to investigate freeway traffic flow is the major objective of the paper. Based on the assumption that the freeway segment as an element of a larger complicated system has a Poisson distributed incoming flow with a certain processing flow, we can use the one-channel classic queuing system to model it. To simplify the system of Kolmogorov's equations, which forms modeling formulas, the deterministic distribution of the flows mentioned above is applied. These theoretical ideas were taken into account while Russian and German National Guidelines were being developed. But the results obtained by applying them are not always realistic. It was established that the process of congestion formation at the bottleneck of a freeway segment is comparable with the analysis of samples that include censored data. The results received by Zurlinden (2003), Brilon et al. (2007) formed the base for freeway variable (stochastic) capacity understanding. The paper also presents the way to bound the function describing the distribution of breakdown probability (which is used to estimate the capacity), to avoid unrealistically small capacities for real-world applications. The estimated parameters of the Weibull distribution have to be bounded by confidence intervals. To find them, the idea of using pivotal function is applied.

2. Approaches to model freeways

A lot of researches describe various ways to model transportation systems in general and freeways in particular. For example, Rice and van Zwet (2004) proposed a method to predict the travel time needed to pass through a freeway section using a simple linear regression approach. This method is based on the combination of historical data and real time information. Chen et al. (2004) use principal curves to describe and analyze the interaction among freeway traffic flow variables and their joint behavior without any assumption on the functional forms. Many authors like Meldrum and Taylor (1994), Dharia and Adeli (2003), Codur and Tortum (2015) suggest using artificial neural networks and hybrid networks to model and further to estimate characteristics of freeway segments or the whole road. The conception of "black box" which underlies neural networks is a very perspective, but not the most common one. Actually average values of traffic flow characteristics within the freeway are only important, that is why the structure of a mathematical model to describe the object must be quite simple. Therefore, the queuing systems and queuing theory are very popular as a way to describe and research traffic systems and their main practically important characteristics.To define a queuing system, it is necessary to indicate the distribution of incoming flow, the distribution of service time and a service discipline. In contrast to the classical stochastic approach based on a Poisson distribution for the arriving process and some stochastic distribution for the explanation of the service time, the deterministic mechanism assumes to use a constant fixed arriving time for every request (or job, message) in a system and constant times for the service process. Though, there are many well-known service disciplines (cf. Ventzel, Ovcharov, 1983). For freeways, the FCFS (first-come-first-served) discipline is assumed to be the only applicable. The appropriate queuing system to describe freeway traffic flow, which is under consideration in this paper, is D/D/1, where D represents the deterministic distribution law and 1 shows that the system is considered as a single-channel system.

[1] Corresponding author: anton_syssoyev@mail.ru

The tendency to use variable structure systems to model freeways is devoted special attention to. Variable structure is understood here as a feature of existing unstable characteristics of a system which has a random distribution through the time and the amount of vehicles. In spite of classical deterministic approaches to estimate the capacity of freeways, which dominate both in Russian and German Guidelines, the systems with variable characteristics to investigate roads are becoming commonly used.

3. Russian and German criteria to detect the quality of the traffic flow

Comparable with the U.S. Highway Capacity Manual (HCM 2010) and the German Handbuch für die Bemessung von Straßenverkehrsanlagen (HBS 2015), the Russian National Guidelines (RNG 2012) focuses on the idea to estimate the performance of freeway segments by analyzing the volume-to-capacity ratio. In its first edition (1982), based on this measure of effectiveness, 5 levels of service (LOS) were defined. The new version contains 6 levels of service; table 1 gives the comparison for LOS as the criterion of the movement convenience for RNG and HBS.

Table 1
Thresholds of the volume-to-capacity ratio defining the Level of Service (LOS) on freeway segments

LOS	A	B	C	D	E	F
RNG 2012	< 0.2	0.2 - 0.45	0.45 - 0.7	0.7 - 0.9	0.9 - 1.0	> 1.0
HBS 2015	≤ 0.3	0.3 - 0.55	0.55 - 0.75	0.75 - 0.9	0.9 - 1.0	> 1.0

Source: Russian National Guidelines to detect the capacity of motorroads (version 2012), Handbuch für die Bemessung von Straßenverkehrsanlagen HBS 2015

The slight differences between the RNG and the HBS in the thresholds defining the LOS for freeway segments under certain traffic conditions can be explained by different theoretical models using different speed regulation regimes and different driving cultures. A brief overview of the RNG and HBS procedures and basic theoretical models for deriving design capacity values is given below.

4. Russian National Guidelines to detect the capacity of motor roads

The Russian National Guidelines to detect the capacity of motor roads (version 2012) include recommendations for calculating the capacity of different types of roads (dual highways, three-lane highways with an intermediate lane for reverse movement, freeways with four or more than four lanes), detecting the capacity of segments with unregulated intersections which are located inside and outside urban areas, estimating the capacity of merge points within different levels, calculating the capacity of signalized intersections; ways to estimate the capacity of freeway segments under certain conditions (as settlements located close to the highway, tunnels, roadside buildings, highlands). According to this document, there are several ways to estimate the capacity of freeway segments depending on the number of lanes, its location, geometrical characteristics, and other factors. All approaches are based on applying coefficients of reduction to the similar mathematical models with a simple structure.It should be mentioned that in terms of RNG, the capacity is calculated for both directions of a freeway segment, this fact must be taken into account to understand the design capacity values presented in RNG. For freeways with four (two in both directions) or more than four lanes, where the traffic flow has no uniform distribution through lanes, the capacity has to be determined for every lane separately considering the consistency of the flow, road, and weather conditions. In this case, the capacity of a freeway segment can be estimated as:

$$P = 2 \cdot (P_1 + ... + P_n), \tag{1}$$

where P is a practical capacity of a freeway segment, $P_1,...,P_n$ are practical capacities of lanes $1,...,n$, when the capacity for every lane is:

$$P_i = P_{\max} \cdot \prod_{j=1}^{5} \beta_j \tag{2}$$

Where; $P_{\max}$: the maximal capacity for the lane i (veh/h), β_j: the coefficients of reduction. These coefficients are responsible for the influence of merge points, geometrical parameters, the existence of an emergency stop lane, and the existence of suburban passengers transport. The tables presented in RNG give design values for the maximal lane capacity under different conditions, recommendations how to choose the correct set of reduction coefficients and their point estimates. Intermediate values (for Eq. 1 and 2) can be found using linear interpolation.

5. German Highway Capacity Manual

The latest edition of German Highway Capacity Manual HBS 2015 (Handbuch für die Bemessung von Straßenverkehrsanlagen) gives guidance for estimating capacities for types of road facilities. This version is the second

edition in which many theoretical results were adjusted. The HBS is divided into volumes describing analysis procedures of freeways, rural roads, and urban roads. Additionally, it contains a set of examples. The main assessment of basic freeway segments still follows the tradition of using deterministic capacities.
Design values for the estimation of freeway segment capacities according to HBS take into account prevailing road, traffic, and control parameters (in case of constant or variable speed limits). The design capacity values were derived by Brilon and Geistefeldt (2010) based on using van Aerde's (1995) model, which gives the traffic volume at the apex of the speed-flow relationship. According to van Aerde's model, the corresponding speed-density relationship is:

$$d(v) = \frac{1}{c_1 + \dfrac{c_2}{v_0 - v} + c_3 \cdot v}, \tag{3}$$

Where; $d(v)$: the traffic density at speed value v; c_1, c_2, c_3, v_0 : the parameters of the model. In unstable speed-flow conditions (a distinct gap between the fluid and congested traffic flows), the application of Aerdes's model (3) gives an unrealistic estimation for the practical capacity. To avoid this weakness the apex volume of the fitted speed-flow curve was compared with the 99th percentile of the distribution of all flow rates in the data sample. If the apex volume exceeded this threshold, the percentile value was considered to be the capacity estimation.
The assessment procedures for freeway segments in HBS use the following parameters, which influence the capacity: the percentage of heave vehicles, the location of the freeway inside or outside the urban areas, the number of lanes, the gradient (if it is greater than 2%), and the control conditions (speed restrictions, variable speed limits, special speed regime in tunnels, hard shoulder running). The HBS contains tables for design capacity values defined by the parameters above. Intermediate values can be found using linear interpolation.

6. Freeways as systems with variable characteristics: stochastic approach to estimate freeway segment capacity

The presented above approaches to estimate freeway segment capacity values given in the RNG and the HBS are deterministi, they deliver the same results for any segment under certain conditions, but this is not exactly the situation which occurs in reality. Under the same conditions the capacity values may vary because of factors with random nature (such as accidents, work zones, drivers' behavior and others). The gaining popularity approach to define freeway segment capacity as some stochastic value is given further. It operates with censored data analysis.

6. 1. Reliability Life Data Analysis for estimation the capacity

Van Toorenburg (1986) proposed to use models for censored data to identify the probability distribution function for modeling freeway capacity. In this approach, the traffic data is divided into “uncensored” and “censored” intervals. An interval is classified as “uncensored” if it contains an observation of the capacity. Van Toorenburg as well as Minderhoud et al. (1997) assumed that the capacity is observed whenever there is a queue on a freeway caused by a bottleneck. According to this, observations during both fluid and congested traffic are included in the capacity analysis. Due to the “capacity-drop” phenomenon (cf. Banks, 1990 and Hall and Agyemang-Duah, 1991), however, the capacity during congestion differs from the capacity before a breakdown. Thus, it is more appropriate to include only those values measured during fluid traffic conditions (cf. Zurlinden, 2003). If so, an interval i is classified as “uncensored” if the observed volume q_i causes a breakdown of traffic flow, thus the average speed drops below a specific threshold in the next interval i+1. The breakdown volume q_i is regarded as the momentary capacity of the facility. If traffic is fluent in interval i and remains fluent in the following interval i+1, this observation is classified as “censored”, which means that the capacity in interval i is greater than the observed volume q_i.
A nonparametric method to estimate the distribution function based on samples that include censored data (it is well known from lifetime data analysis applications) is the so-called “Product Limit Method” (PLM) by Kaplan and Meier. Based on this approach, the survival function $S(q)$ can be estimated by:

$$S(q) = \prod_{i:\, q_i \le q} \frac{k_i - d_i}{k_i}, \; i \in B, \tag{4}$$

Where; q: a flow rate (veh/h), q_i : a flow rate in interval i (veh/h), k_i: a number of intervals with the flow rate of $q \geq q_i$, d_i: a number of breakdowns at a flow rate of q_i, B: a set of breakdown intervals.
The capacity distribution function $F_c(q)$ is the complementary of the survival function:

$$F_c(q) = 1 - S(q) = 1 - \prod_{i:\, q_i \le q} \frac{k_i - d_i}{k_i}, \; i \in B. \tag{5}$$

The product within this equation is calculated over all observed time intervals i with a traffic volume $q_i \leq q$ that were followed by a traffic breakdown. Usually, each observed breakdown is used as one q_i-value, so that d_i is always equal to

1. The distribution function will only reach a value of 1 if the maximum observed volume is an uncensored value (i.e. a breakdown was following). Otherwise, the distribution function terminates at a value of $F_c(q) < 1$, where q is the maximum volume of an uncensored observation.

For a parametric estimation, the function type of the distribution must be predetermined. The distribution parameters can be estimated by applying the Maximum-Likelihood technique. For capacity analysis, the Likelihood function is:

$$L = \prod_{i=1}^{n} f_c(q_i)^{\delta_i} \cdot (1 - F_c(q_i))^{1-\delta_i} , \tag{6}$$

Where; $f_c(q_i)$: the statistical density function of the capacity c, $F_c(q_i)$: is cumulative distribution function of the capacity c, n: is a number of intervals, $\delta_i = 1$, if interval i contains an uncensored value, and $\delta_i = 0$, if interval i contains a censored value.

According to Brilon, Geistefeldt empirical comparison between different function types based on data samples from different German freeway sections revealed that freeway capacity is Weibull distributed (cf. Geistefeldt and Brilon, 2009). The Weibull-type capacity distribution function is:

$$F_c(q) = 1 - \exp\left(-\left(\frac{q}{b} \right)^{a} \right) \tag{7}$$

Where; $F_c(q)$ is a capacity distribution function, q is a flow rate (veh/h), a is the Weibull shape parameter, b is the Weibull scale parameter (veh/h).

The shape parameter a of Eq. 7 determines the variance of the distribution. According to Brilon and Geistefeldt (2010), the shape parameter of German freeway segment capacity distribution functions typically ranges between 10 and 22. The scale parameter mainly represents the systematic factors affecting freeway capacity, such as the number of lanes, the gradient, and the driver population.

6.2. Interval estimates of Weibull parameters

There are well-known standard assessment procedures to find point estimates of Weibull distribution function parameters. But the question how to detect confidence intervals for them was investigated skin-deep based on the assumption that they are normal distributed. It is not exactly correct. The interval notations for the parameters are presented below.

Let a and b are the shape and scale parameters respectively of a shape-scale distributed variate and $\hat{a}$ and $\hat{b}$ are the Maximum Likelihood Estimators of a and b. According to several authors (cf. Thoman et al., 1969, Lawless, 1974), the pivotal function can be used to estimate the possible distribution of shape and scale parameters. For example, Rinne (2009) give a detailed explanation based on the proving of theorems to find out the two-sided interval definition formulas for a and b Weibull parameters. According to them, with the parameterization $a = \ln b$ and $b = \frac{1}{c}$, the following interval estimations are valid:

$$\frac{\hat{c}}{\ell_1\left(\mathrm{n}, 1 - \frac{\alpha}{2}\right)} \le c \le \frac{\hat{c}}{\ell_1\left(\mathrm{n}, \frac{\alpha}{2}\right)} \tag{8}$$

$$\hat{b} \cdot \exp\left(\frac{-\ell_2\left(n, 1 - \frac{\alpha}{2}\right)}{\hat{c}} \right) \le b \le \hat{b} \cdot \exp\left(\frac{-\ell_2\left(n, \frac{\alpha}{2}\right)}{\hat{c}} \right) \tag{9}$$

where the tables for $\ell_i(n, \mathrm{P})$ are presented in Thoman et al. (1969). These tables based on combinations of different confidence levels and numbers of observations describe the distribution of the pivotal function which its underlay parameter Maximum Likelihood Estimators.

6.3. Boundary of Weibull distribution function

As it was mentioned above, queuing systems are the most popular way to simulate and find statistical characteristics of many technical processes including freeway traffic flow. According to the stochastic capacity approach, the capacity of the queuing system which is under consideration has a random meaning in every particular road segment and traffic conditions. In terms of freeway modeling, the Weibull distribution depicts how the capacity dynamically varies within a certain segment. The problem engineers face during simulations is how to limit the produced value not to obtain the capacity too small for the real outer conditions.

From the point of view of classical Kinematics, the density function of the distribution could illustrate the speed of variable changing if the probability $F(x)$ is compared with the position of some body and the meaning of a random value x is compared with a discrete moment. Deducting from these assumptions it is possible to suppose that the second derivate of the distribution function with respect to the same variable is responsible for the acceleration of the variable changing. The investigation of this function could give an answer to the question where the function has minimal and maximal values of the acceleration. Concerning the Weibull distribution and the application to freeway capacity, the determined global maximum doesn't exactly describe the lower threshold, because the probability rate of 1% (instead found 10%) must be included into consideration as being sufficient enough for the onset of congestion on a freeway. It means that the lower threshold is required for the further adjustment. The fist derivative of the density function, as before, is responsible to the speed of its changing. The analysis of this gradient function is associated with finding a new adjusted lower threshold. This curve is not interesting by itself, but the analysis of its changing could be beneficial for detecting the point where the function suffers the minimal change of its growth. This "changing" function has a band and it is supposed that this band is exactly the point where the gradient function has the lowest growth. It is proposed to calculate the band point as an average curvature of the graph of the "changing" function.

There were qualified possible values of Weibull distribution parameters for German freeways. The shape parameter a was varied from its minimal limit 10 to the maximal value 25 in steps of 0.5 when the scale parameter b was changed from 4000 to 7000 in steps of 100. All their combinations underlay the further numerical experiments. It must be mentioned that the same parameters could be applied also for Russian freeways. To improve the accuracy of calculated lower threshold, 10000 realizations of Weibull distributed random value were produced. Based on calculations, the following multiple linear regression model was found. It gives the dependency of realistic values for stochastic capacities based on Weibull distribution parameters:

$$c_{REAL} = -1937 + 108.9 \cdot a + 0.6693 \cdot b \tag{10}$$

Where; c_{REAL}: the realistic value for the stochastic capacity (veh/h); a, b: shape and scale parameters of the Weibull distribution respectively.

Fischer’s F-test applied to the model Eq. 10 allowed rejecting the hypothesis about the simultaneous equality to null for all the estimators; it means that the model is statistically significant and should be taken for the further analysis. Student’s t-statistics for standard errors of all estimators also had a successful result.

7. Conclusion

In spite of the fact that the latest editions of Russian and German National Guidelines still follow the tradition to apply a deterministic understanding of traffic flow characteristics (cf. capacity), the idea to use the stochastic capacity approach is very promising. It was proved that a freeway segment has the capacity exactly fitted with the Weibull distribution. The way to prevent the capacity when modeling smaller than the real value is presented. It is based on the Kinematic understanding of changing the distribution function. Distribution parameters must be bounded by confidence intervals whose construction was based on using pivotal functions.

SESSION 17: TRANSPORT OPTIMIZATION PROBLEMS

ANALYSIS OF APPROACHES FOR TRAJECTORY COMPARISON

Ekaterina Grakova[1], Jan Martinovič[2], Kateřina Slaninová[3], Tomáš Martinovíč[4], Radek Tomis[5]
[1,2,3,4,5] IT4Innovations, VŠB - Technical University of Ostrava, Ostrava, Czech Republic

Abstract: Measuring similarity between trajectories is undoubtedly one of the most important tasks in trajectory data management since it serves as the foundation of many advanced analyses such as similarity search, clustering, and classification. The paper is focused on distance/metrics to compare two or more trajectories. The authors compared trajectories obtained from several implemented algorithms (Dijkstra's algorithm, A*, Bidirectional Dijkstra, Bidirectional A*) and from external public available routing systems. A collection of the selected routes in the Czech Republic were used for the experiment. The selection of the most suitable metric/distance is very important for the quality enhancement of the routing algorithms; for example, revealing inaccuracies in implemented algorithms or in map data.

Keywords: trajectory similarity measure, GPS trajectories, algorithms, distance/metric.

1. Introduction

The search of paths is an ordinary task for the GPS navigation, and yet most of the navigations easily find a different path, because it depends on the used routing algorithms, used optimizations, and map data. Routing is the process of selecting a suitable route and it takes place in a simplified model of the real transport network – graph. In this graph, there are intersections with nodes of graph and the paths between them are the edges of the graph which are oriented according to the direction. Each vertex has given its GPS coordinates, mainly for the purpose of later plotting of the found path into the map. GPS coordinates consist of two values indicating the position, namely the length and the width. Typically, a GPS trajectory consists of a sequence of points with latitude, longitude, and timestamp information (Bollobás, 1998).
Thanks to this conversion, we can use for the search of paths algorithms that are used for the search of paths in the graphs. The best known algorithm for finding the shortest path in the graph is the Dijkstra's algorithm (Dijkstra, 1959). This algorithm can be used in a graph (either undirected graph, or directed graph). For proper function, the edges must be assessed by their length, which must not be negative, but this case does not occur if the graph represents a road network. Another algorithm that can be used for searching the shortest path is A* algorithm (Hart at al., 1972). It is based on Dijkstra's algorithm and it uses heuristics for searching the path. Its main advantage is that it uses only a fraction of the data for searching the path in comparison with the previously mentioned Dijkstra, so it's much faster. Heuristics consist in the ability of the most accurate estimation of the distance from the current node to the destination node. On the basis of this ability, the path is led directly from the initial node to the end node, which is searched. Therefore, not all the nodes in the graph have to be browsed, but only those lying on the shortest paths. Despite the fact that the shortest path is not found, which is fault of the heuristics, the found path is almost the shortest one.
If we need to find a path only occasionally or if we do not want to buy a GPS for our car, web applications will help us while searching the paths. Among the best known are Google.com, Here.com, Bing.com, Graphhopper.com, Mapquest.com, Tomtom.com. Web applications for routing contain many different functions, e.g. (paid or unpaid highways), which allows us to find a way based on the needs of the user. Most of the web applications search for the shortest and the fastest paths. In this paper, we will concentrate on the shortest paths.
In the experiment, the GPS trajectories from the implemented algorithms and the trajectories from the web applications were compared, and the similarity between two or more trajectories was measured. The similarity of the trajectories can be measured by several metrics. During the last ten years, there were introduced various distance/similarity measures in the literature. Jonkery at al. (1980) suggested Euclidean Distance, Dynamic Time Warping (DTW) was suggested by Soong and Rosengerg (1988), distance based on Longest Common Subsequence (LCSS) presented in (Kearney and Hansen, 1990), Fréchet Distance in (Alt and Gadau, 1995), or Hausdorff Distance in (Huttenlocher at al., 1993). We chose the most common Hausdorff Distance, Fréchet Distance, Dynamic Time Warping for the comparison the trajectories.
The aim of this article is the selection of suitable metrics to compare the results of routing. A suitable metric will enhance the quality of the routing algorithm and reveal inaccuracies in implemented algorithms or in map data.

2. Trajectory Distances

The concepts that were used in the experiment are defined in this section. First of all, let look at the definition of a *trajectory*, which is often used to describe the motion of the moving objects in 2D environment with respect to a given coordinate system:
Definition 1. A trajectory T is a function $F_t : T \to R^2$ which maps a given (temporal) interval $[t_b\,,\ t_e]$ into a one-dimensional subset of R^2. It is represented as a sequence of 3D (2D geography + time) $(x_1\,,\ y_1,\ t_1), (x_2, y_2, t_2), \dots, (x_n, y_n, t_n)$, where $t_b =\ t_1$ and $t_e = t_n$ and $t_1 \le t_2 \le \cdots \le t_n$.

[1] Corresponding author: ekaterina.garakova@vsb.cz

Each point (x_i, y_i, t_i) in the sequence represents the 2D location (x_i, y_i) of the object at the time t_i. For every $t\ (t_i, t_{i+1})$, the location of the object is obtained by a linear interpolation between (x_i, y_i) and (x_{i+1}, y_{i+1}) with the ratio $\frac{(t-t_i)}{(t_{i+1}-t_i)}$, which is, in between two points the object is assumed to move along a straight line-segment and with a constant speed. The 2D projection of T is a polygonal chain with vertices $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$ which is called a route of T (Trajcevski at al., 2007). In this paper we chose to use trajectory T in 2D projection.
In the following paragraph we will introduce the most common metric/distance for comparison similarity of two and more trajectories.

2.1. The Fréchet Distance

The Fréchet Distance is amongst the most popular of the similarity measures (Eiter and Minnila, 1944). There was done a lot of studies in which the authors used the Fréchet method to compare the trajectories. (Aung at al. 2013) used metric/distance as the similarity measure in grouping sub-trajectories. Authors of (Buchin at al. 2010) compared similarity geometry of the two trajectories. This method which measures the similarity of the curves is used e.g. when comparing shapes, or when comparing two trajectories or geometries of paths. It is nicknamed "distance of walking dogs" (dogwalk distance). The curves that are subject of comparison can be imagined as trajectories of the dog and his master, who go for a walk and are connected through the leash. Dog and its master can adjust their speeds, they can stop, but must not go back and have to go through the entire route. Fréchet Distance is then the length of the shortest leash with which it is possible to complete such a dogwalk.
The definition of the parameterized continuous curves is presented in Definition 2, and the standard definition for the Fréchet Distance (Alt and Gadau, 1995) follows in Definition 3.

Definition 2. A continuous parameterized curve $A \in R^d$ can be represented by a continuous mapping $f: [a, b] \to R^d$ such that $a, b \in R$ and $a < b$.

Definition 3. A monotone reparameterization α is a continuous non-decreasing function α: $[0,1] \to [0,1]$ such that $\alpha\,(0) = 0$ and $\alpha\,(1) = 1$.

Definition 4. Given two curves, A, B in a metric space, the Fréchet Distance, $d_f\ (A, B)$ is defined as defined as

$$d_f\,(A, B) = inf\ \max_{\alpha,\beta\ t\in[0,1]}\{\mathrm{d}(\mathrm{A}(\alpha(\mathrm{t})), B(\beta(t)))\} \qquad (1)$$

Where; $, \beta$: range over all monotone parameterizations and $d(\cdot,\cdot)$: represents the Euclidean Distance, and *inf* : the infimum.
In the early 1990s, the Fréchet Distance was applied to polygonal curves by Alt and Godau (Alt and Gadau, 1995). With the restriction of polygonal lines, they proved that the Fréchet Distance can be found between two curves *A, B* efficiently with a time complexity of $O\ (mn \log(mn))$ where $m = |A|, n = |B|$.

2.2. The Hausdorff Distance

Another metric/distance, which is used for comparison of two GPS trajectories, is the Hausdorff Distance. The Hausdorff Distance was first defined by Felix Hausdorff in 1914 (Hausdorff, 1914). Since its introduction, the Hausdorff Distance has become one of the most widely used similarity measures across many disciplines. In the paper, the authors (Zhang at al. 2006) compared different similarity measures used for trajectory clustering in outdoor surveillance scenes. Evans at al. (2013) extended the original version of the metric/distance to Network Hausdorff Distance Trajectory Similarity Matrix (NHDTSM). The metric/distance is to quickly calculate the commonly used network Hausdorff Distance between all pairs of the input trajectories. Definition 5 is the basic formulation of Hausdorff Distance.
Definition 5. Let X and Y be two non-empty subsets of a metric space (M, d), where M is the space and *d* the distance measure. We define their Hausdorff Distance $D_H\ (X, Y)$ by

$$D_H(X, Y) = \max\ \{\sup inf_{x\in X,\ y\in Y}\, d(x, y), \sup inf_{y\in Y,\ x\in X}\, d(x, y)\}, \qquad (2)$$

Where; *sup* : represents the supremum, *inf* : the infimum.
In this paper, the metric/distance will be represented as follows. It is the measure of similarity between two arbitrary finite sets *A* and *B*. The classic Hausdorff Distance $H\ (A, B)$ is given by

$$H(A, B) = \max_{a\in A} \min_{b\in B} \|a - b\| \qquad (3)$$

$H(A, B)$ will be small, if each element from *A* is close to an element from *B*. Conversely, $H(A, B)$ will be large if only one element of *A* will be distant to all elements from *B* (Zhang at al., 2006), (Nutanong at al., 2011).

2.3. The Dynamic Time Warning

The method of Dynamic Time Warping (DTW) is an algorithm that takes advantage of the principle of dynamic programming and has been known since the fifties of the last century when it was discovered and began to be popularized through the American mathematician Richard Ernest Bellman (Bellman, 1957), (Psutka, 1996). Subsequently, this method was accepted especially in the area of automatic classification of words and its use in this area has been thoroughly investigated since the seventies. The ability of this method consists in effective measuring the similarity of two time courses.
For two trajectories T_A and T_B, with lengths m and k, an $m \times k$ grid can be created, where each grid point (i, j) represents the distance between points a_i and b_j (Toohey and Duckham, 2015).
Definition 6: If w_l represents a grid point $(i, j)_l$, then a warping path W can be represented as the following sequence of grid points:

$$W = w_1, \dots, w_p \tag{4}$$

The compared time courses processed in the most practical tasks are usually not comparable, and can be shifted against each other or outspread – they are not aligned on the timeline. Because these deviations are not linear, it is not possible to apply the linear comparison (e.g. by measuring the distance of corresponding samples). At linear comparison (for example by measuring the Euclidean distance of corresponding points or vectors), we can two identical time courses erroneously indicate as dissimilar due to uneven alignment on the timeline, though they are only mutually shifted. DTW allows to nonlinearly adapt these time courses by introducing a so-called non-linear, so called collapsing function, which adapts either the tested time course to the referential course or both mutually, in order to achieve the greatest possible conformity.
In the literature, there was introduced a large number of studies for use of DTW to compute the similarity between the trajectories. (Sankoff and Kruskal, 1987) introduced DTW to measure trajectory distance. The authors in (Sankararaman at al., 2013) created framework that uses the advantages of both DTW and sequence alignment based approaches for identifying trajectory similarity, and that it is able to exceed their accuracy. Quantitative analysis on the effectiveness of the trajectory similarity measure was presented in (Wang at al., 2013).

2. 4. Data Description

For the comparison of the trajectories, a set of places among which we searched for the paths was selected. It was necessary to test all of the possible paths. The experiment included the search of short paths, long paths and paths leading from one end to the other end of the Czech Republic. Each path in Table 1 contains the GPS coordinates for the start and the end of the journey. GPS trajectory represents a sequence of points with the latitude and longitude. The resulting GPS trajectories were obtained by means of the implemented algorithms Dijkstra, A*, Bidirectional Dijkstra and Bidirectional A*, which searched for the shortest path.

Table 1
Route for similarity trajectories

Routes	(Start) Latitude / Longitude	(End) Latitude / Longitude
Route 1	50.5732/16.2381	49.1927/17.2903
Route 2	49.1553/15.6161	50.5934/13.5800
Route 3	49.9940/17.5404	49.6767/14.4882
Route 4	49.1726/16.1099	49.4542/15.5905
Route 5	49.9316/12.8500	49.9520/16.1610
Route 6	50.0599/16.4839	49.1345/18.0092
Route 7	50.2096/17.7399	50.5241/16.4257
Route 8	50.6659/14.0911	49.0078/14.8487
Route 9	50.2962/14.2503	49.2496/17.6495
Route 10	50.1057/14.6052	49.9636/13.7695

For the comparison of the results of the tested algorithms, the following web applications for the search of the paths were chosen: Google.com, Here.com, Bing.com, Graphhopper.com, Mapquest.com, Tomtom.com. Each selected application searches for the shortest path. GPS trajectories for similarity comparison were gained by Directions API provided by the web applications. We used Directions API to create a route that included two or more locations and to create routes from major roads. It is possible to create driving or walking routes. Driving routes can include traffic information. Each XML file contained a sequence of points with the latitude and longitude.
Fig. 1 shows a visual trajectory of the routing algorithms and web applications.

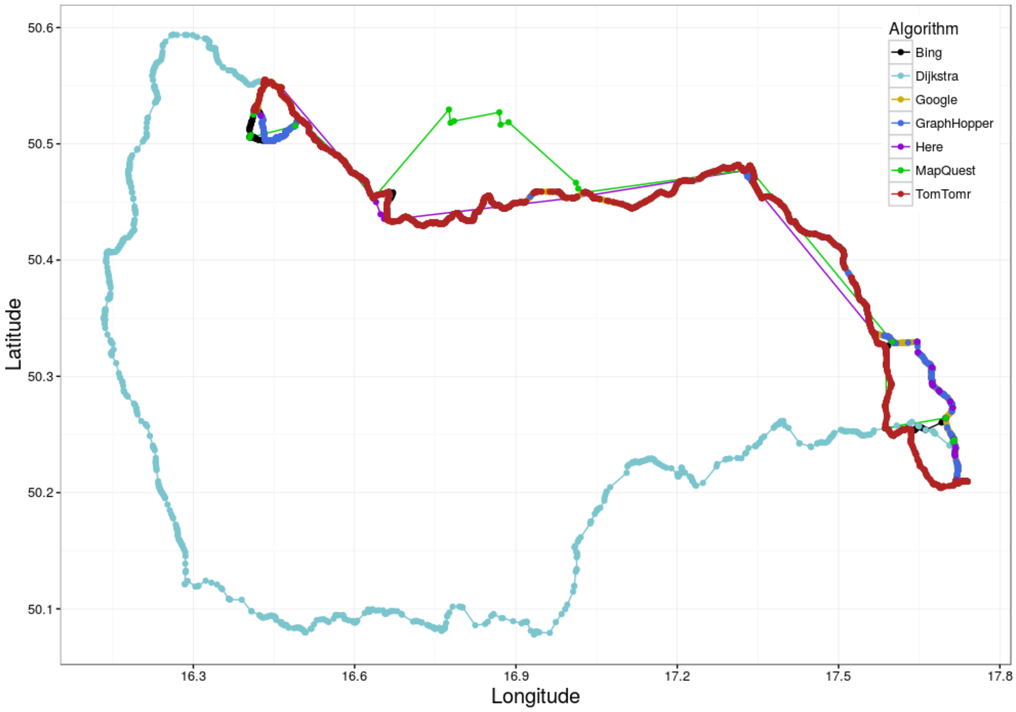

Fig. 1.
Comparison of the trajectories

3. Experiments

To compare the trajectories, we used the Fréchet Distance, Hausdorff Distance and Dynamic Time Warning measure. The implemented similarity measures compare the trajectory of the path of the tested algorithm and the trajectory of the path from the web applications for search of the paths. The points at the start and at the end of the trajectory were identical. Each trajectory in the dataset contained a different set of points. At the beginning, we did the comparison of GPS trajectory from Dijkstra routing algorithm and GPS trajectory of the web applications. In the next step, we made a similarity comparison of a routing algorithm A* trajectory with trajectory from web application. We also compared the bidirectional (Dijkstra and A*) routing algorithms. The results always show the similarity of two trajectories between themselves.

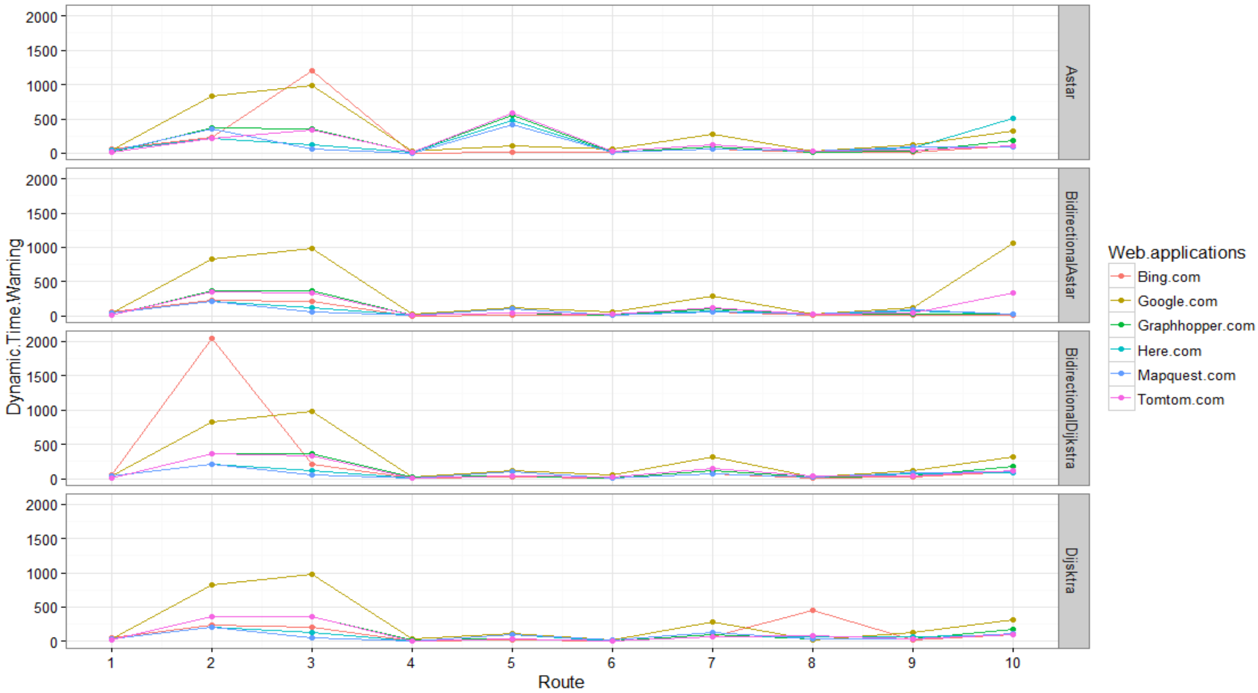

Fig. 2.
The results of a comparison using Dynamic Time Warning

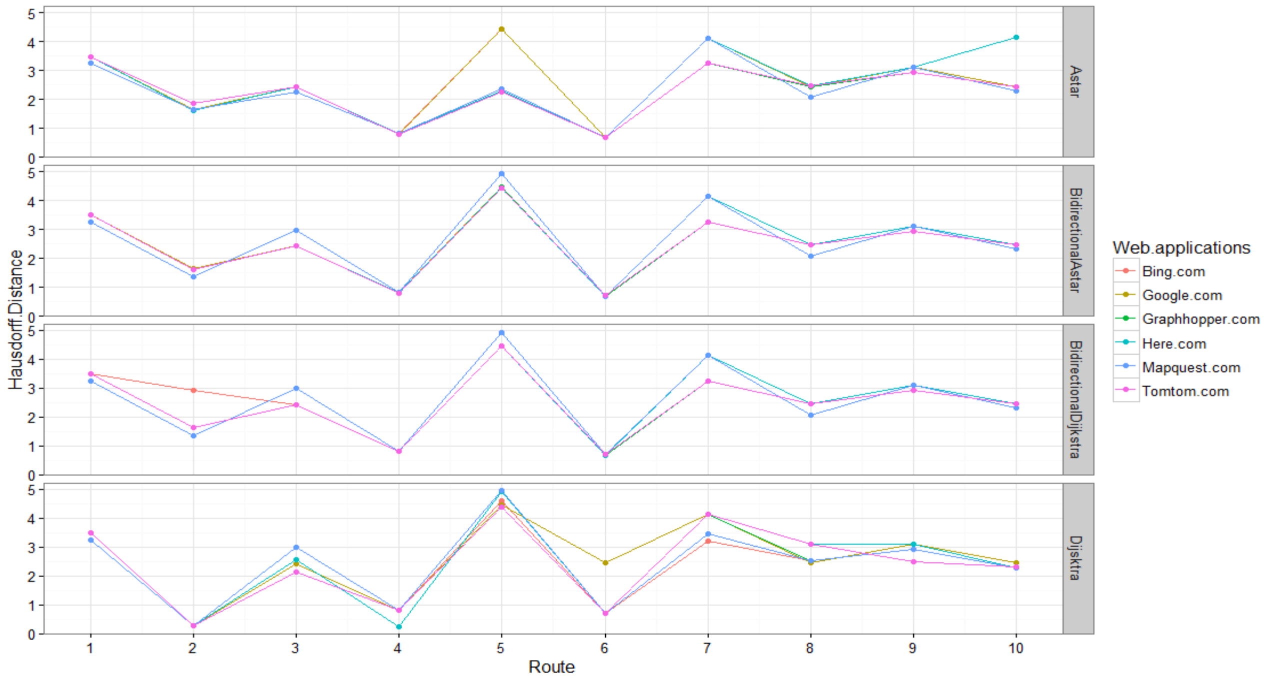

Fig. 3.
The results of a comparison using Hausdorff Distance

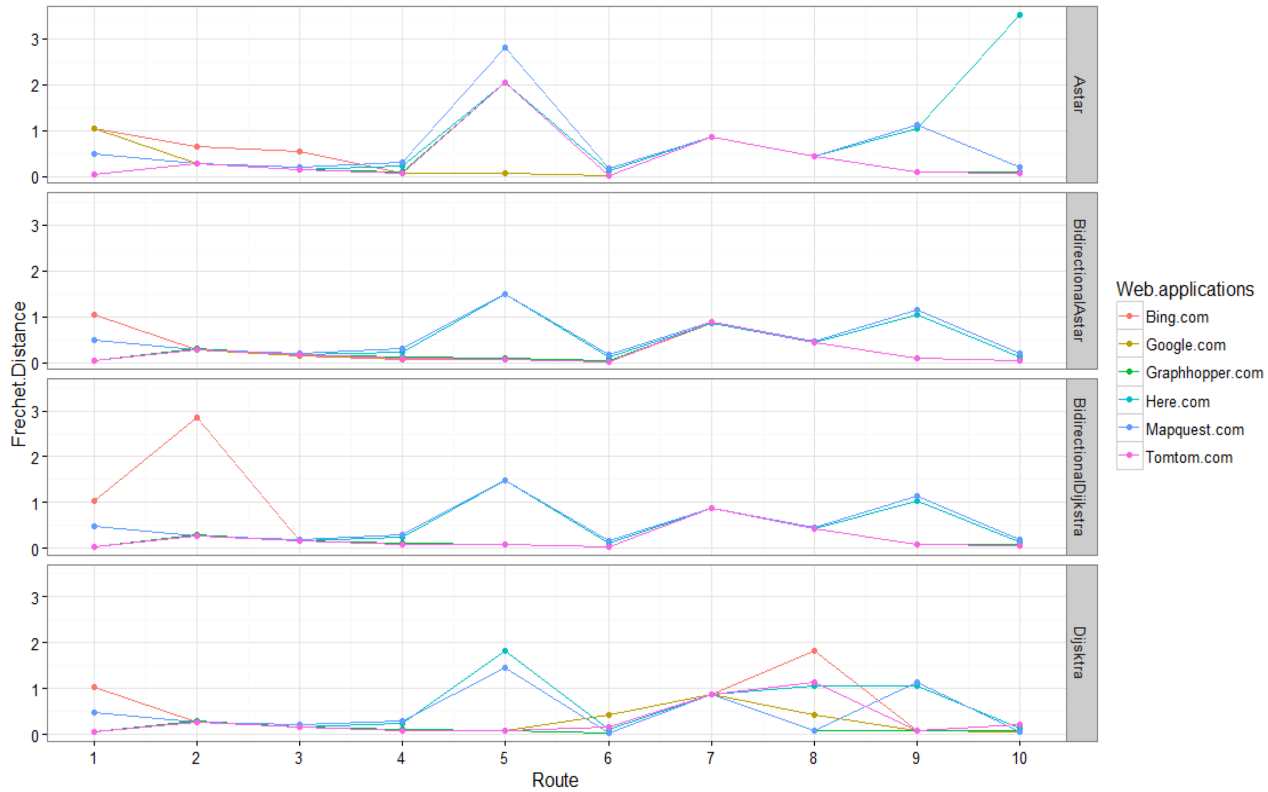

Fig. 4.
The results of a comparison using Fréchet Distance

The values in the pictures are not normalized. The bigger the value of the similarity measure, the smaller similarity between the trajectories is. The Fréchet Distance results are not so big, that they mean; the distance between the two trajectories is minimal, and therefore the trajectories are very similar. The worst comparison similarity results of the two trajectories for Fréchet Distance is route 5. It could have been caused by the quality of the obtained data, which are supplied by the web application or by the calibration of the implemented routing algorithms. Relatively the same similarity results we obtained by Hausdorff Distance. The bigger the Hausdorff Distance, the bigger is the distance between the points in the two trajectories. The high results of the Hausdorff Distance are caused, by the trajectories, which were routed by borders with the Czech Republic by our routing algorithms, which are different from the trajectories from web application. Our routing algorithms searched for the shortest way only within the Czech Republic and web application, for example, had the shortest way going through Poland. As a result the web application algorithms show a different trajectory as opposed to our own routing algorithm. From the results we can see, that the bigger the value of similarity of two trajectories, the smaller similarity is between the trajectories. The worst similarity results we obtained using DTW. The high values of the results could be caused by not defining the distance for points to be considered equivalent. The length of the trajectories between two points can vary by one hundred of meters to one thousand kilometres, and so it can cause big differences in the trajectories.

4. The similarity measures

Table 2 shows us a correlation between the different values of the three used similarity measures. There is a strong correlation between the different similarity values of Fréchet Distance and Dynamic Time Warning. The extreme correlation coefficient (0.7598704) between Fréchet Distance and Dynamic Time Warning was probably caused by the big differences in the length of trajectories. On the other hand, the lowest correlation was between the similarity values, which were executed by Hausdorff Distance and Dynamic Time Warning. Some semi-strong correlation similarity values show Hausdorff Distance and Fréchet Distance.

Table 2
The correlation coefficients between each of the similarity measures

	Fréchet Distance	**Hausdorff Distance**	**Dynamic Time Warning**
Fréchet Distance	−	0.6514869	0.7598704
Hausdorff Distance	0.6514869	-	0.3983476
Dynamic Time Warning	0.7598704	0.3983476	-

Fig. 5 on the left shows that the resulting values have direct dependency. The bigger the values in Table 2 between the Fréchet Distance trajectories we can see of the lower similarity with DTW results (For example route 9). Large discrepancies are always possible when comparing DTW and Fréchet Distances, because they present no bounds on how large the (dis)similarity can be. The high values of DTW could have been caused by its sensitivity and so caused extreme differences in the trajectories. In the left part of the Fig. 5, we can see the results with the weakest coefficient of correlations. It can be caused by Hausdorff Distance not using point matching as opposed to DTW. Fréchet Distance is not really influenced by point matching between the trajectories so much. On the other hand, the value of DTW is influenced, because it requires point matching. Trajectories obtained from the web application are very different in the length of trajectories. For example, trajectory from Here.com contains 30 trajectory points which means that there are large gaps between the points. The trajectory from Dijkstra algorithm has 250 points and therefore, the DTW will show higher values even though the trajectories look similar.

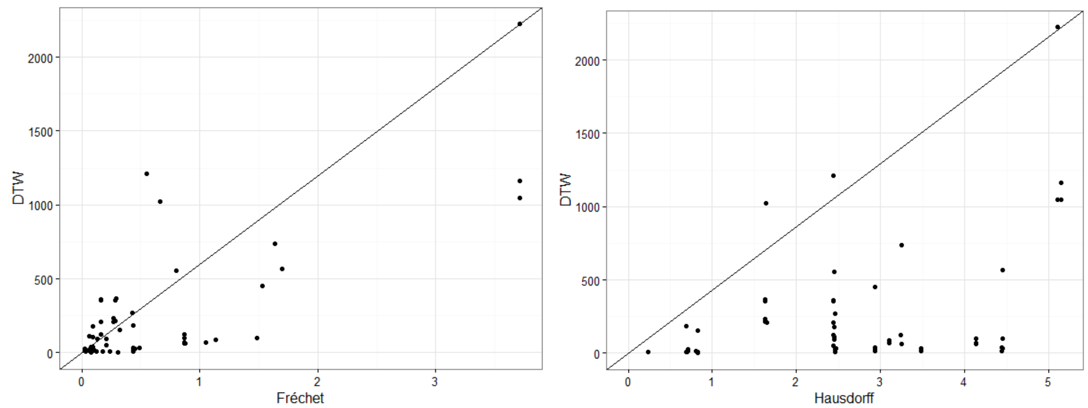

Fig. 5.
Scatter plots comparing the most largely correlated similarity measures, DTW against Fréchet Distance (left) and DTW against Hausdorff Distance ratio (right).

We have found from the obtained results and from the mentioned behaviour typical for DTW, that this method is not suitable for measuring the trajectories. The most suitable metric for the comparison of the trajectories could be Fréchet Distance or Hausdorff Distance. On the one hand, Hausdorff Distance is mathematically simple and is not so much sensitive to the changes in the trajectories. Moreover, Hausdorff Distance allows us to recognize only big differences between the trajectories while ignoring small ones. This behaviour seems the most suitable for the comparison of the two trajectories. Fréchet Distance takes more time to process the information then Hausdorff Distance. On the one hand, the Hausdorff Distance is too ”static”, in the sense that it neither considers any direction nor any dynamics of the motion along the curves. But Fréchet Distance by definition allows us using time to measure the similarity of the two trajectories. For example, one trajectory is faster than the other. It also allows as tracking the speed on the route. In essence, Fréchet Distance considers only the direction (the man and his dog are not allowed to walk back) and the shape of the curves (it chooses the minimum among the leashes for all ways of progression they can make). The best metric/distance for comparison of trajectories from web application and trajectories from our routing algorithms is Fréchet Distance. Fréchet Distance is more accurate and can be adapted to input parameters.

5. Conclusion

In this work, we presented use of similarity measures to compare two or more trajectories in real data. The measures were used to compare GPS trajectories. The data were obtained from well-known web application and from our implemented algorithms. We found differences in the metrics. We determined that the best metric for comparison of trajectories from our routing algorithms and trajectories from web application is Fréchet Distance. Fréchet Distance allow as to compare trajectories in 2D projection, as well as in 3D projection. That way we can detect inaccuracies in implemented route algorithms and so to improve the quality of the routing results.

COMBINING SENSOR TRAFFIC AND SIMULATION DATA TO MEASURE URBAN ROAD NETWORK RELIABILITY

Vincenza Torrisi[1], Matteo Ignaccolo[2], Giuseppe Inturri[3], Nadia Giuffrida[4]
[1,2,3,4] *University of Catania – Department of Civil Engineering and Architecture, Catania, Italy*

Abstract: Travel time is likely to be dissimilar for same spatial trajectories. This underlines the need to think about travel time in terms of frequency, and not just of magnitude. A measure of the dispersion of the travel time distribution is Travel Time Reliability (TTR). Its valuation has been receiving considerable attention in recent years, in freight and especially in passenger transport.
This study addresses this need by proposing a methodology for estimating travel time reliability of an extended traffic network at different aggregation level, by using historical radar detector data and a real-time traffic simulation model, incorporating the analysis and the comparison of various TTR measures. The basic variables used are travel times and traffic flows of each link which belongs to the traffic network. Travel times are estimated through an assignment traffic simulation model and the application of a periodic update with movable horizon called rolling horizon, in order to reproduce the dynamic interaction between the level of congestion and users route choices of a congested road network, that is significant non-linear. The statistical measures used to quantify travel time reliability are Standard Deviation, Travel Time Window, Buffer Index, Planning Time and Buffer Time. The described methodology is applied to the urban area of Catania (Italy). Model is calibrated and tested for different network's sizes at various aggregation levels. The findings of this study should be of interest to transportation planners, traffic engineers, and transit agencies in the form of recommendations for implementing travel time reliability in an extended transport network.

Keywords: Travel Time Reliability (TTR), dynamic traffic model, urban road network, standard deviation, Buffer Index.

1. Introduction

The importance of scheduling in personal and freight activities has grown, so that transport unreliability has an increasingly-marked effect on downstream activities. The expectation from these demand trends is more and more that transport should provide high levels of reliability.
Reliability is unanimously regarded as a desirable transport network attribute. There is less unanimity in defining reliability. Technically, a reliable system is one that performs its required functions under stated conditions for a specified period of time. An alternative definition of reliability draws on the attribute of predictability. In this context, a congested road system where speeds at different times of day and different days of the week are consistent with the forecasting, and hence predictable, would be ranked as highly reliable.
It has been widely recognised that travellers do not only take travel time into account, but also travel time reliability. When travel time is affected by high level of variability, travellers typically allow more time for their trips in order to reduce the possibility of arriving late at their destination. Reducing unreliability means that this extra time allowance could be decreased or avoided completely, presenting a clear user benefit.
For these reasons, the evaluation of travel time reliability (TTR) has been receiving considerable attention in recent years, also in consideration of the current extraordinary availability of real time traffic data from sensors, floating car data and traceable personal mobile devices.
This paper proposes a method for estimating travel time reliability on an extended traffic urban network at different aggregation levels, incorporating the analysis and the comparison of various TTR measures based on the combination of real time collected and simulated traffic data.
The remainder of the paper is divided into six sections. Section 2 provides a description of TTR measures in the general context of transportation and discusses the importance of using different indicators representing reliability for specific purposes. Section 3 describes the methodology identifying the significant model variables. Section 4 describes the case study with the relevant data collected for the model development. Section 5 provides the modelling results. Section 6 is the concluding section where the research findings are summarized and their implications for transport planning are discussed.

2. Measures of reliability in transportation

With the growing recognition that road users are more concerned with travel time variability than delay, recent studies have suggested a greater emphasis on increasing reliability than reducing average travel time for transport planning purposes (Noland and Polak, 2002; Brownstone and Small, 2005; Lyman and Bertini, 2008).
It is important to note that "reliability" will mean different things to each of the parties involved. The network provider perspective and the user-perspective are clearly different. This has led to a clear dichotomy in performance indicators, as reported in Figure 1.

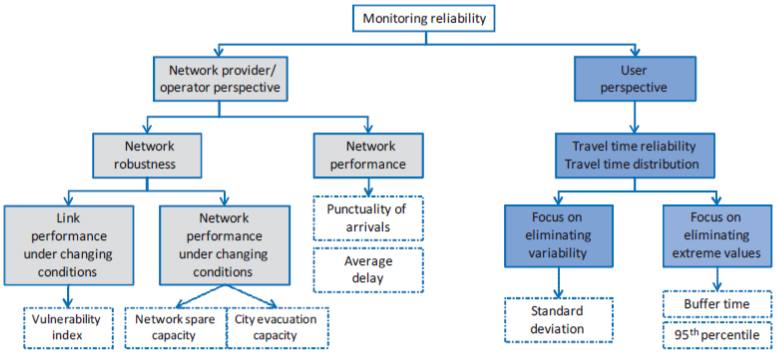

Fig. 1.
Network and uses perspective of reliability
Source: (OECD, 2010)

The user perspective considers specific characteristics of travel times and how he may response to prevailing reliability levels. Research findings suggest that route travel time characteristics are key reliability indicators on road networks (Lo, 2002; Cassir et al., 2001).
The temporal indicators to monitor user perspective of reliability should be used taking into account some considerations regarding the situation for which they can best be used.
Standard deviation is a useful indicator in situations where there is a need to look at the variability in travel times around an average value and it is expected that this variability is not much influenced by extreme delays, the travel time distribution will be not very much skewed (Bates et al. 2001; Lomax et al. 2003).
The 95-percentile value can be used to overcome the eventual problem of not giving much specific attention to possible extreme. This indicator is very appropriate to focus on the range of the travel time distribution and can be very useful to analyse the development of high travel time values.
The Buffer Index can be explained as the extra percentage of travel time due to travel time variability on a trip that a traveller may take into account in order to have a “high” probability of arriving on time. The Buffer Time is the extra time that travellers should add to their average travel time when planning trips relative to the average travel time. The Planning Time Index represents the extra time most travellers should add to a free-flow travel time so as to be fairly confident of arriving at the destination by a certain time. Because these indicators use the 95-percentile value of the travel time distribution, they take into account more explicitly the extreme travel time delays.
This study focuses on Standard Deviation, Travel Time Window, Buffer Index, Planning Time and Buffer Time. These measures are mathematically expressed in the next following section.

3. Methodology

This section presents a methodology for estimating travel times reliability of an extended traffic network at different aggregation levels by using historical radar-detector data and a real-time traffic simulation model, incorporating the analysis and the comparison of various TTR measures.
Travel time is understood as the time elapsed when a traveller displaces between two places in a network. Its duration is related to several factors and it could be dissimilar for similar trips. This underlines the need to think of travel time in terms of frequency, and not just of magnitude. In other words, travel time is defined as a statistical distribution, where the statistics of the variations are thought to exhibit statistical regularity. In this way, travel time reliability can be defined as a measure of the dispersion (or spread) of the travel time distribution.
As stated in section 2, the statistical measures which have been used to quantify TTR are Standard Deviation, Travel Time Window, Buffer Index, Planning Time and Buffer Time.
The Standard Deviation of travel times can be used to describe the extent of travel-time dispersion. It is usually a measure defined in minutes and it can be calculated as shown in Eq. (1):

$$\sigma = \sqrt{\frac{1}{N-1}\sum_1^N (TT_{d,i-j} - M)^2} \qquad (1)$$

where σ is the standard deviation, N is the number of travel time observations in a particular time of day or day of week period, $TT_{d,\,i\text{-}j}$ is a travel time observation on day d during time interval i-j and M denotes the mean travel time.
The Travel Time Window (TTW) is obtained by adding and subtracting the Standard Deviation to the mean trip time (M), as shown in Eq. (2):

$$TTW = \sigma \pm M \qquad (2)$$

The Buffer Index is a buffer time measure, which is normalized to the recurrent travel time and it is calculated with the Eq. (3):

$$B = \frac{(TT_{95} - M)}{M} \qquad (3)$$

where TT_{95} indicates the 95^{th} percentile travel time.
The Planning Time Index represents how much total time a traveller should allow to ensure on-time arrival and it is represented by the Eq. (3):

$$PTI = M \pm M * B \tag{4}$$

The basic variables used are travel times and traffic flows of each link which belongs to the traffic network, estimated through an assignment traffic simulation model (Meschini and Gentile, 2011), periodically updated by real time traffic data through the "rolling horizon" technique, as proposed by Mahmassani (2001), to reproduce the dynamic interaction between the level of congestion and users route choices of a congested road network.
The methodology is tested for different sizes of networks at various aggregation levels. Although many previous studies have focused on corridor- or link-level travel time reliability, this research performs a full range of analysis addressing network level, O-D and path-level, and link-level.
First, N sets of links indexed k = 1, …, N were analysed. It was assumed that estimated travel times and flows were representative of the corresponding link for each time interval during a day d.
The simulation model aggregates traffic data in 15-min intervals to obtain stable values. As a result, each day was divided into 96 time intervals and indexed as i= start of time interval and j= end of time interval. Further, $t_{k,d,i-j}$ is defined as the average travel time at link k on day d during time interval i-j. An array of travel times, symbolised by $T_{d,i-j}$, were constructed for each time interval i-j for all analysed days through the sum of these travel times $t_{k,d,i-j}$, featuring the average total travel time of the considered traffic network, or path or link, as shown in the Eq. (5):

$$\mathrm{T}_{\mathrm{d,i-j}} = \sum_{\mathrm{k=1}}^{\mathrm{N}} \mathrm{t}_{\mathrm{k,d,i-j}} \tag{5}$$

A similar procedure was employed to calculate traffic flows. The total entry flow and the total exit flow of the traffic network can be calculated for the identical set of links by using the same method for estimating $T_{d,i-j}$, as shown in Eq. (6) and Eq. (7):

$$\mathrm{F}_{e_{d,i-j}} = \sum_{\mathrm{k=1}}^{\mathrm{N}} \mathrm{f}_{e_{k,d,i-j}} \tag{6}$$

where: $F_{ed,i-j}$ is the total entry flow of the traffic network, on day d during time interval i-j, in vehicles equivalent units (VEU); $f_{ek,d,i-j}$ is the entry flow at link k on day d during time interval i-j, in vehicles equivalent units (VEU).
Similarly, the total exit flow can be calculated:

$$\mathrm{F}_{u_{d,i-j}} = \sum_{\mathrm{k=1}}^{\mathrm{N}} \mathrm{f}_{u_{k,d,i-j}} \tag{7}$$

where: $F_{ud,i-j}$ is the total exit flow of the traffic network, on day d during time interval i-j, in vehicles equivalent units (VEU); $f_{uk,d,i-j}$ is the exit flow at link k on day d during time interval i-j, in vehicles equivalent units (VEU).
Traffic behaviour changes under different weather conditions and temporal effects (Park et al., 1998; Chung, 2012). Weekdays (from Monday through Friday) and weekends (Saturday and Sunday), have different traffic patterns and characteristics. Therefore, it is essential to analyse them separately. Hence, the traffic data of weekdays and weekends are examined, distinguishing them in working days and non-working day.
This paper also focuses on day-to-day and with-in day travel time variations. The day-to-day variations (variations in travel time when departing at the same time each day) are typically most of interest, as this is the uncertainty that travellers predominantly have to deal with.

4. Case study: data description and model development

Catania is a city of about 300.000 inhabitants, located in the eastern part of Sicily (Southern Italy). The heightened inclination to private mobility has favoured the rise of high car ownership rates and congestion that greatly affects the network reliability.
The described methodology is applied to the urban area of Catania. The study area for this research is broadly represented by the white coloured portion of the territory, whereas the grey portion identifies the neighboring municipalities, which are not included (Figure 2).

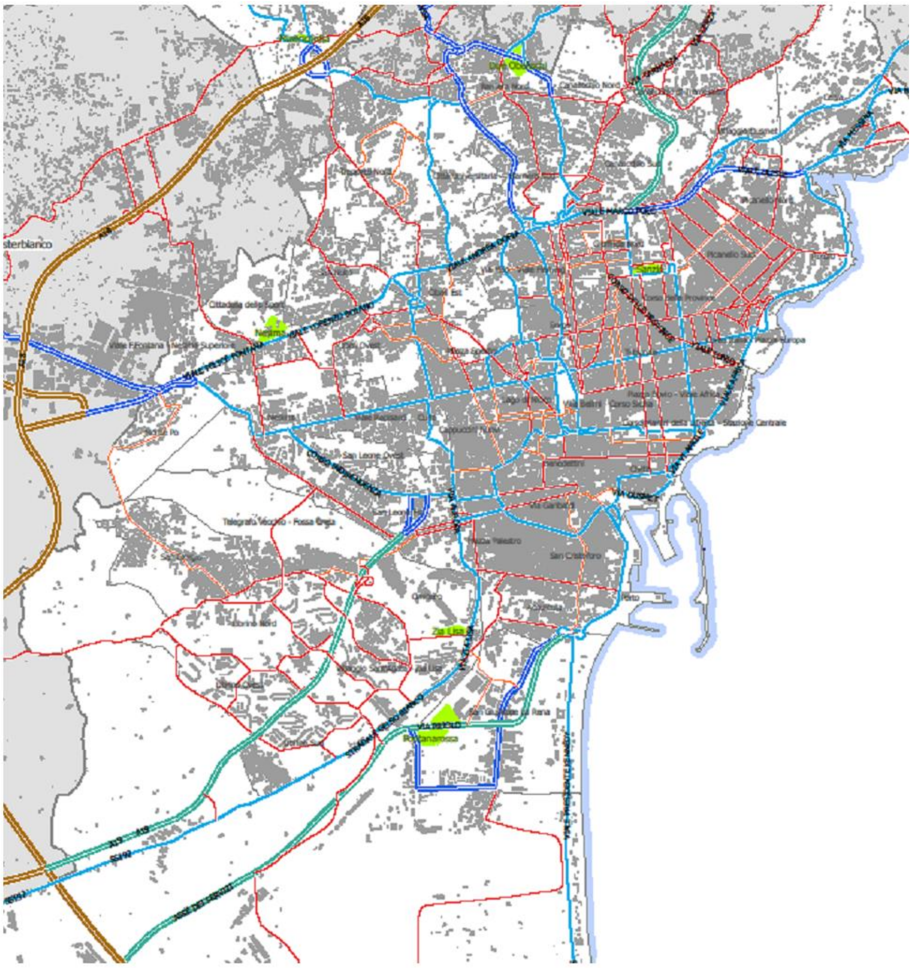

Fig. 2.
Study area and simulated road network

The basic variables used are travel times and traffic flows of each link which belongs to the considered traffic network. They were obtained by the traffic supervisor centre operated by the Department of Civil and Architecture Engineering of Catania's University, where real-time sensor traffic data are combined with simulated traffic data.
This system propagates the spatial and temporal traffic flows measured in less than 1% of the network links and reaching a high level of precision in short term traffic predictions over the whole graph, calculating actual traffic state and predicting its development in the near future. It supplies traffic data including flow, speed, density and queue from simulations integrating available radar detectors' data and Floating Car Data (about 1500 cars), with 15 minutes' time intervals. The amount of data is huge, and so a very precise information can be extracted from them. The 15-min travel times and traffic flows data are simulated for the last year and this year, including weekends and holidays. Because computations are referred to time interval of one hour, simulated traffic data of each 15-min are aggregated and the general form of the proposed model coincides according to these following Eq. (8, 9, 10):

$$\mathrm{T}_{\mathrm{d,i-j}} = \frac{\sum_{\mathrm{k=1}}^{\mathrm{N}} \mathrm{t}_{\mathrm{k,d,i-j}}}{\mathrm{n}} \tag{8}$$

$$\mathrm{F}_{e_{d,i-j}} = \frac{\sum_{\mathrm{k=1}}^{\mathrm{N}} \mathrm{f}_{e_{k,d,i-j}}}{\mathrm{n}} \tag{9}$$

$$\mathrm{F}_{u_{d,i-j}} = \frac{\sum_{\mathrm{k=1}}^{\mathrm{N}} \mathrm{f}_{u_{k,d,i-j}}}{\mathrm{n}} \tag{10}$$

with n = 4 which represents the number of simulation during the time interval of one hour.
These computations refer to traffic data of two weeks, taking into account both working days and non-working day. It was also carry out an analysis on day-to-day travel time variations and on with-in day variations.
As data are distributed according with the Gauss distribution, the general form of Buffer Index of Eq. (3) can be substituted for the proposed model with the Eq. (11):

$$\mathrm{B} = \mathrm{Z} \cdot \frac{\sigma}{\sqrt{\mathrm{n}}} = 1{,}96 \cdot \frac{\sigma}{\sqrt{\mathrm{n}}} \tag{11}$$

where n is the sum of average travel times, σ is the standard deviation for travel times and Z is the reliability coefficient associated to the required level of confidence, equal to 1,96 according to the Z table of the standardized distribution.
Reliability measures have been performed with three aggregation levels: Network level, Path Level and Link Level.
For the first level analysis, the study network is represented by the graph shown in figure 2.

For the second level, three routes with similar lengths connecting the same O/D pair has been selected (figure 3), named in the following “Ognina”, “Passo Gravina”, and “Corso delle Province”. This origin/destination is often used by students, because it connects the University with one of the most important squares for its strategic location, adjacent to many attractions point such as the waterfront, Corso Italia (characterized by numerous shops) and viale O. Pordenone (which allows the connection between the city centre and neighboring municipalities).
The third level concerns the comparison of two links with similar length but different location: Corso Italia link (1.061 meters) in the city centre of the urban area and Viale Marco Polo link (1.262 meters) in the peripheral zone.

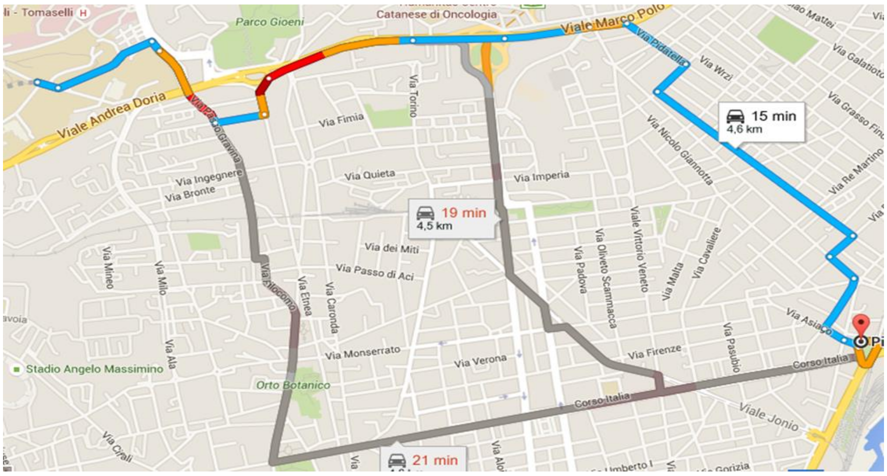

Fig. 3.
Three selected routes: Ognina (right), Passo Gravina (left) and Corso delle Province (middle)

5. Modelling results

In this section the value of TTR at different network aggregation levels are examined to evaluate the significance and utility of different measures.
The analysis at network level was performed by using average travel times and traffic flows calculated starting from the characteristics of each individual link that belongs to the considered transport network. Thus, it is possible to globally describe the characteristics of the network. Table 1 summarizes the results related to Buffer Index, Planning Time and Buffer Time and the difference between average travel time and planning time is represented in figure 4. Figure 5 shows the relationship between average travel times and traffic flows: with increasing traffic flows there is also a proportional increase in travel times. This happens particularly at peak hours and on weekdays due to commuting phenomenon.
Path level analysis is also focused on the same traffic variables. For an even more detailed study, it was performed a day-to-day variations and with-in day variations analysis of travel times and traffic flows, determining the values of average travel time, standard deviation, buffer index, planning time and buffer time for each selected path, as shown in Tables 2 and 3. The same methodology was applied to the third aggregation level and results are shown in Table 4.

25/06/16	2.758	2.87	0.59%	2.774	0.976	3.100	2.18	0.83%	3.126	1.544
26/06/16	2.670	0.10	0.01%	2.670	0.016	3.030	0.18	0.05%	3.032	0.091
27/06/16	2.773	3.79	0.78%	2.795	1.297	3.125	3.63	1.37%	3.168	2.569

As shown in these tables, all standard deviations of parameter distributions were significantly different from zero. When travel time on a link varies widely, Standard Deviation is high and reliability is low. On the other hand, when all trips take more or less the same time, Standard Deviation is low and reliability is high.
The analysis of Buffer Index indicates that as the buffer time metric decreases, TTR increases. The elaborations deriving from the comparison of different paths, show in some cases that routes with higher values of average travel time presents best results as regards travel time reliability.
These results indicate that it is possible to test the direct link between traffic congestion and TTR. In fact, the higher divergence is during weekdays, when the phenomenon of commuters is greater. However, a congested network does not have to be unreliable. Unreliability refers to unanticipated delays, and therefore a congested network is not necessarily unreliable because journey time along a congested road can be fairly predictable. That said, it is also recognised that remedial actions directed at congestion can improve reliability and, similarly, actions that improve reliability can reduce congestion. This assessment is synthesised in the next section into recommendations for implementing travel time reliability in extended transport network.

6. Conclusions

In this paper, reliability is defined as the ability of the transport system to provide the expected level of service quality, upon which users have organised their activities. The key word is "expected". According to this definition, reliability can be improved either by supplying a higher level of reliability, or by changing expectations of the level of reliability.
As stated in the introduction, the evaluation of travel time reliability has been receiving considerable attention in recent years, and a robust and consistent assessment of network performances should be developed in order to ensure good level of reliability.
In this way, the paper proposes a methodology for estimating travel time reliability of an extended traffic network, incorporating the analysis and the comparison of various TTR measures. Although many previous studies have focused on corridor- or link-level travel time reliability, this research performs a full range of analysis addressing to different aggregation level: network level, path-level, and link-level.
In this regard, an effective and efficient procedure for collecting and gathering traffic data is essential to perform an accurate assessment and analysis of transport network and its components. However, the collection of comprehensive and reliable traffic data is challenging in many ways. Data collection is often inadequate, incomplete, imprecise and expensive.
This study overcome this issue taking advantage of Intelligent Transportation Systems (ITS) technologies, in particular by using the traffic data obtained through an assignment traffic simulation model.
The basic variables used are travel times and traffic flows of each link which belongs to the network and they were used for calculating and comparing different TTR measures: Standard Deviation, Travel Time Window, Buffer Index, Planning Time and Buffer Time.
Results show that these temporal indicators to monitor user perspective of reliability should be used taking into account some considerations regarding the situation for which they can best be used. Their use is important for informing decisions on achieving more optimal levels of reliability on surface transport networks, and for the selection of best action strategies. For this purpose, there are many techniques and instruments available that can be used to improve the reliability of the transport network: physical expansion of capacity, better management of capacity, pricing mechanisms to deliver a market for reliability and information systems intended to mitigate the adverse consequences of unreliability, rather than to reduce the incidence of the unreliability.
Focusing on the last one, information systems can reduce the consequences of network unreliability. Network demand can be deflected away from the site of congestion or traffic incidents. Information can be provided to users to mitigate the effects of poor reliability; it can also reduce stress associated with unreliability, and enable the problems associated with delays to schedules to be managed. Different tools exist for delivering this information, including variable message signs, car navigators, the internet, and text messages on mobile phones.
In conclusion, by conducing similar analysis in other regions, transport planners and agencies can determine how local factors affect travel time reliability and whether they can improve reliability by imposing travel-time penalties or other mechanisms on trips to and from specific locations based on real-time traffic data.
Further research needs to be conducted to investigate the temporal and spatial stability of the proposed models as well as to validate the results of this study. The presence of only some traffic parameters in the models might suggest that other variables may improve the model specifications, thus additional variables might be examined in future studies.

THE VITALITY OF TRAFFIC DIRECTIONS IN ROAD NETWORKS WITH RECURRENT CONGESTION AND ITS EFFECT ON ROAD TRAFFIC DESIGN

András Szele[1], Lajos Kisgyörgy[2]
[1] Institute for Transport Sciences, Hungary
[2] Budapest University of Technology and Economics, Hungary

Abstract: In a case study about congestion in Budapest it is presented that in case of excessive congestion in the main direction of traffic flow, traffic from minor directions can still very easily access the overcrowded main direction. This phenomenon was named the vitality of the minor directions. Our study focuses on the vitality of these traffic directions, its changes during congestion, and its applicability in traffic design. The vitality of traffic directions was defined. The aggregated vitality of the minor directions and the speed of the main direction were found to be closely linked. The concept of vitality quantifies the change of traffic routing, including its network effects under congested and normal traffic conditions, on road networks with recurrent congestions. The methodology for designing a congestion-related road network provides a design method that can play a key role in effective urban traffic control strategies at both a strategic and a tactical level.

Keywords: congestion-related approach, road design in road network, recurrent congestion, congested intersection, traffic direction vitality.

1. Introduction

Congestions in modern cities have become a customary and accepted attribute of traffic operation. On the road networks of urban areas, congestions are usually caused by the lack of capacity of one, or sometimes more, cross sections. The lack of capacity takes a variety of forms: long queues, unacceptably low speeds, unreliable travel times and delays, which all result in a transport system with higher costs. The main roads in urban areas are so heavily and recurrently congested for longer periods that forecasted traffic volumes have in recent decades regularly exceeded the design capacity of the roads. Therefore, designing congested road transport networks is the biggest challenge in contemporary transport planning.

According to the OECD-ECMT Summary Document (2007), congestion in cities is generally the result of prosperous urban economic increase. The most important task nowadays is not to eliminate congestion but to avoid excessive congestion, principally when worthwhile solutions are applicable. The congestion can be considered excessive when the marginal costs of congestion top the marginal costs of reducing congestion. Much remains to be done to solve the problem caused by the oversaturated roads, but there is no ideal solution. The traditional strategic and design solutions either release existing capacities or build new road capacities. Both of them represent a temporary solution: the traffic of congested road networks will need to be managed in the near future. Goodwin (2004) pointed out that there is no known worthwhile solution to solve the congestion problem and only road charges and its complementary actions work in practice.

Recurrent congestion is caused by regularly or periodically acting factors on the road network and shows a high degree of variability in some of its factors. When near full capacity, the vulnerability of traffic to rapid disruption is very important in the formation of traffic jams. Congestion has an impact on both average travel speed and travel time reliability, with reliability being more important for road users (OECD-ECMT, 2007).

Literature contains a wide range of studies on road congestion. The findings are generally either too sophisticated for traffic design, too complicated, or are not compatible with the design system. New methodologies for the traffic design of road networks with recurrent congestion is not within the focus of attention of designers and was not included in the standard design procedure until the 2000s (Garber and Hoel, 2009), even though the necessary calculation procedures had been available since the 1950s. These procedures have stood the test of time well. However, it is worth underlining that these calculations generally will not be implemented in the design process (Hobbs, 1979) and the methods only appeared in comprehensive design books around the end of the 2000s (Bell at al., 2006). The most cited calculation method is the shock wave theory (Lighthill and Whitham, 1955), which can be easily applied by traffic designers.

During the design process of road networks for densely built-up areas, designers generally do not have enough space or funds for a good solution to improve traffic operation. Congested traffic cannot be efficiently managed by the traditional tools of traffic engineering: they require a new, congestion-related approach. This congestion-related approach accepts congestions and rather tries to influence, regulate and manage the existing demands. The use of the tools of the congestion-related approach requires a thorough analysis of the reasons for and effects of road networks with recurrent congestions. New approaches are needed to improve the new design tools for this well-known traffic phenomenon. The signs of a promising new approach were described by Vörös and Szele (2005) in a case study about congestion in Budapest. As Vörös and Szele pointed out, in excessive congestions the traffic of the minor directions could very easily ingress in the congesting main direction. This phenomenon was named the vitality of the minor directions.

[2] Corresponding author: kisgyorgy@uvt.bme.hu

Literature contains no studies on the chosen topic, so this research aims to fill a void. The study focuses on the vitality of the traffic directions, its change during congestions, and especially on its applicability in traffic design. Using the vitality of the traffic directions to study road networks afflicted with recurrent congestion is a new approach that quantifies the network effects of the congestions. The preparation of a congestion-related road network design methodology provides to elaborate a design method that actually works in practice.

2. Methodology

The vitality of a traffic direction was interpreted in the following framework model. The users of a road network with recurrent congestions generally use a certain road section on an everyday basis, with most drivers being familiar with the usual traffic jams and the rat-runs. Motorists formulate their own strategies to cope with the problem. The most important coping method is routing, by which drivers decide which route they prefer for their trip. The basic decision is choosing between the congested main direction or one of the rat-runs. Unfortunately, drivers located at the decision points are not always in possession of enough information to make a good decision (for instance, the congested road section is not visible), as a result of which many motorists plan their journeys by using the rat-runs in the usually congested periods, without taking into account the rate of congestion at all.

In the period before congestion, the traffic of the main direction remains on the main road and doesn't look for rat-runs. The traffic from the minor directions seeks out the fastest (which is also the shortest) path to merge with the main direction. During this time, drivers choose the main direction. When the congestion time starts, often independently of the actual traffic situation, an increasing number of motorists choose the rat-runs. During the congestion, the drivers avoid the main direction and search for the fastest route that leads to the congestion-causing cross section, to thereby merge into the overcrowded main direction as closely as possible to the bottleneck.

The reason for the congestion in the main direction is the lack of capacity in the congestion-causing cross section. The small available capacity of this cross section should be used by the main direction, but the vehicles entering at nearby intersections overuse this capacity when they overtake the vehicles in the queue formed in the main direction. That is the reason why the congestion spreads and becomes excessive. The consequences of these processes are the increased amount of traffic on the rat-runs and more merging traffic near the congestion-causing cross section, which further deteriorates the flow of the main direction. The recurrent congestion of the main directions is partly caused by the drivers' expectations of traffic and their decision to use rat-runs. Consequently, the formation and spreading of the congestion is a self-generating process.

The traffic demand behind this process is the well-known principle that drivers take the routes with lowest costs and that are generally the fastest as well. In the case of the congested road network, the lowest cost route for drivers queuing in the main direction is to choose the rat-run to avoid the congestion. However, for drivers arriving from the minor directions, the lowest cost route is to avoid the congested road sections and enter the network as closely as possible to the congestion-causing cross section. The result of both coping strategies is the development of traffic on the rat-runs, which seeks out the merger point closest to the congestion-causing cross section. This process generates a significant traffic demand near the bottleneck.

On a road network with recurrent congestion, all traffic directions have a certain capability, which is determined by its location, design, and regulations. These capability shows the extent to which certain traffic directions allow traffic to reach the congestion-causing cross section. This capability is referred to as the vitality of the direction. To quantify vitality, it is proposed to use the quotient of the traffic volume in the examined direction and the egressing traffic volume of the congestion-causing cross section (Fig. 1.). The unit of measurement is the percentage value (%). The capacity of the congestion-causing cross section is finite. As a result, as the vitality of one direction increases, the vitality of another direction decreases. If the vitality of the minor directions increase, the vitality of the main direction will decrease. The aggregated vitality of all minor direction is the reciprocal of the vitality of the main direction. It is assumed that the concept of vitality will play an important role in the description, understanding, and design of road networks with recurrent congestion.

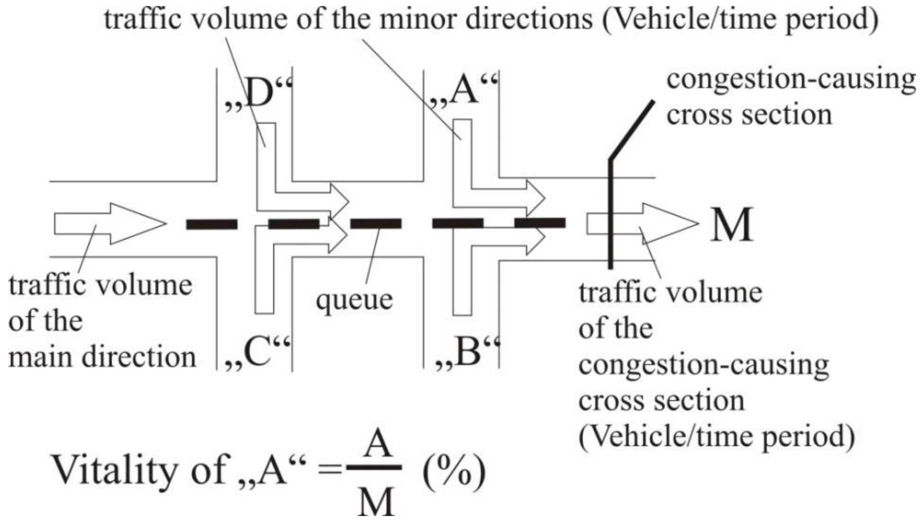

Fig. 1.
The vitality of the traffic directions on a road network with recurrent congestion

The study has to find an answer to the question: Is there a relationship between the vitality of the directions and the degree of congestion? The study used the aggregated vitality of the minor roads, which is equal to the sum of the vitality of all the minor directions. Traffic observation, traffic measuring, and simulation were used to determine the principal components behind vitality. The examinations were implemented on road networks with traffic lights where there was no way to avoid the congestion-causing cross section. It was important that there should be no other congestion-causing cross section or congested crossing roads on the chosen network, so traffic directions could clearly be segregated. For the proper results, the traffic had to make it possible to select both routes and the merging-point to the main direction freely. Such a road network was found in a suburb of Budapest.

3. Data collection

Data was collected by recording videos in Budapest and in its suburbs. This was followed by the determination of changes in the traffic volumes of the main direction and the merging minor directions, as well as of travel times in the main direction. The data collections were conducted in the morning peak hours. The temporal change of traffic volumes and vitality was calculated on the basis of the data. The minor roads with excessive vitality and the most important traffic factors are shown in the figures. Two locations were chosen to collect data for the research.
The first location, Egér Road in Budapest (Fig. 2.), links the southwestern suburbs and the south of Budapest. The involved four-lane road section is 3.5 km long, with traffic regulated by 6 signalized intersections. The collected data was used to perform traffic simulations, the outcomes of which were used for the analysis.

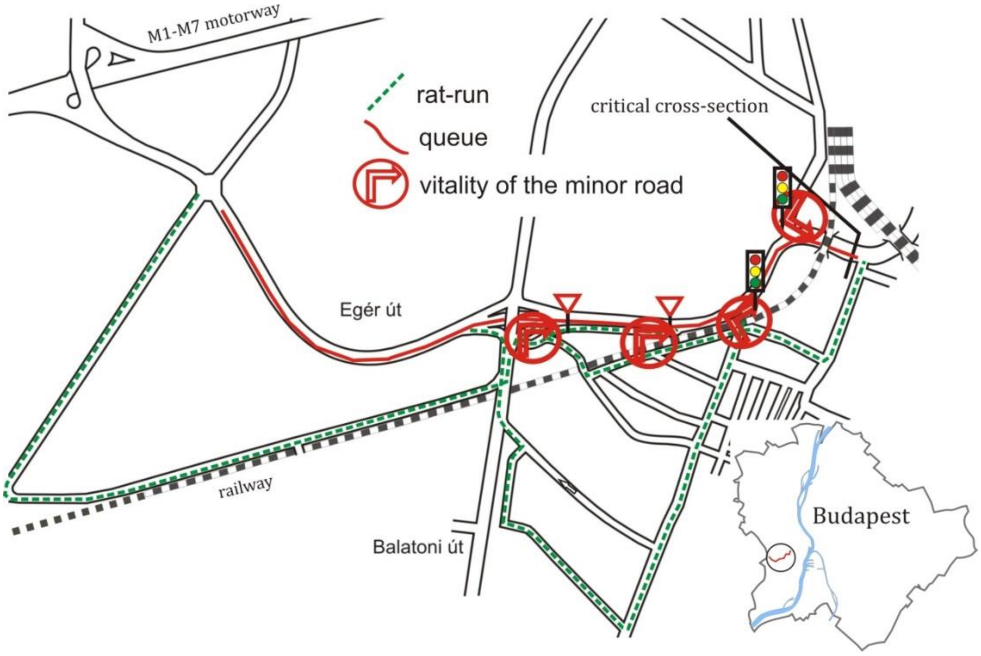

Fig. 2.
Minor directions with excessive vitality on Egér Road, Budapest

The second location, Balatoni Road in Diósd (Fig. 3.), plays an important role in commuter traffic to Budapest and the M0 ring around Budapest. The involved two-lane road section is 1.2 km long and contains two roundabouts and 6 additional minor roads regulated by “Give Way” signs at their respective junctions. The outcomes of the collected data were used directly for the purposes of the analysis.

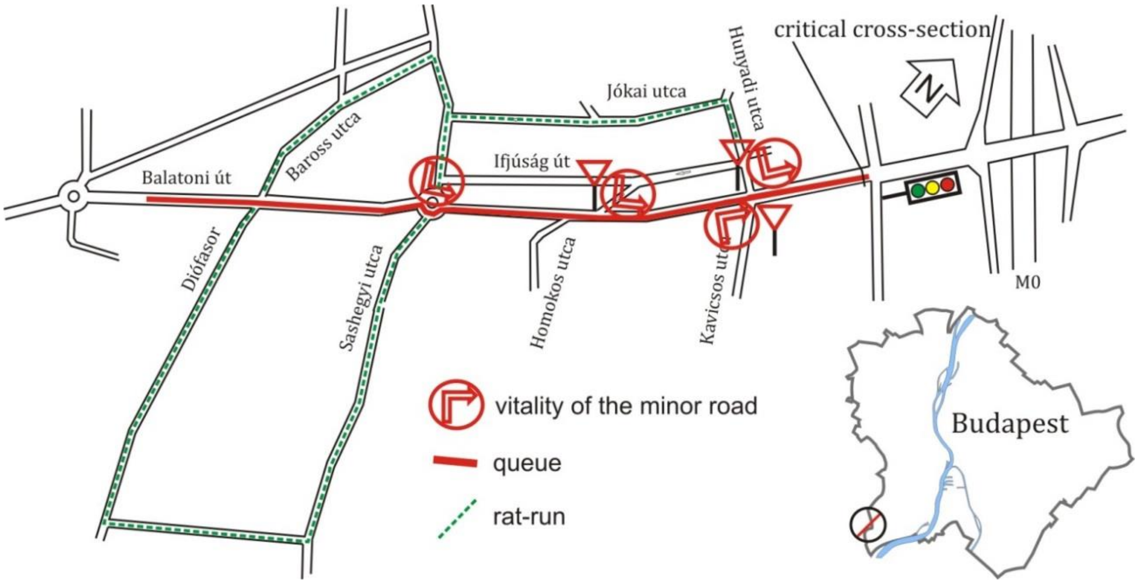

Fig. 3.
Minor directions with excessive vitality on Balatoni Road, Diósd

4. Is there a relationship between the vitality of the directions and the degree of congestion?

To answer this question, a traffic simulation was based on the traffic measured on Egér Road during congested conditions. Five minute units of the simulation traffic volume results were added together to specify the vitality of all directions. The vitality of all minor directions was aggregated to compare the vitality of the main direction. The congestion degree has been taken into account as the 5-minute-average travel speed of the congested main direction. A faster travel speed means a lower degree of congestion. The aggregated vitality of all minor direction (Fig. 4.) before the formation of the congestion was 36%, which increased to 64.5% as the congestion worsened. Though the variation of the vitality showed a clear increasing tendency, the increase was volatile: there were significant differences even in the 5-minute-average values. During the congestion, the speed of the main direction was almost uniformly descending. The aggregated vitality of the minor directions and the travel speed of the main direction change together.

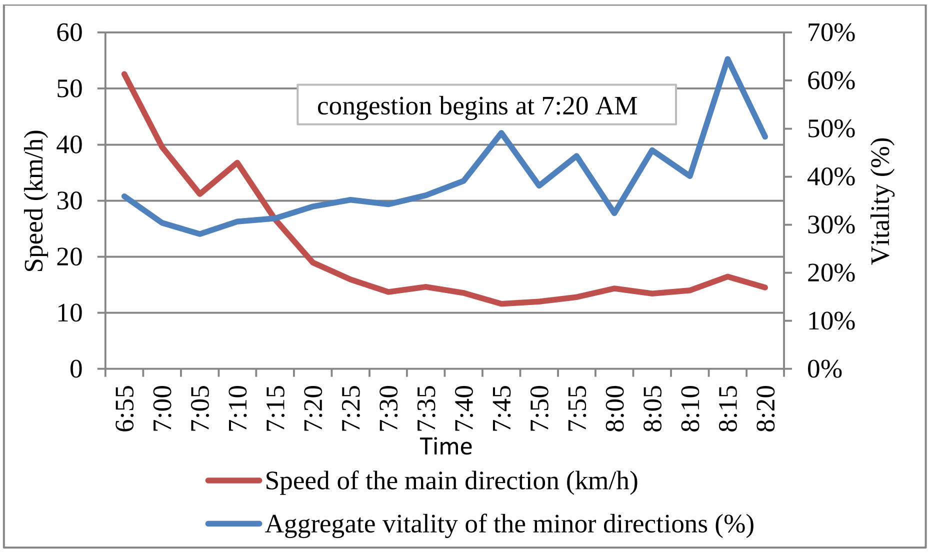

Fig. 4.
The change of the aggregated vitality of the minor directions and the speed of the main direction during the congestion time on Egér Road, Budapest

In the case of Balatoni Road in Diósd (Fig. 5.), the traffic volumes of all directions were counted and aggregated to a 5-minute-average to specify the vitality of all the directions. The travel speed of the main direction was measured and averaged to a 5-minute-average as well. In this case, the aggregated vitality of all minor directions showed a non-uniform ascending tendency starting from 32.3% (before the formation of the congestion) to a value of 67.7% (at the lowest speed in the main direction). The non-uniformity of the increase can be explained by the temporary decrease in the vitality of the minor roads as the queue accelerates at the green signal. During the congestion, the speed of the main direction was almost uniformly descending. In this case, the aggregated vitality of the minor directions and the travel speed of the main direction also changes together; however, the relationship between these factors is not clear.

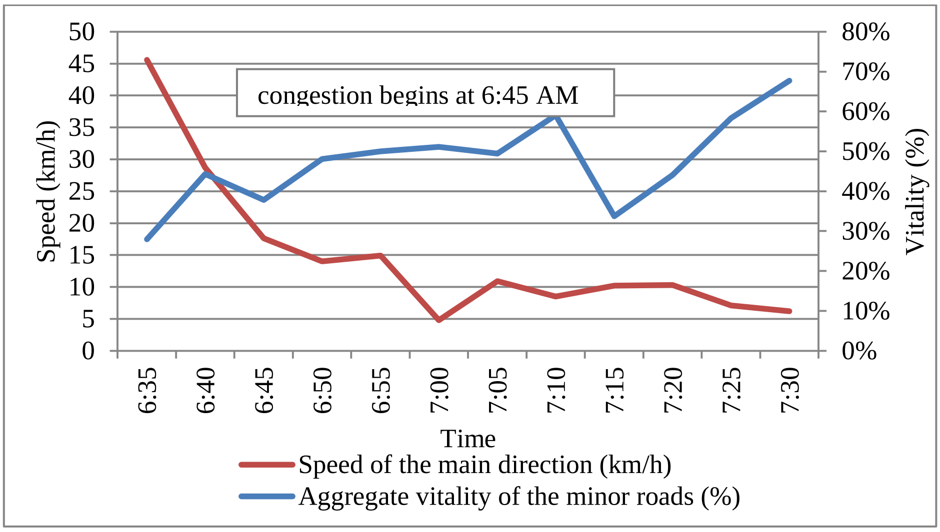

Fig. 5.
The change of the aggregated vitality of the minor directions and the speed of the main direction during the congestion on Balatoni Road, Diósd

To understand the relationship between the speed of the main direction and the aggregated vitality of the minor roads during the congestion, charts were created based on the results of the measurements that examined congested road networks. As shown by Figure 6, Egér Road experienced only small changes in the aggregated vitality of all minor roads during the formation of the congestion, while speed decreased from 52.6 km/h to 15.9 km/h. After the increase of the congestion, the speed remained within the range of 11.6-16.5 km/h, while the vitality fluctuated widely between 32% and 64%.

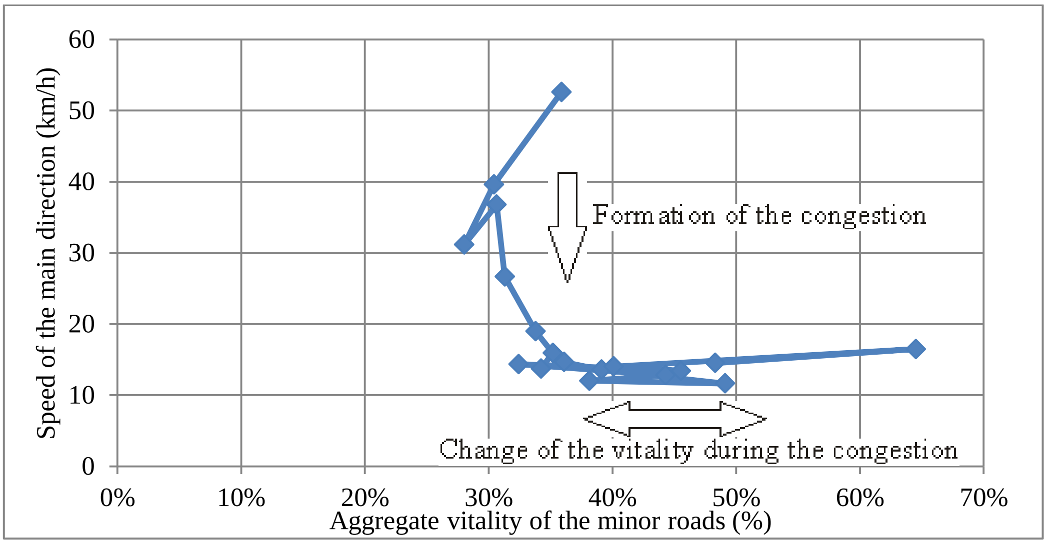

Fig. 6.
The relationship between the speed of the main direction and the aggregated vitality of the minor roads during the congestion on Egér Road, Budapest

Considerable changes were observed on Balatoni Road during the formation of the congestion (Fig. 7.). Speed and vitality decreased almost equally, with considerable fluctuations in both. The speed reduction from 45.6 km/h to 14 km/h was parallel to the growth in aggregate vitality from 27.9% to 48.1%. In this case as well, speed remained within the range of 10.9-6.2 km/h even after the building up of the congestion, while vitality fluctuated widely in the range of 33.7% to 67.7%.

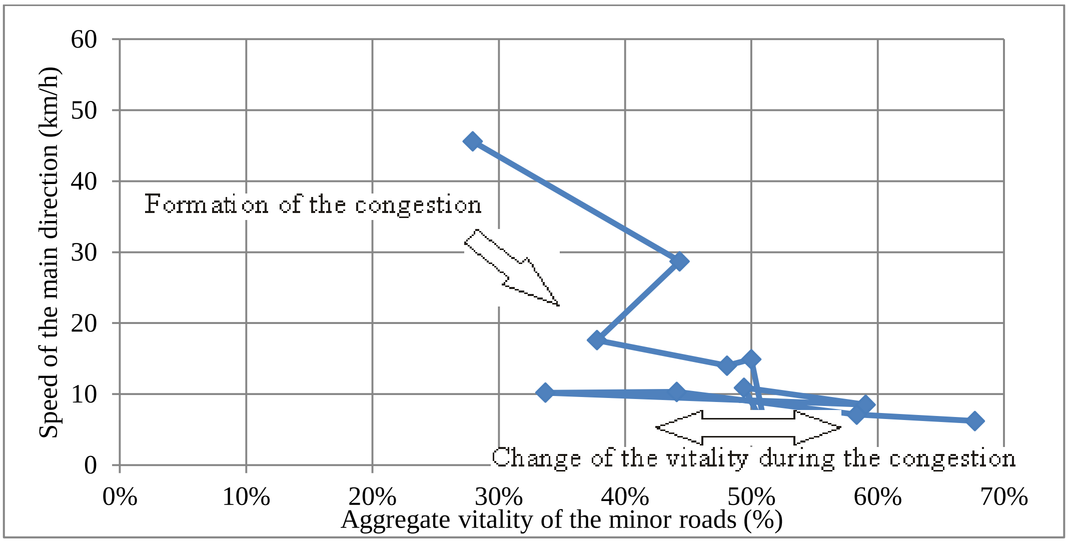

Fig. 7.
The relationship between the speed of the main direction and the aggregated vitality of the minor roads during the congestion on Balatoni Road, Diósd

5. Discussion

According to the research, the role of the directions also changed in addition to the speed of the main direction during the formation of the congestion. There is a close, not thoroughly clarified relationship between the aggregate vitality of minor directions and the speed of the main direction, and consequently the degree of the congestion. Simultaneously to the decrease in speeds of the main direction, the aggregated vitality of the minor directions increased from around 30% to around 70%. At the same time, the speed of the main direction decreased from 45-50 km/h to 5-12 km/h. During the formation of the congestion in the first examined case, the decreasing of the speed occurred without a change in vitality. In this case, the increase of the traffic volume in the main direction probably slowed the main direction, then the minor directions could ingress very effectively into the low-speed main direction. In the other examined case, the decrease in speed was parallel to the change in vitality. It is assumed that the increasing rate of the minor direction contributed to the slowing of the main direction. The most important observation is that the aggregated vitality of the minor directions is generally very high and variable at the low speed of range. The very narrow range of speed of the congestion and the similar vitality and speed values of the two fundamentally different examined road sections are remarkable. During the formation of the congestion and during the congestion itself, vitality can change significantly. This change characterised the vitality. Based on detailed research, it is advised to classify vitality.

6. The vitality of traffic directions in traffic design

The concept of vitality quantifies the difference and the change of traffic routing under congested and normal traffic conditions on road networks with recurrent congestions. The change of traffic routing and the existence of the minor directions with excessive vitality indicates the inadequacy of current road network traffic designs and questions state-of-the-art traffic regulations and traffic design methodologies. Cutting back minor directions with excessive vitality is essential to the success or failure of the traffic design. Excessive vitality could principally be limited by the capacity distribution of the intersection traffic design. Significantly slowing rat-run traffic could play an important role in the limitation of excessive vitality. The declared strategic objective is to secure the adequate vitality of the congested main direction. Including the vitality of the traffic directions into the traffic design process provides a new and effective congestion-related tool. This tool could play a key role in making effective urban traffic control strategies both on the strategic and on the tactical level. The development of the detailed methodology is therefore justified.

7. Conclusions

The concept of the vitality of traffic direction was defined. On road networks with recurrent congestions, the aggregated vitality of the minor directions and the speed of the main direction are closely linked. The specific characteristics of this connection deserves additional consideration. The vitality of minor directions helps us clarify the role of traffic directions. The findings imply that the designing of road networks with recurrent congestion should include the effects of the vitality of minor traffic directions. The elaboration of a toolkit is an urgent issue. Another important challenge is to set the territorial division of the road network to be designed and the definition of the design targets.

TRANSPORTING GOODS BY FOOT – AN APPROACH FOR URBAN AREAS

Volker Hartl-Benz[1], Petra Matzenberger[2], Bernhard Rüger[3]

[1,2] *Vienna University of Technology, Institute of Transportation, Research Centre for Railway Engineering, Traffic Economics and Ropeways, Vienna, Austria*
[3] *St. Pölten University of Applied Sciences, St. Pölten, Austria*

Abstract: There's plenty of traffic in today's urban and suburban areas. Although of course the car still has a high share of the modal split, much of this traffic is done by foot, bicycle and by means of public transport. Especially traffic by foot is one of the most important modes of transport in urban areas, often largely underestimated. What if we could use this already existing traffic, especially if it is done in an environmentally friendly way, to transport small goods? The exploratory project "GutZuFuß" ("*Transportation by foot*", founded by the Austrian Ministry for Transport, Innovation and Technology and the Austrian Research Promotion Agency) wants to find out if such a system is realizable, and if yes, under which conditions and requirements. Caused by increasing online-shopping activity and the tight networking of the business world, the amount of transported small goods is growing in the private sector as well as in the area of B2B-operations. "*Transportation by foot*" works as an electronic interface between a registered person who is on her/his way and a client (private or company), who has to ship a good. As a first step, due to the complexity of the problem and in order to minimize risks, extensive customer surveys were conducted. Learning more about the customer's interests and needs should help to establish an attractive goods transportation service by using already existing mobility in urban and suburban areas, accepted by the customers and focused on their needs. This article presents the results of the surveys and gives an outlook what they mean for the future of the project.

Keywords: cargo transport, public goods transport, environmentally friendly, traffic reduction, traffic by foot, needs and requirements, customer surveys.

1. Introduction

Transportation by foot has the goal of using already existing, active and sustainable passenger mobility for small goods transport in cities. The system will connect (for example via smartphone app) persons or companies that want to send small parcels or letters with people who are traveling. Due to the large number of people who are traveling in cities, flexible and fast delivery could be one of the strengths of the system. The project aims to analyze whether and under what conditions the existing active and sustainable mobility may be merged with the need of small-parcel-dispatching.

1.1. Problem and Objective

How should a system like *Transportation by foot* be designed so that it is accepted by potential customers? To clarify this issue, in order to get more knowledge about the frame conditions and success-preconditions for such a service, it is necessary to know something about the interests of potential customers. The aim of this project step is therefore the collection, analysis and interpretation of the wishes and needs that different user groups have on a system like *Transportation by foot*.

1.2. Method

For learning something about the requirements of potential users of the system *Transportation by foot* - customers as well as those offering transport services – surveys by questionnaire were conducted from December 2015 to February 2016. The interviews were held in streets and in certain areas of metro stations. Overall, 675 people were interviewed.

2. Results of the survey

2.1. Basic information

Below, the most important results of the survey will be presented. The number of respondents ("N = ...") noted in the various diagrams varies from chart to chart, as not all respondents answered all questions.
The gender distribution shows a clear imbalance in favor of men: 61% of respondents are men, 39% women. The reason for this imbalance is unclear.
Except for the group of 15-19 year olds, the age categories were divided in ten-year-steps, e.g. 20-29 years, 30-39 years, etc. Almost one third of respondents are between 20 and 29 years old. Slightly less than 20% are each between 30 and 39 and between 40 and 49 years old. The rest of the respondents are distributed among the other age groups, the proportion of each is in the single digits. With rising age, the number of respondents drops.

[1] Corresponding author: volker.hartl-benz@tuwien.ac.at

Most respondents have a job: 43% in full-time, 13% part-time. 28% of respondents are students, 8% pupils. 11% are retired. 3% are unemployed. For this question, multiple answers were possible, i.e. it could for example a student also have a job.

As the reason why they were traveling at the time of the interviews, 25% of respondents said they were on leisure activities. Slightly less, namely 23%, were on the way to or from work. Each just under 20% were on the way to shopping or to certain places such as post office, office, library, etc. 12% were on way to or from their place of education. 4% of respondents said they were on the way to or from medical appointments.

2.2. General results

On the fundamental question of whether a person wants to participate as a customer in *Transportation by foot*, the respondents answer as follows (see Fig. 1):

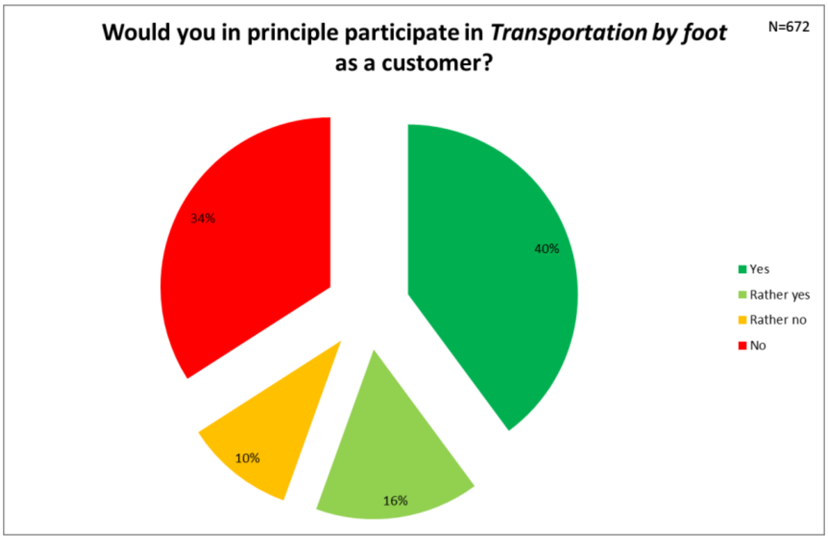

Fig. 1.
Participation in Transportation by foot as a customer

Participation as a customer means to receive a packet from a person who works for the system. Just over 50% of respondents can imagine participating in the system in this way.

The benefits that customers see in *Transportation by foot* are shown in Fig. 2. The greatest benefit of the system is seen in more flexible delivery times and shorter or less routes for the customer. But also "fast delivery", "more cost-effective" (as previous systems, note) and "environmental protection" receive widespread support. When it comes to "environmental protection", it has to be considered that the approval to this answer-option may mainly be given because it is seen as socially desirable. "Real-time shipment tracking" and above all "personal relations to deliverer" experience lesser support.

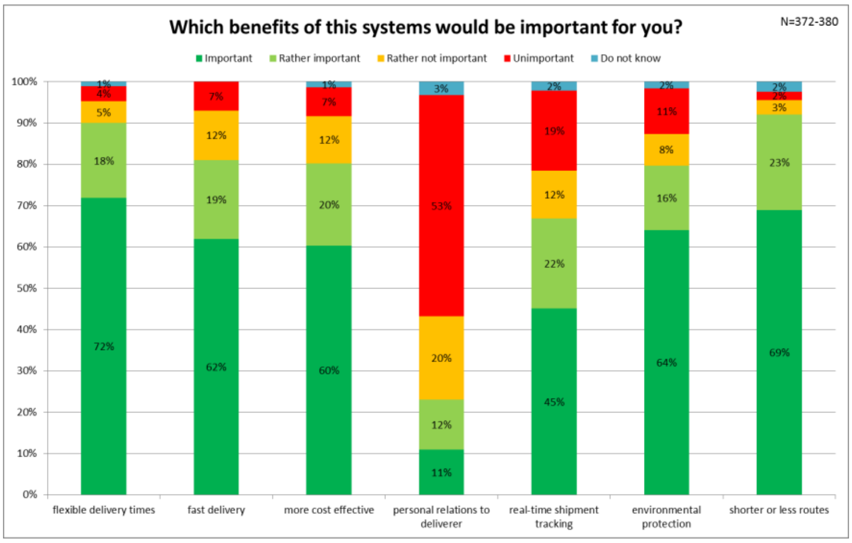

Fig. 2.
Benefits for customers

About 40% of respondents can think of active participation in *Transportation by foot* as the carrier of (small) shipments (see Fig. 3). 47% clearly rule this out; further 12% tend to rule out active participation.
Which packages would be transported by those who have an interest in participating actively? 95% say they would transport small packages. Letters would be picked up by 67%, food purchases by 51%. 43% say they would also transport fragile items. Unsurprisingly, substantially sized packages experience the slimmest willingness to transport: Only 24% said they would pick them up.

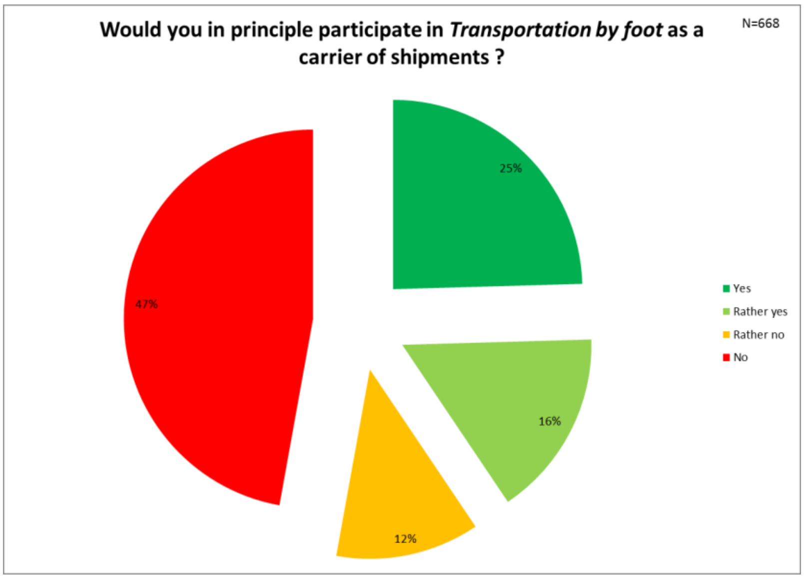

Fig. 3.
Participation in Transportation by foot as carrier of shipments

An important question is: What motivates people to participate actively in *Transportation by foot* as carrier of packages. This is a key point especially for any real implementation of the system. Fig. 4 reveals:

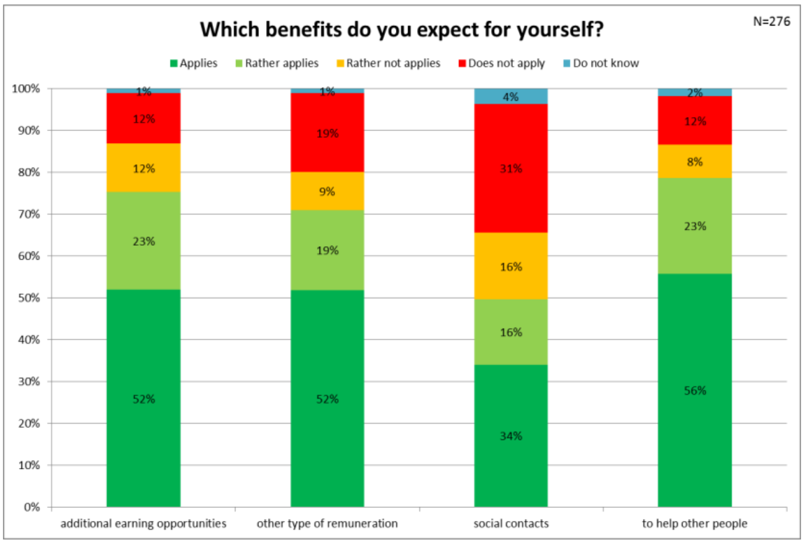

Fig. 4.
Expected benefits of Transportation by foot when participating as a carrier of shipments

Evidently, the three answer choices "Additional earning opportunities", "Other type of remuneration" and "To help other people" each experienced about the same high levels of agreement. The answer choice "Social contacts" (meaning the social interaction in the packet transfer) drops significantly in contrast. Attention is given to the answer choice "To help other people" in the interpretation of the result. With a total of almost 80% this answer option received the highest approval to the question of what benefits one personally sees for himself as a carrier at *Transportation by foot*. But here there is again the possibility of the influence of social desirability, i.e. respondents give a certain answer not because they are actually of this particular opinion, but because they believe that this particular answer is expected of them.
"Other type of remuneration" means primarily a kind of service exchange. For example, it is conceivable that a person in exchange for the delivery of a package provides a service such as help with shopping, household or working in the garden. A further stage of expansion would be the introduction of a credit system, allowing to compensate the varying

efforts of the different activities (e.g. three deliveries of shipments correspond with once helping with gardening, etc.). The idea of the service exchange was discussed but not elaborated in detail within the project *Transportation by foot*.
Fig. 5 shows the obstacles that could occur at the recruitment of active participants. Only 51% and 63% respectively agree completely or rather with GPS positioning. However, a positioning system like GPS is a prerequisite for the operation of the system. The registration of all participants is also a basic requirement, and with a total of 86% it experiences a substantially higher compliance than GPS. With 85%, the vast majority of respondents agree with the entering of houses with more than one flat. Although this is not a necessary prerequisite for the system, it is helpful for practical implementation in any case.
The most interesting and perhaps most critical point is the agreement to additional spent time at pickup and delivery of shipments. 52% (of those who have an interest in participating actively as carrier) clearly agree to invest some time; another 27% rather agree. Here it may be assumed that it depends very much on the extent of the additional time required, whether it is accepted or not.

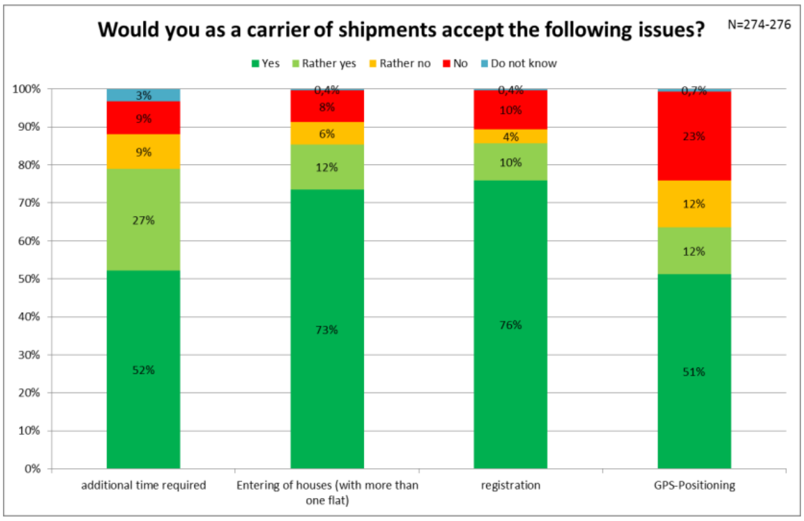

Fig. 5.
Approval with certain issues

Time is a critical factor! This is also shown in the answers to the question what reasons there are to not participate as a carrier of shipments. This question was only asked to persons who showed no willingness to participate as a carrier. The main reason not to participate is the belief of not having time for it. 58% say that they agree, a further 9% rather agree. Thereby "I have no Time" is by far the most important reason to not participate in *Transportation by foot*. Other reasons include the worry of being unable to deliver the shipment at the destination (22% "agree", 19% "rather agree"), reservations due to the unclear legal situation (26% "agree", 13% "rather agree"), a rejection due to a feeling of great responsibility (22% "agree", 16% "rather agree") and the already mentioned refusal of a GPS positioning (31% "agree", 4% "rather agree") by some people.
A concept like *Transportation by foot* must meet certain frame conditions in order to be attractive to people. Fig. 6 shows some of the issues that are expected. 97% of those who have interest in participating either as a consumer or as a carrier want legal protection regarding the transported goods. This means that the carried package should be assured against loss or damage. The participating individuals do not want to bear the risk by themselves. Also, a high percentage of 94% expect safety, for example in terms of transport of consignments (e.g. dangerous goods) or regarding the smooth handover of shipments at start and finish. This requested safety could for example be achieved by the compulsory registration of all participants. A fallback system if the recipient is not there and the package carrier is unable to deliver the consignment is expected by 95%. This would help to avoid that someone is forced to keep a package by himself. When asked whether they expect an evaluation system, 52% say this applies and another 23% say it rather applies. Although the agreement to this proposal is significantly lower compared to the others, a rating system can still be very useful. It can strengthen the trust in the system. Recipients of shipments could rate the carrier for punctuality, reliability etc. and vice versa. These reviews should be visible to all participants in *Transportation by foot*. This would be a strong incentive for all parties to actually keep to agreed times, places etc.

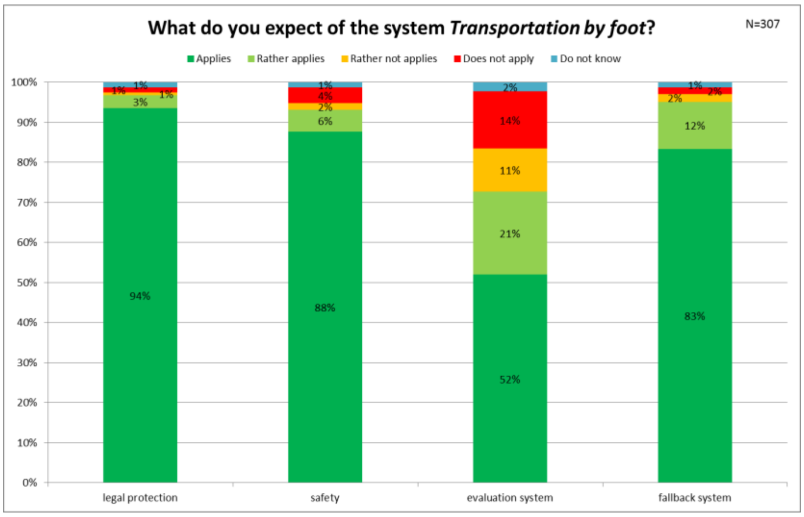

Fig. 6.
Expectations of the system Transportation by foot

2.3. Results from individual groups

<u>Effect of age of respondents:</u>
Surveys in previous projects have shown that younger people are often open about new ideas; older people face such ideas rather skeptically. *Transportation by foot* is no exception in this regard. In both the participation as customers and as carrier of shipments, younger people show significantly more interest than older ones. So 68% of 20-29-year-old would participate as customers in *Transportation by foot*, but only 45% of 60-69 years and only 26% of 70-79-year-old would do so. The picture is very similar when it comes to the participation as a carrier of shipments. 55% of 20-29-year-old would participate as a carrier, but only 29% of 60-69-year-old would do so (and even only 8% of 70-79 year olds).
The questions about the benefits of the system show a different picture. In some cases both the benefits for a customer and for a carrier of shipments is estimated lower with rising age. Such is the case with the benefits of fast delivery, real-time shipment tracking and additional earning possibilities. In most cases, age has no influence on the perception of benefits. And in some cases, the benefit is estimated higher with age, e.g. the benefits of personal contacts and the possibility of another form of compensation. As explained above, this could be a kind of service exchange by providing help with craft activities, purchasing etc. (see Fig. 7). This point deserves special attention because it is obviously a way to appeal to those who at first glance see little benefit for themselves in *Transportation by foot*.

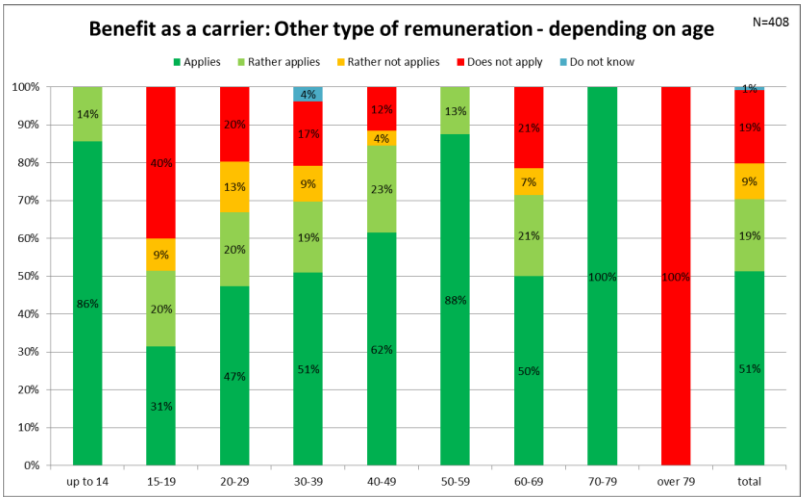

Fig. 7.
Benefit as a carrier: Other type of remuneration, depending on the age of respondents

Age does not have much influence on the approval of certain issues and on what people expect from the system. One can only mention that a rating system is expected relatively more by the younger age groups.
If one analyses the reasons why people don’t want to participate in *Transportation by foot* (e.g. "I have no time" etc.), interesting results are obtained. The approval rates to nearly all of these reasons decline with increasing age. Particularly from the age of 60 years on this effect can be observed. There was no reason not to participate in the system which showed an increase in approval with age.

This means that the elderly, although less interested in *Transportation by foot* than the young, have fewer reservations and fears about the system. Perhaps the low interest is therefore only due to an initial skepticism about a new idea, and potential is also available in the long run among the elderly population.

Influence of employment of respondents:

Respondents were also asked about their employment. The categories were full-time employment, part-time employment, student, pupil, housekeeping (without employment), unemployed, pensioner, military or civilian service, apprenticeship and parental leave. The results for people on parental leave, persons who are engaged in housekeeping, military and civil service as well as for apprentices have to be interpreted with caution, as the sample size of these groups includes only a few people.

When asked about participation in the system as a customer, part-time workers, pupils and students showed high interest relative to the average. Lower interest among full-time workers, the unemployed and pensioners were identified. One hypothesis for this result is that the groups that have actual or subjectively perceived less free time available are less interested in participating than the groups with actual or subjectively perceived more free time. This hypothesis is supported by the fact that of the people who do not want to participate in the system as a carrier, 73% of full-time workers say they are unable or unwilling to participate in *Transportation by foot* due to time constraints. Among part-time workers only 55% list this reason, among unemployed 40% and among pensioners 54%.

However, the unemployed and pensioners as outlined previously are also the groups that have little interest in participating as a customer in the system. However, the disinterest of pensioners is mainly connected to age as explained above. The low interest of unemployed people remains unclear.

However, when asked if they would participate as a carrier of shipments for *Transportation by foot*, among the group of unemployed 37% answered "yes" – giving them first place, although this result is put into perspective by the low number of "rather yes" answers (5%). Compared to the average there is also high interest among part-time workers (30% "yes", 23% "rather yes"), pupils (36% "yes", 20% "rather yes") and students (32 % "yes", 24% "rather yes"). The smallest interest is among pensioners with 16% "yes" - and 5% "rather yes" - answers.

Additional earning opportunities are especially important for students (65% "agree", 31% "rather agree") and the unemployed (88% "agree", 12% "rather agree"). For unemployed people the importance of social contacts is above average (63% "agree"). The majority of unemployed people also agree to additional time requirements (88% "agree", 12% "rather agree"), while the majority of students and to a slightly lesser extent the full-time employed are more skeptical.

Influence of gender of respondents:

The effects of gender on the answers in this survey are rather low. Both in participating as a customer as well as a carrier, women show slightly greater interest than men. Also concerning the benefits derived by *Transportation by foot*, women see slightly greater benefits for customers in all points than men. The one exception is the personal contact with the deliverer. In this aspect men see more benefits. The benefits of *Transportation by foot* as carriers are estimated to be slightly higher by men in all issues.

The answers on consent to certain points, the expectations of the system and the reasons against participation are practically identical between men and women. Not being able to drop off a shipment at the destination is the only concern where women show slightly higher percentage than men. Accordingly, more women than men also expect a functional fallback system for such cases. Finally, it is striking that women showed significantly more fear of dangerous goods carried than men (men 28%, women 40%, total 33%).

3. Conclusion

Transportation by foot would make use of existing personal mobility in cities for transporting small goods. The system connects (for example via smartphone app) individuals or companies who want to send a shipment with people currently travelling or planning to do so in the near future. Due to the large number of people who are traveling in cities, flexible and fast delivery could be one of the strengths of the system.

To study the needs and desires of potential participants in *Transportation by foot*, extensive surveys were conducted. Each around half of the respondents showed a basic interest in participating as a customer or carrier of shipments. The deciding factor is the existence of a functioning payment system, which provides monetary incentives as well as new, alternative payment options (e.g. service exchange) to increase attractiveness.

By analysis of the surveys it became clear that time is a very precious resource. A realistic chance for the participation of a larger number of persons is only given when participation is managed with a minimal amount of time required. Good organization and knowledge of the package carrier routes and especially the organization of the package transfers are prerequisites to ensure operation. Other basic requirements include registration of all participants, the legal protection (insurance) and a fallback system, should a shipment not be able to be delivered.

Young people show greater interest in the idea of *Transportation by foot* than the elderly. But older people see quite a benefit in certain points. Fears and reservations about *Transportation by foot* are even less pronounced among the elderly than among young people. In particular, the benefits of an alternative type of compensation are appreciated with increasing age, for example means of exchange of services by helping with handiwork or shopping. So it could be possible to appeal to the older population with a thoughtful and tailored to their needs concept. Due to lower fears and reservations, the conclusion can state that the interest of the elderly for *Transportation by foot* will increase once the system has been introduced and become generally known.

Examining employment shows that the interest in participating in *Transportation by foot* is greater among people who have actual or subjectively perceived more free time, such as part-time workers, students and unemployed people. A focus on these groups - at least for the active participation as a carrier of shipments - is worth considering.

Abstract: There is presented a software product intended for evacuations by using road transport while keeping to all the binding conditions. This software displays all the points important for evacuation and its process by means of digital maps puts out routes in dependence on an extraordinary event. It is possible to manually control inputs, parameters and process of the solution.

Keywords: evacuations, software, road transport.

1. Introduction

One of the basic means for saving a human life is an escape (or evacuation) from affected area to safer area. In the occurrence of an extraordinary event (which endangered human life or health) is necessary to decide about evacuation or about another sheltering process. This decision depends on the responsible authority. From the realised analyses is no doubt that evacuation of citizens or group of persons is a basic mean for saving human lives. Moreover, evacuation could be necessary at every moment in every place.
An evacuation could be characterised like a transfer of endangered persons, animals or endangered things from designated area. In the basic form, evacuation is characterised like a summary of activities including management and realisation for timely and good organised moving of citizens, moving of necessaries, moving of animals etc. It could be realised during the peacetime or during the war or state of emergency, too. Evacuation is organised moving of persons, animals from the definite area. Stay in that definite area could be caused serious injury or restriction of living conditions (Soušek, 2008; SSHR, 2015; The Czech Ministry of Transport, 2011, Matuška, 2010).

2. Definition of areal evacuation system

With the controlled long-time evacuation of the large area occurred problem about moving of demanded numbers of persons (or animals, or necessary thing) in the possible shortest time period in the definite area. For this evacuation should be used all available transport means. During evacuation, persons are concentrated in the evacuation centres. They are transported from evacuation centres to the reception centres. These reception centres could be situated near the short-time emergency accommodation.
For management during evacuation is necessary to know input data about:

- Transport network ,
- Location of evacuation centres and reception centres,
- Location and capacity of the short-time emergency accommodation ,
- Numbers of evacuated persons,
- The structure of rolling-stock, numbers and capacity of vehicles, location of vehicles.

Like a next step is a necessary draft of evacuation routes with sufficient capacity. On these routes, evacuation will be realised. The solutions are optimal location of evacuation centres to short-term emergency accommodation. Like criteria for the location could be used the distance between definite places or time for transport between these places. Furthermore, is necessary solve allocation of transporting vehicles (stands or garage places) for definite evacuation centres (it is necessary for minimalizing of vehicles delivery delay) (Kamenický et al., 2011; Szabo, 2015; Soušek et al., 2011; Soušek and Viskup, 2011; Fuchs et al., 2015).

3. Modelling of the long-term areal evacuation

For finding another input of data and evacuation process realisation is necessary to use minimum paths search algorithm on the transport network.
Upgraded Danzig algorithm can be found minimal path length, the approximate time for passing, as well. Algorithm is suitable for using distance like criteria (length of minimal path) or time for passing like criteria. For calculation of driving time could be used planned time of passing on designated roads (definite by the class of the road). In this algorithm is easy to use for riding ban on selected paths. With these banned paths algorithm couldn't calculate due to some restrictions on operation.
Like a data input for evacuation is an information about numbers of evacuation centres m with numbers of evacuated persons $a_1, a_2, \ldots, a_m$ and n numbers of short-term emergency accommodation places with capacity $b_1, b_2, \ldots, b_n$. Location of the bus garage (bus stand) $c_1, c_2, \ldots, c_k$ is included, too. These data are pasted in the matrix. First matrix X is

[1] Corresponding author: martin.sustr@student.upce.cz

pasted evacuation centres with places of short-term emergency accommodation for the consumer. In this matrix is solved allocation of evacuation centres to the accommodation (reception centres). In the second matrix Y is bus stand (or bus garage) like a supplier for places of short-term emergency accommodation (the placing of buses for the definite centres). The capacity of garages $c_1, c_2, \ldots, c_k$ are well known and the need for individual evacuation centres $d_1, d_2, \ldots d_m$ will be settled by evacuation manager.
Like criteria in both matrix could be used the time for movement between this places with the capacity respecting. For solution is necessary equality between needs on the consumer side and capacity on the supplier side. This problem could be used by the *simulated supplier* or *simulated consumer*. In the matrix X is not possible to create simulated (fictional) member (any person couldn't stay in evacuation centres. It is necessary to be valid:

$$\sum_{i=1}^{m} a_i \leq \sum_{j=1}^{n} b_j \tag{1}$$

The numbers of evacuated persons must be same or smaller than the capacity of all property for emergency accommodation. In the cases:

$$\sum_{i=1}^{m} a_i < \sum_{j=1}^{n} b_j \tag{2}$$

Create a factious supplier with capacity

$$a_{m+1} = \sum_{j=1}^{n} b_j - \sum_{i=1}^{m} a_i \tag{3}$$

In the matrix Y is necessary to take in the account limitation in a number of buses for individual evacuation centres (it couldn't exceed the total number of vehicles). In this case valid:

$$\sum_{i=1}^{k} c_i \geq \sum_{j=1}^{m} d_j \tag{4}$$

For cases that Eq. 4, will be added to the matrix factious consumer with demand

$$d_{m+1} = \sum_{i=1}^{k} c_i - \sum_{j=1}^{m} d_j \tag{5}$$

For optimisation of X matrix and Y matrix is available Danzig algorithm. Optimisation of evacuation centres allocation to the places of short-term accommodation centres and allocation of vehicle garage to the evacuation centre is realised by that. The calculated value of movements (in matrix X) is numbers of evacuated persons from evacuation centre to the short-term emergency accommodation centres. Values in Y matrix are a number of buses from i-garage to j-evacuation centre.
The evacuation coordinator, try to minimise total time for evacuation process. The basic allocation of the object couldn't be optimal (because there is a lot of necessary movements between centres), Therefore is defined optimal location and allocation of objects and means, but this location couldn't be optimal with accordance numbers of journeys which are necessary for the move of all persons between objects. The decision about evacuated persons from evacuation centre to the short-term emergency accommodation is necessary to divide to the two phases.
In the <u>first phase</u> number of persons are replaced by an integer number of buses (capacity of buses). The number of buses must cooperate with a number of persons in an evacuation centre. The volume of transport in this assign matrix is information about total seat capacity or about transported persons (after multiplying with numbers of seats) from evacuation centre to the short-time emergency accommodation centre. A number of persons transported in the first phase are subtracted from the number of persons in evacuation centres and available places in place of accommodation. The number of persons in evacuation centres after the first phase is smaller than the capacity of one vehicle.
<u>The second phase</u> of the solution is about the placement of remains persons in evacuation centre of the free capacity in short-term emergency accommodation. For the second placement is possible to change the charge of the journey between evacuation centres and accommodation places. It is applicable for minimization of journeys numbers. Volumes calculated in the second phase are added in the volumes in the first phase and it is a complete assign of evacuated persons by Danzig algorithm.
In the basic of the calculated values, distances, travel times, etc., between individual points, etc. is solved continuance of evacuation. Total time of evacuation for one vehicle t_{e1} is consist of time for ride from time to depart t_v, time for ride between garage and evacuation centre t_{ges} time for Getting of persons t_{nc} time for journey from evacuation centre to the place for short-term emergency accommodation t_{esmnu}, time of getting-out person $t_{vc,}$ time for ride between place of

accommodation to garage t_{mnug}. Time for getting-on t_{nc} and getting-off t_{nv} depends on numbers of passengers and the average time for getting-on (getting-off) for one person. Total time for one evacuation vehicle is:

$$t_{e1} = t_v + t_{ges} + k \cdot (t_{nc} + t_{esmnu} + t_{vc}) + (k-1) \cdot t_{mnues} + t_{mnug} \qquad (6)$$

Where; k: a number of journeys between evacuation centre and accommodation centre. The value k depend on numbers of evacuated persons, numbers of used vehicles and on the capacity of vehicles. The total time of evacuation for all evacuation centres equals to the maximal time of individual vehicles using (GA 103/03/1077, 2004; Soušek and Kasal, 2013; SSHR, 2015; Hrůza et al., 2014; Dubec and Hrůza, 2012).

The continuity of evacuation must be solved in one time for all vehicles. Algorithm about continuity of evacuation could be in the form:

1. Evacuation announcement (start); time 0,
2. The time between announcement and departing from garage – time of depart,
3. Arrival to the evacuation centres – time of arrival,. From the total number of the person in i-evacuation centre is subtract capacity of the vehicle. If is there fewer persons that capacity of the vehicle, subtract that number,
4. A number of persons multiply time of getting-on of one person → Result is dwell time and by the dwell time could be found time of depart from an evacuation centre,
5. Time of arriving to the short-term emergency accommodation centre,
6. A number of persons in vehicle multiply time of getting-off of one person → Result is dwell time in accommodation centre and by the dwell time could be found the time of depart from accommodation centre. Check of person, whether is still necessary go to evacuation centre:
   - A. If yes: in evacuation centre will be reserve proper number of persons. The vehicle will travel back to the evacuation centre and the algorithm continues with step no. 3.
   - B. If no: vehicle goes back to the garage.
7. Time of arriving to the garage is recorded.
8. Total time of evacuation is the maximal time from individual operation times of vehicles.
9. End

4. Software model for solution

The software is a graphical environment for a map of road network edit, for pasting important point for evacuation planning and for evacuation process management. Graphics outputs of that program could be printed of exported in BMP or JPEG format.

The core part of the software is digital maps of the area. These maps are saved in ESRI Shapefile format (for the ESRI Browsers). For the minimal path, algorithms are necessary to edit data to the graph theory logic (especially about the description of the graph: the edge of the graph is a connection of two incident vertexes). In this data are not included cross (vertex of the graph) and therefore is necessary create an algorithm that the crosses found on the map. After finding the vertexes and incidence assignment to the edges of the graph was there another complication for data use. The curves (individual roads) not correspond with vertexes. It was also necessary to decide about incidence with vertexes and assign them the correct information about incidence with vertexes. Function for that assignment and data editing are an integral part of the software. Information about the geographical location of individual points, curves are saved in the coordinate system S42, it is another advantage of the digital data. This system identifies distance by the coordinates X and Y from the imaginary point [0,0]. Thank this method, the geographical identification of individual points and distance between that points can be calculated, very easy (GA 103/03/1077, 2004; The Czech Ministry of Transport, 2011; Szabo, 2015; Soušek et al., 2011; Pitas et al., 2014; Fuchs et al., 2015; Říha and Tichý, 2015).

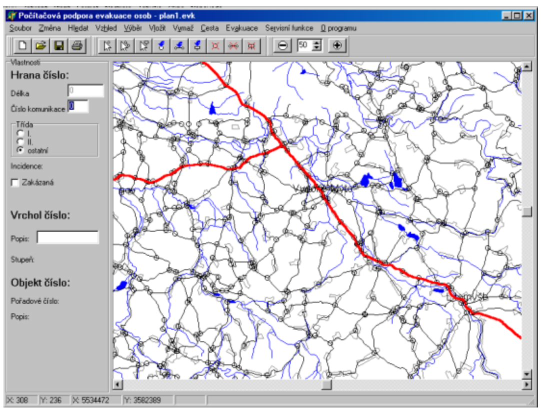

Fig. 1.
Software
Source: Authors with using software

The program is typical for Microsoft Windows (control by mouse and keyboard, like another application created for Microsoft Windows environment). Access to the individual functions of the program is possible through the application menu.

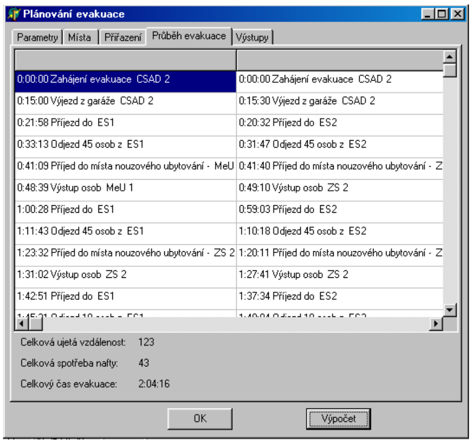

Fig. 2.
Process of evacuation
Source: Authors with using software

5. Conclusion

For planning and decision making during a crisis situation is software one of possible auxiliary and support tool. Software support allows making a decision in limited time with evaluation of the large volume of information.
The process of transport ensures planning for evacuation can be automatized with mathematical modelling followed by a software solution.
Currently, any tool is not used for planning of evacuation. By the author's opinion it a detrimental, because software solution can help with planning in the financial cost and reaction speed.

BANDWIDTH PROVISIONING IN ELASTIC OPTICAL NETWORKS

Suzana Miladić[1,2], Goran Marković[2], Valentina Radojičić[2]
[1] *University of East Sarajevo, Faculty of Transport and Traffic Engineering, Bosnia and Herzegovina*
[2] *University of Belgrade, Faculty of Transport and Traffic Engineering, Serbia*

Abstract: The concept of elasticity has recently emerged as an important research area in optical networking and it is a promising solution to cope with the 100 Gb/s and beyond data transmission in future optical networks. In this paper, we address an offline routing and spectrum allocation (RSA) problem as one of the most important issues of elastic optical networks design. The main idea behind elastic networks is that the spectral resources on each optical link are classified into spectrum slots, where each slot corresponds to an OFDM subcarrier. The main benefits of this approach as well the main differences compared to traditional routing and wavelength assignment problem are considered. We present the RSA research results on a small network topology where we have minimized the number of frequency slots used over all fiber links in the network.

Keywords: elastic bandwidth provisioning, routing and spectrum allocation, frequency slots.

1. Introduction

Telecommunications development has changed its direction in a manner of extending the channel capacity by utilizing the spectrum resources more efficiently and adaptively according to the transmission path characteristics and bandwidth requirements. To provide higher spectrum efficiency and flexibility in the future elastic optical networks, the Orthogonal Frequency Division Multiplexing (OFDM) technology is adopted (Zhang et al., 2012). Since Shannon limit becomes overcome and commercial systems will need to support Tb/s link capacity in the near future (Winzer, 2014), elastic bandwidth provisioning brings new opportunities to meet the increasing capacity requirements and open a new generation of optical networks based on *bandwidth on demand.*

The concept of elasticity allows that some parameters such as modulation format, channel spacing, optical bit rate which have been fixed in conventional WDM networks become adaptable in elastic optical networks (EON, Elastic Optical Networks). With this in mind, ITU-T adapted recommendations G.694.1 and G.872 to include flexibility within ITU standards. The nominal central frequency granularity of 6.25 GHz, the channel width (12.5 GHz) and the concept of frequency slots (FS, Frequency Slots) are defined in G.694.1 (ITU-T, 2012). 12.5 GHz frequency slot is nothing else than the frequency range an optical signal can take. The total spectrum is than divided on FSs and every connection is assigned a different number of slots, so EONs are also called flex-grid optical networks.

The goal of this paper is to address one of the major problem in EONs- RSA (Routing and Spectrum Allocation) and to show that spectrum resources or frequency slots, could be minimized and therefore more efficiently used compared to currently deployed networks. The rest of the paper is structured as follows. Section 2 provides the basic concept of elastic optical networks and differences compared to traditional WDM networks. The RSA problem formulation is presented in section 3. Numerical results obtained by solving the integer linear programming model are shown and discussed in section 4 while section 5 concludes the paper.

2. Concept of elastic optical networks and differences compared to currently deployed networks

Currently deployed optical networks use fixed channel spacing, ITU 50 or 100 GHz, what would not be suitable for future 100 Gb/s and higher bit rates because spectrum will be sized for every demand based on its bit rate and the transmission distance. Also, traffic requirements are typically much smaller than the available capacity so lightpath establishing with small level of utilization is not rational. Considering that traditional WDM networks allow that all demands use the same spectrum what results in capacity wasting, elasticity in EONs is the main difference and this concept overcomes the holes or unused spectrum in large bandwidth paths (depicted in Figure 1).

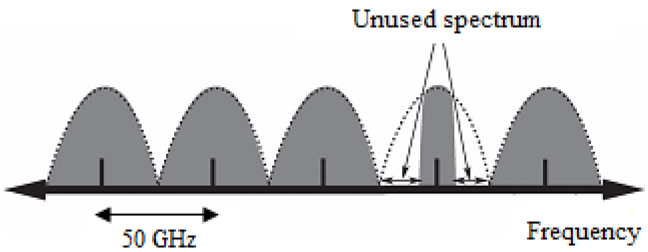

Fig. 1.
Spectrum allocation in traditional WDM optical networks
Source: Chatterjee et al., 2015

The term elastic in optical networks implies optical spectrum dividing in accordance with traffic volume and elastic optical paths establishing or paths with variable bit rates. Chatterjee et al. (2015) described in detail the main

[1] Corresponding author: suzana.miladics@stfdoboj.net

characteristics of such networks: bandwidth segmentation, bandwidth aggregation, efficient accommodation of multiple data rates, elastic variation of allocated resources, reach-adaptable line rate, etc (presented in Figure 2). This area is reaching much attention recently, so there are many opened issues and research challenges. Some of them are discussed in (Gerstel et al. 2012; Talebi et al. 2014; Dantas et al. 2014; Shen et al. 2015).

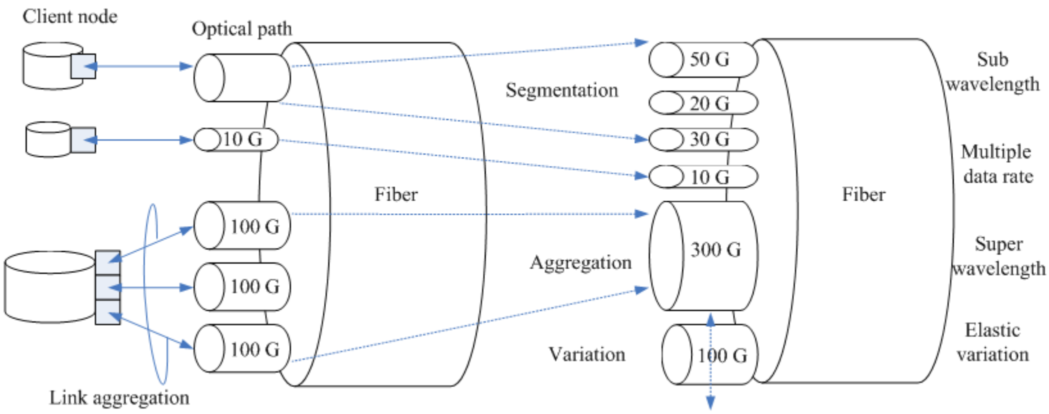

Fig. 2.
Elastic optical networks characteristics
Source: Socrates-Dantas et al., 2014

The major problem in EONs, RSA, is analogue to RWA (Routing and Wavelength Assignment) problem in WDM networks. In RSA, every demand is allocated a different number of frequency slots instead of a whole wavelength. The number of spectrum slots in each fiber link equals the number of wavelengths for any lightpath request. So, if RWA requires 1 wavelength along the lightpath, it is equivalent to a 1 spectrum slot along the lightpath in the RSA problem.

3. RSA problem statement

RSA problem as a generalization of RWA is relatively novel and also could be presented as ILP problem but for networks with large number of slots and demands solution becomes unattainable and heuristics are applied. RSA problem could be splitted into two subproblems: the routing and spectrum allocation subproblem. The first one includes finding the available physical route between a pair of nodes while the second focuses on allocation of appropriate frequency slots around the central frequency or spectrum part to the requested lightpath. Therefore, optical spectrum is quantized into frequency units with appropriate width, for example 12.5 GHz, and signals are modulated on frequency slots in form of subcarriers. Each FS represents an optical channel and, accordingly, an optical path can be established by assigning the required number of contiguous FSs according to the user signal spectrum width.
The main constraints configuring in the RSA statement are the spectrum contiguity and continuity constraint. Spectrum contiguity constraint means that spectrum slots must be placed near to each other and if enough contiguous slots are not available along the desired path, the connection can be broken up into several small demands. Each one of these smaller demands would then require a lower number of contiguous subcarrier slots. The second constraint is equivalent to the wavelength continuity constraint in RWA (continuity of contiguous slots on all links of the path). So, the RSA objective could be defined as: for a given set of demands, the goal is to find the end-to-end optical paths and assign the requested FSs in a contiguous way and to avoid FSs overlapping in network links.
In this paper, we analyzed a static or off-line RSA problem, where traffic demands (each demand corresponds to a connection request) are known in advance. Also, traffic volume is translated into a number of requested FSs (number of subcarriers required for connection) and network has enough capacity to serve all offered demands.
We considered OFDM network as a graph $G = (N, E)$ where N is a set of nodes and E is a set of bidirectional links. A number of FSs is given in each link of the network $F = (f_1, f_2, \ldots, f_{|F|})$. The set of connection requests is denoted with D and for each demand d the source and destination nodes, as well as the number of FSs requested are known (s_d, t_d, n_d respectively). So, a bandwidth demand can be mapped to a certain number of subcarriers or FSs. The list of predefined candidate paths (k- shortest paths) for each demand is denoted with P_d. The total number of paths is P while subset $P_e \subseteq P$ denotes all paths that contain link e.
The ILP model, where some constraints are taken from Klinkowski and Careglio, 2011, but modified with the last one, relies on the following problem variables :
$x_{pf} \in (0,1)$- equal to 1 if FS $f \in F$ on path $p \in P$ is selected to be the lowest indexed slot that is assigned to a demand, 0 otherwise.
$y_{pf} \in (0,1)$- equal to 1 if FS $f \in F$ on path $p \in P$ is assigned to a demand, 0 otherwise.
$x_{ef} \in (0,1)$- equal to 1 if FS $f \in F$ is occupied in link $e \in E$, 0 otherwise.
The objective of the model is to minimize the total number of FSs used over all fiber links in the network:
$F = \sum x_{ef}$
subject to:

$$\sum_{p\in P_d}\sum_{f\in F} x_{pf} = 1, \forall d \in D \quad (1)$$
$$x_{pf_i} - y_{pf_j} \le 0, \forall d \in D, \forall p \in P_{d,} \forall f_i, f_j \in F, \text{ where } i = 1, \dots, |F| - n_d + 1 \text{ and } j = i, \dots, i + n_d - 1 \quad (2)$$
$$x_{pf_i} = 0, \forall d \in D, \forall p \in P_d, \forall f_i \in F, \text{ where} i = |F| - n_d + 2, \dots, |F| \quad (3)$$
$$\sum_{p\in P_e} y_{pf} - x_{ef} = 0, \forall e \in E, \forall f \in F \quad (4)$$
$$\sum_{p\in P_d}\sum_{f\in F} y_{pf} = n_d, \forall d \in D \quad (5)$$
$$x_{pf}, y_{pf}, x_{ef} \in (0,1), F \in \mathbb{Z}^+, \forall\, p \in P, \forall\, f \in F, \forall e \in E \quad (6)$$

Constraints (1) are related to the path selection from the list of candidate paths and slot selection as the lowest indexed slot assigned to a demand, for each demand *d*. Constraints (2) are related to the spectrum contiguity, what means if slot f_i is selected as the lowest indexed slot for demand *d*, the next slot near to it (consecutive slot) f_j should be also assigned to a demand. FS selection is not allowed if there is no enough space for FS assignment in the frequency spectrum and it is guaranteed by third (3) constraint. Constraints (4) state that FS in each network link could be assigned to at most one demand at the same time so there is no overlapping. Equation (5) ensures that each demand *d* is assigned with the requested number of subcarriers (n_d). At the end, constraints (6) are the variable range constraints that state the problem variables are binary.

4. Numerical results

ILP formulation is applied to the small network with 6 nodes and 9 links topology (shown by Figure 3). The algorithm was implemented using Matlab R2014a (v. 8.3) and Intel Pentium Dual CPU 2.16 GHz 2 GB computer. The number of frequency slots, n_d, required for connection was chosen between 1 and 5. In our simulation we used three different values of *D* to represent load scenarious: 10, 20 and 30 demands (demand pairs). The paths are shortest paths and their number is assumed to be $P_d = 2$.

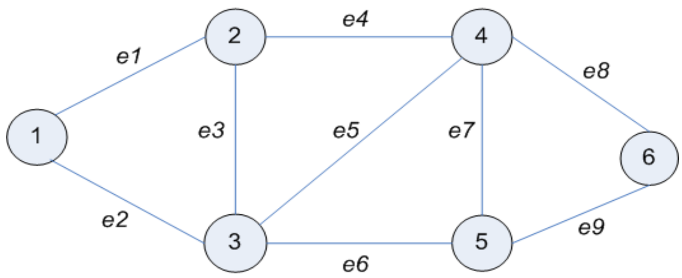

Fig. 3.
Network topology used for simulations
Source: Authors

The results in terms of spectrum usage (total number of FS), the running time and the FS occupancy in network links are presented in Table I and the following histograms. We observe that for all values od *D* the optimal RSA ILP algorithm was able to find solution. The main difficulties of this algorithm are caused due to larger number of demands and FSs thereby resulting in a huge number of constraints and a more running time. So, the optimal solution may be infeasible (scenario for *D*=30, 15 FSs) or a lack of memory could happen.
Figure 4 shows a histogram of the link occupancy where the x-axis represents the network links (from 1 to 9) and a number of slots occupied in each link for all traffic load scenarious are represented in the y-axis. In our case most of the links are almost equally used. Link 4 is the most frequently used. Utilization of less used links (for example link 1) could be increased with a higher number of candidate paths.
A histogram of the FS occupancy in network links (x-axis) is shown in Figure 5. The size of the FS subset (several contiguous slots) is represented on y-axis. The links are grouped as follows: 1-3, 4-6 and 7-9. We wanted to show which FS subset has been most frequently used (FU) as well as the maximum subset size (max). It could be observed that some FSs are released at some links while others are allocated more frequently. This is due to the spectrum contiguity and continuity constraint which in certain cases implies the problem of spectrum dividing into parts which could not be used (isolated), so called fragments. That is why multi-path routing or some techniques of defragmentation should be considered (see Abkenar and Rahbar, 2016). Therefore, our ILP model formulated the routing and spectrum assignment problem in flex-grids optical networks. Because of the running time, the model is not suitable for large networks and some heuristics should be applied.

Table 1
Spectrum usage for all load scenarious

Load- demands (*D*)	FSs in each link	Spectrum usage (total number of FS)	Running time (in seconds)
10	6	32	0.07
10	10	32	0.27
20	10	60	5.10
20	15	60	22.60
30	15	89	633.24
> 30	15	no feasible solution found

4. Concluding remarks

Elastic optical networks represent logical direction in the development of currently deployed networks since the main goal of the next generation optical networks will be the efficient utilization of network resources that could be achieved by flexible bandwidth allocation. It is theirs main difference compared to traditional WDM networks where a large optical spectrum remains unutilized. However, it can not be stated for sure that all networks will become elastic but currently it is the main development trend.

This paper studies the basic concept of flex-grid optical networks and the major problem that should be solved – the problem of routing and spectrum allocation. Our further research directions could be focused on metaheuristics that could solve this problem more efficiently since more complex mesh network topologies, with larger number of FS and traffic demands complicate the ILP formulation and the solution could not be obtained.

WAREHOUSE PROCESS OPTIMIZATION – CASE STUDY

Ivona Bajor[1], Margareta Rihtarić[2], Dario Babić[3]
[1,2,3] *Faculty of Transport and Traffic Sciences, University of Zagreb, Zagreb, Croatia*

Abstract:
Warehouse processes are, from optimization viewpoint, significant to observe in supply chain regarding process optimization. If the warehouse activities are not well organized, in this important subject of the supply chain it can produce bottlenecks and increase logistics costs. The basic warehouse processes include goods receiving, storage, order picking and shipping.
The paper will analyze problem of defining and measuring warehouse processes, in form of a case study. Aim of the paper is to describe the current state of certain warehouse processes in logistics distribution center at the Croatian market and finally suggest optimization possibilities for the benefit of reducing process time and reducing bottlenecks of this significant part of the supply chain.

Keywords: supply chain, warehouse, processing, process time, case study.

1. Introduction

Processes in the warehouse are of large importance for circulation of goods throughout the supply chain. Warehouse processes refer to loading, unloading, packing, picking, outbound operations and include processes of reverse logistics.
In the past, warehouses were seen mainly as stock-holding points acting as a buffer between manufacturer and consumer. Stock visibility along the supply chain was limited and information flow was very slow, resulting in companies holding more stocks than necessary. In today’s market with often over expensive land, buildings, labor and energy costs, together with the introduction of concepts such as just in time (JIT), efficient consumer response (ECR) and quick response (QR), companies are continuously looking to minimize the amount of stock held and speed up throughput. (Richards, 2011)
The warehouse, which will in form of a case study be described in the paper, is one that acts as a logistics service provider and processes finished goods. Researched warehouse processes consist of receiving operation, positioning, order picking, packing, outbound operations and generally predefined processes for goods in return.
Paper analyzes warehouse processes and its role in the supply chain. It focuses the organization and provides possible suggestions for optimization.
Analysis includes:

- Current state analysis of forwarding processes,
- Processes measurement on predefined sample,
- Comparative analysis of statistical data and optimization proposal.

2. Warehouse operations

Warehouses are the points in the supply chain where product pauses its throughput, it provides additional services and forwards products to the next level of the supply chain. According to mentioned, warehouse requires labor, capital (land and storage with handling equipment) and information systems, all of which are expensive. Warehouses, provide useful services those of significant importance under the current economic scene. (Bartholdi, 2011)
Warehouse management has a mission to effectively process products at the right time, right place, and right quantity without damages or differentiation. (Manzini, 2012)
In today`s supply chain there are many different roles. The warehouse can be operated by raw materials suppliers, manufacturers, retailers, service providers, companies involved in reverse logistics, etc. Warehouses fulfill following roles: (Richards, 2011)

- Raw materials storage,
- Intermediate, postponement, customization or sub-assembly facilities,
- Finished goods storage,
- Consolidation centers and transit warehouses,
- Transshipment or break-bulk centers,
- Cross-dock centers,
- Sortation centers,
- Fulfilment centers,
- Centralized return centers,
- Public sector warehousing.

Basic processes include: receiving, put-away, internal replenishment, order picking, accumulating and sorting, packing, storage, dispatch and shipping. These processes is shown in the Figure 1.

[1] Corresponding author: ivona.bajor@fpz.hr

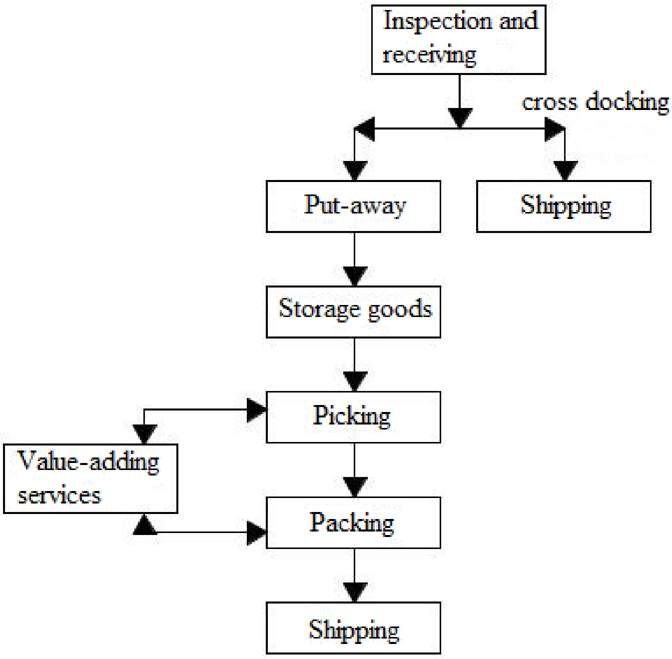

Fig. 1.
Warehouse processes
Source: Created by authors according to (Richards, 2011)

Figure 2 shows each process of warehouse as a percentage of cost, emphasizing the importance of the pick, pack, and dispatch operations. Order picking has majorly been researched as most significant process for optimization and according to mentioned has largest costs. Order picking process forms as much as 55 % of operation costs within any distribution center, compared to shipping, storage and receiving stages, because this process is a labor-intensive activity for traditional manual warehouses.

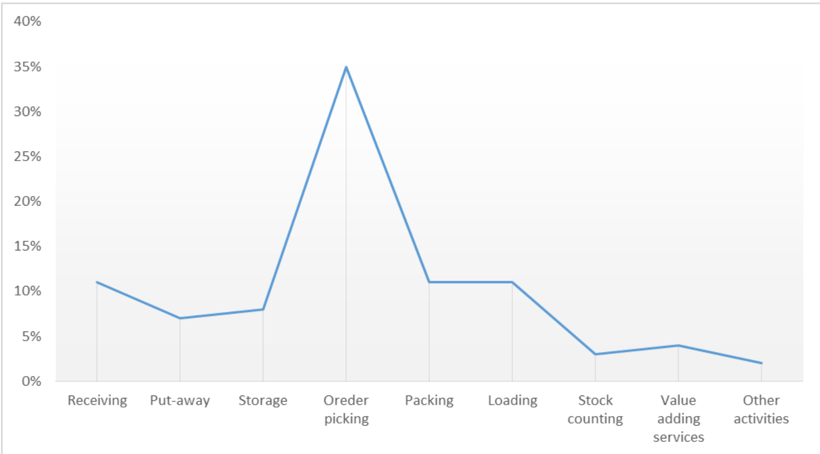

Fig. 2.
Warehouse activities as a percentage of total cost
Source: (Richards, 2011)

2.1. Receiving

The receiving process is one of the most important process and first in line in the warehouse. Because all downstream processes depend upon the accuracy and efficiencies achieved during receiving. Accurate data entry at this phase is critical for preventing costly cascading errors.
The typical procedures of receiving activities consists of four steps: (Warehouse and storage management, 2013)

- Unloading and checking the shipment,
- Unpacking and inspecting the material,
- Completion of the receiving report,
- Delivery of the material.

Ensuring that the correct product has been received in the right quantity and in the right condition at the right time is one of the mainstays of the warehouse operation. However, it is our contention that once goods have arrived at the warehouse it is usually too late to rectify most receiving issues. There are many steps that need to be taken before the actual act of receiving takes place. (Richards, 2011)
In most cases the process of receiving begin with advance notice of the arrival of goods. When goods arrive, unloading begins after document control. Each warehouse must provide the zone for receiving, where the goods are often temporarily positioned. Altogether, process of receiving accounts for only 10% of operating costs in a typical warehouse, but it is supposed to be reduced by use of RFID. (Bartholdi, 2011)

2.2. Put-away

Stock keeping unit (SKU) locations must be determined in advance, whether the positions are predefined or random. There are several storage policies: (Mendes, 2011)

- A predefined storage policy prescribes a particular location for SKU to be stored,
- A random policy leaves the decision to the operator.

One warehouse can also use both of these forms.
Utilizing fixed locations implicates designating a specific location for a particular SKU. A random location is as it states, where the SKU is placed in the most efficient slot available. Fixed positions enable the picker to memorize the actual location and speed up the picking process. However, if there is no stock for that particular product at any one time, the slot remains empty and pallet storage utilization reduces significantly. (Richards, 2011)
Determining the location in advance is important to a large extent directly influencing how quickly and for what cost later it will be retrieved for a customer. When product is put away, the storage location should also be scanned to record where the product has been placed. This information will subsequently be used to construct efficient pick-lists to guide the order-pickers in retrieving the product for customers. (Bartholdi, 2011)
The warehouse manager needs to take into account that items could be stored in groups by similarity. For example, hazardous items need to be stored in an appropriate area. Items of high value will also require special storage conditions, which might mean a lockable cage or the use of a secure carousel. (Richards, 2011)
Many of today’s WMSs allocate product locations in advance and instruct the operator as to where to place the SKUs. In order for this system to work effectively, a great deal of information needs to be programmed into the system. This includes the following: (Richards, 2011)

- Size, weight and height of palletized goods,
- Results of an abc analysis or slotting, where fast-moving goods are placed closest to the dispatch area,
- Current order data,
- Family product groups,
- Actual sales combinations,
- Current status of pick face for each product,
- Size of pallet locations,
- Weight capacity of racking.

The process of put-away can require a larger amount of work because SKU may need to be moved considerable distance to its storage location. Put-away typically accounts for about 15% of warehouse operating expenses. (Frazelle, 1996)

2.3. Order picking

Picking is process which has most work, intensive process, in the warehouse and is also the most error prone, which makes it an ideal workflow for optimizing. Process of the order-picking in the warehouse involves selecting and gathering specified amount of right SKUs in accordance with the order and is composed of lifting, moving, picking, putting, packing and other related works. (Lee, 2015)
The order picking process methods include as following: (Richards, 2011)

- Paper pick lists,
- Pick by label,
- Pick by voice,
- Barcode scanning,
- Radio frequency identification,
- Pick by light/pick to light,
- Put to light,
- Automated picking.

Receipt of a customer order signals the warehouse to perform checks such as verifying that stock is available to ship. The warehouse must produce pick lists to guide the order-picking. Finally, it must produce any necessary shipping documentation and schedule the order-picking and shipping. These activities are typically accomplished by a warehouse management system (WMS), a large software system that coordinates the activities of the warehouse. (Bartholdi, 2011)
Every outbound processes in the warehouse are initiated by receipt of a customer order. This receipt may be thought of as a shopping list. Each entry on the list is referred to as an order-line and typically consists of the item and quantity requested. Pick-lines are instructions to the order-pickers, telling them where (locations of items) and what SKU to pick, including details as quantity and units of measure. (Bartholdi, 2011)
The process of order picking can be manual or automated. In manual order picking, picker gathers SKUs from their locations and then transports them to a packing area. In a case of automated picking, that is automated storage and retrieval systems, system retrieves one or more unit loads and place them to a picking station. After, picker takes products on orders, the remaining items on unit loads are transferred to the storage again. (Lee, 2015)
The WMS may reorganize the list to match the layout and operations of the warehouse for greater efficiency, checks the order against available stock and identifies any shortages. For example, if a customer has ordered 20 of a particular item, the WMS may check to see how the item is packaged and if 15 of the items comprise a carton, the WMS may convert the order-line for 20 items to two pick-lines, one line for one carton and the other for 5 items. In most of warehouses the pick-lines are diverted appropriately and each-picking and carton-picking are separate processes.
Goods are selected from order picking stock in the required quantities and at the required time to meet customer orders. Picking often involves break bulk operations, when goods are received from suppliers in whole pallet quantities, but ordered by customers in less than pallet quantity. (Mohan, 2006)

2.4. Packing

Packing can be labor-intensive due to necessity of handling individual piece. Packing results partly as a complex process according to fact that customers generally prefer to receive all the parts of their order in as few containers as possible because this reduces shipping and handling charges. Otherwise partial shipments must be staged, waiting completion before packing, or else partial orders must be packaged and sent. (Bartholdi, 2011)
The worker during packing checks each product, in order to determine the accuracy. After the packing process, the transport packaging is directed to shipping.

2.5. Shipping

The shipping process generally handles larger units. The shipping process is the last process amongst warehouse processes. After the packing process and preparing cargo for shipping, administration, cargo is positioned into the transportation vehicles and transported to the destination. (Bartholdi, 2011)

3. Case study of warehouse operations in LDC at the Croatian market

The research has been made at location of a logistics service provider at the Croatian market. Croatian service provider is a significant company that offers basic logistics service and some value added services. Service provider`s warehouse has surface of 8555 m^2. The warehouse space is physically divided into three parts, the zone of receipt, dispatch and zone for reverse logistics processes. The workers are working in two shifts: in the morning 8 a.m. to 4 p.m. (12 warehouse workers); and in the afternoon 12 to 8 p.m. (17 warehouse workers).
The processes which service provider offers in warehouse are:

- Receiving,
- Put-away,
- Order picking,
- Packing,
- Checking,
- Shipping,
- Reverse logistics,
- Value adding services.

The process of receiving begins with the announcement of the arrival of goods. At arrival of the truck, the warehouse workers perform control of the documents and start with unloading the goods from the trucks. The goods are in cardboard boxes. During unloading, warehouse workers are grouping cardboard boxes on the pallet according to type criteria. Once the goods are on pallets the workers begin the process of labeling. Each box is opened and declarations, instructions and warranty are put into the box. Once the goods are officially declared, pallets are ready for storage on the first available location. The goods are mostly stored so that the goods whit high turnover are located at the first location (pick location), and if there are goods of the same type to another location. The goods with low turnover and seasonal goods are positioned at several locations on the shelves. Once the goods are stored the process of picking can begin. According to customer orders, order picking process has two channel:

- I channel: the ordering goes from the final customer – the goods after picking process are directed to the packing location for further processing;
- II channel: the ordering goes from wholesale - the goods are directed to control location and further processing.

When the goods of the first channel enter packaging zone, workers according to customer orders pack products in cardboard boxes, grouping orders and placing them on a pallet according to the type of the carrier. In the end pallets are taken to the dispatch ramp. Goods from second channel are directed to zone for control where workers check items and ship final packaging to the dispatch ramp.
In the end products are ready for shipment positioned at the dispatch ramp for shipment. Once the products are shipped and arrive to destination, can be returned if the consumers is not satisfied or the product is damaged. Warehouse processes are shown with Figure 3.

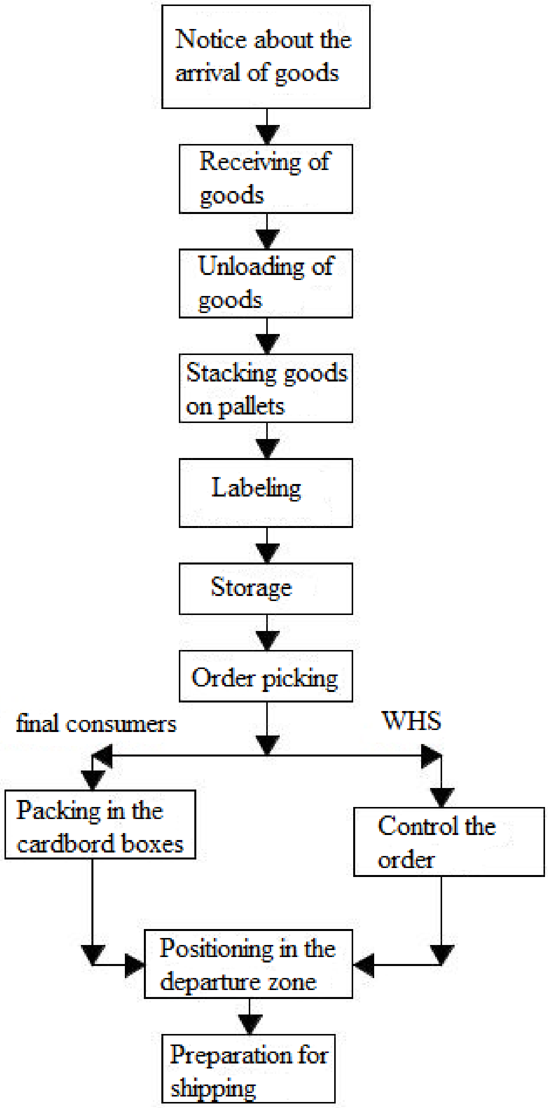

Fig. 3.
Croatian logistics service provider warehouse processes
Source: Created by authors

The analysis was done in the following way:
- Analysis of the current situation in the process, including specification regarding warehouse space,
- Bottlenecks analysis,
- Proposing solutions regarding bottlenecks,
- Analysis after the implementation.

For the purposes of conducted research, measurements of the warehouse process were conducted. Table 1 implicates the time duration of receipt, labeling, storage, order picking and packing.

Table 1
The average time of the processes

Time of receipt (per pallet) [s]	Time of labeling (the cardboard box) [s]	Time of storage (per pallet) [s]	Time of order picking (by order) [s]	Time of packing (per account) [s]
0:10:05	0:02:13	0:02:37	0:09:27	0:06:25

Source: Created by authors

The next chart shows the average time per activity for the receipt, from which is evident that most time is required for positioning the vehicle on the ramp which is not connected with the activities within the warehouse. While activity of unloading cardboard boxes on a pallet on average takes more than two minutes per pallet, and the average number cardboard boxes in a single means of transport is about 1 000, or about 65 pallets. If we consider that for the formation of a pallet two minutes are needed, the average time of unloading takes two and a half hours. It often happens that during unloading the pallets are missing, so the cardboard boxes first land on the floor of the warehouse, and later again on the pallet.

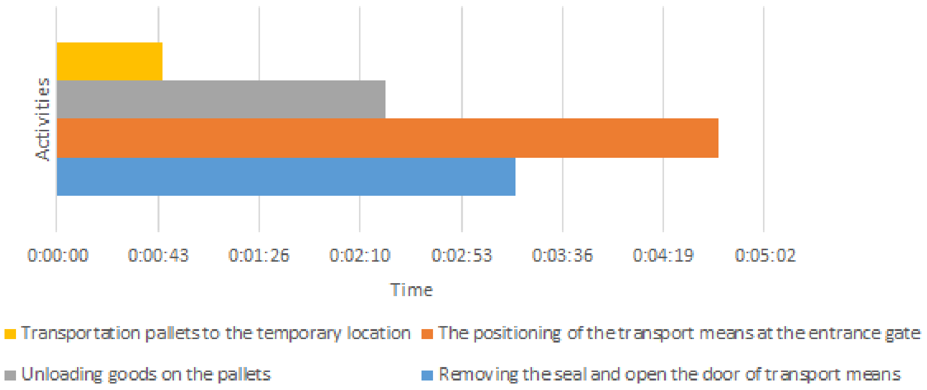

Fig. 4.
Receipt of goods
Source: Created by authors

The graph below shows the process of labeling. During the research it was concluded that significant problem in the labeling process is that there is no pre-prepared declarations for complete product arsortiment. Since the arrival of the truck is advised two days earlier, the necessary declaration could be prepared the day before. From the next graph we can see how type of goods influences the time of labeling. Considering the type of labeling products, the products are divided into three categories:

- I product category – includes instructions,
- II product category – includes instructions and declaration,
- III product category – includes declaration on each product in the packing.

The graph implicates that most time required is for products of third category, the procedure is the easiest because it's just pasting the labels, but the package has multiple products so the process of labeling takes longer.

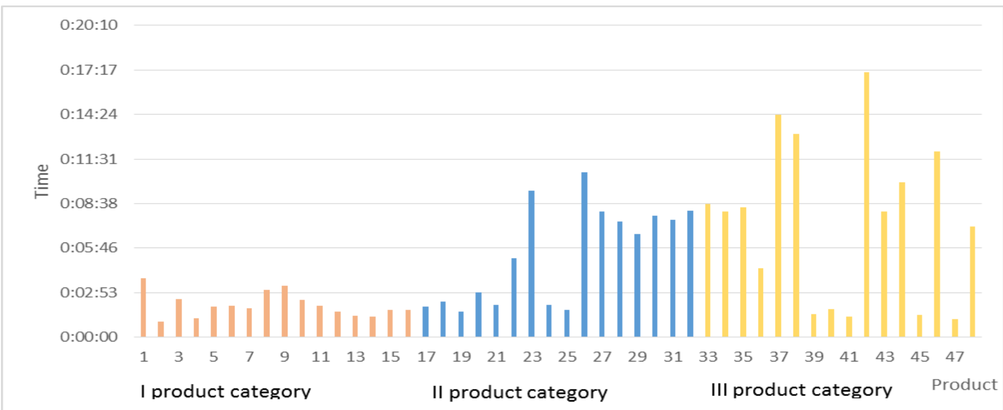

Fig. 5.
Process of labeling
Source: Created by authors

The graph below implicates the order picking process activities. It can be seen that the most time consuming is activity of collecting the product from the shelf. This is due to the fact the products are not arranged on the shelves according to ABC categorization, but are in randomly positioned in the warehouse.

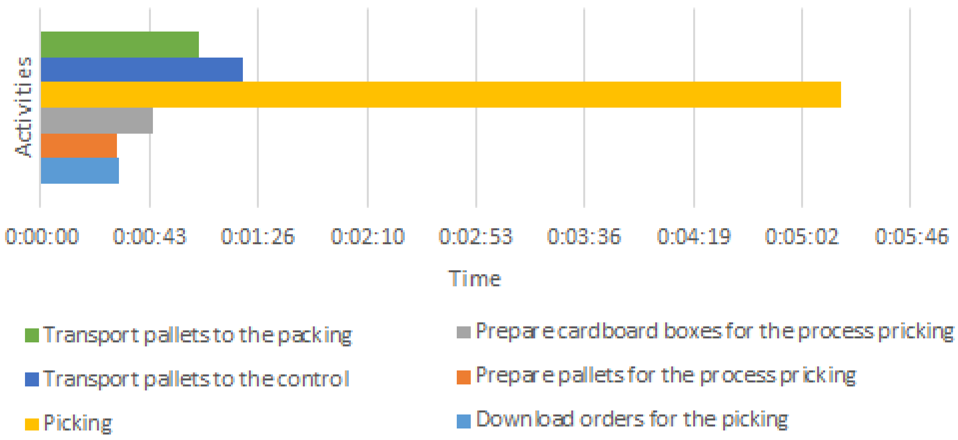

Fig. 6.
Process order picking
Source: Created by authors

Although the warehouse processes are well-organized, certain segments were found, which could be improved. From the overall analysis, it is concluded that the company has some room for optimization, which will be detailed and explained in the next section.

4. Proposal for warehouse operations improvement

The proposal to improve logistics activities within the warehouse is made on the basis of the aforementioned analysis. With the improvements it is possible to some extent to shorten the time of existing processes and achieve higher levels of efficiency.
Analysis of the warehouse processes indicates more optimization possibilities, and some of these features are:

- To reduce the preparation work it was suggested to organize the goods by packaging (pallets, cardboard boxes),
- Sorting the cardboard boxes for packaging by size and better organization for ordering,
- Reducing the necessary time for putting the receipts in the envelopes and picking of the products according to the receipt for the packing process,
- Detailed procedure of activities to increase the transparency of worker obligations.

Based on conducted study and regarding the warehouse processes, it is possible to propose certain directions for further optimization. Some of the suggestions for optimizing relate to the observed processes:

- **the receipt of goods**
  During the research it was noted that the goods are in receipt often received after 8 am as a pre-set schedule, and that for this process the company hired a number of students (temporary workers). With a view to better planning the necessary resources should consider accurate notice of arrival of the conveyance by the carrier. This information could result in a cost reduction. In addition, there is the possibility of employment for one worker. This worker can control the course of the unloading process and thus reduce errors that occur while temporary workers are obtaining activities and to reduce necessary time period. In addition to this, while conducting research, the lack of pallets has been noted, which are necessary for the temporary storage of goods during unloading. This deficiency causes the double handling of goods, and unnecessary waste of time in the process of receiving and resources used. To solve this problem, it is proposed dedicating zone for empty pallets and to provide a sufficient number of pallets which are necessary for reception of the goods.
- **process of labeling**
  When analyzing the process of labeling, temporary workers have to take each cardboard box of the pallet then open it, put the instructions and declarations, close and then put again on a pallet after labeling. Such a procedure results with double manipulation. If the preparation of instructions and declarations is made in advance, there is no loss of time in the process. During the measurement it was noticed that almost always declaration and the instructions are prepared during the execution of the process, which prolongs the process. Since the arrival of goods is known in advance, the preparation of the necessary instructions and declarations for all goods which are coming in the transport vehicle should be arranged before. Because the students are doing the process of labeling, there should be an employee to control them.

- **Order picking and packing**
  During the research it was noticed that warehouse workers (pickers) spend some time searching for pallets for orders picking, which increases the process time. Empty pallets are located at different locations in the warehouse or even at storage locations within the rack.
  One proposition would be to organize empty pallet zone, in the order that the workers could easily reach them. In addition, it was noted that a worker has to go often to the higher level racks to pick goods. For this operation he needs electric forklift, which worker must wait for the release, but it also increases the time. For this problem better organization of manipulation means is proposed.
  The analysis implicated that workers in the packing zone do not have a sufficient amount of transport packaging in form of card boxes.
  This results with creating packaging of needed dimensions, which requires a certain commitment of workers and extending the time of packaging process. In order to avoid this, it is proposed to predefine dimensions and quantities of cardboard packaging and plan inventories of those according to available data.

5. Conclusion

The warehouse processes are significant to optimize in the supply chain. Every process, from receiving until shipping, is vital since it causes certain costs. Order picking process is the one that accounts for the major percentage of warehouse operating costs and is most time consuming for warehouse workers.
The logistics service provider at Croatian market is well organized but analysis implicates certain possibilities for optimization within receiving of goods and order picking process.
The analysis of the logistics processes was done in the segment of storage at the Croatian company, providing logistics services. During the research it was noticed that all the actions in the given segment were well organized and that there are only minor disadvantages, which can be bettered with reorganization of the preparatory work and some activity reorganization.
During the analysis there have been some problems noted, related to following cases:

- Lack of pallets during unloading goods from the means of transport and order picking process,
- Lack of cardboard packaging in the packing zone,
- Lack of organization while preparing declarations and instructions for the process of labeling.

For all the problems proposition is made for possible improvements that could:

- Uniform work processes in the warehouse,
- Reduce the warehouse costs,
- Improve the quality of services.

Continuous control and process measurement can provide optimal processing and it is highly recommended for subjects of the supply chain. Transparency of the processes assures its visibility and provides easier control of resources used.

SESSION 18: TRANSPORT SAFETY AND SECURITY ANALYSIS

HOW DO WE PERCEIVE TRAFFIC RISK?

Jiří Ambros[1], Lucie Viktorová[2], Richard Turek[3], Matúš Šucha[4]
[1,3] *CDV – Transport Research Centre, Department of road safety evaluations and strategies, Líšeňská 33a, 636 00 Brno, Czech Republic*

Abstract: Traffic risk perception has been defined as a subjective interpretation of the risk involved in traffic situations; this concept is important for road safety, since it may predict how road users behave in traffic. In addition risk perception is often reflected in safety assessments: both from experts (during road safety inspections or investigations) and lay persons (in road user safety complaints). Subjective risk perception is also valuable in cases when other safety data are missing, for example due to underreporting or newly-built infrastructure; hence it is of interest to study the factors which determine how we perceive traffic risk.
In this respect an on-line test was prepared, consisting of general questionnaire (gender, age, driving experience), risk perception assessment (rating level of risk in video clips of traffic situations), personality questionnaire, and Driver Behaviour Questionnaire. With objective of studying the links between subjective risk assessment and personality traits, as well as differences across several dimensions (such as male vs female drivers, less/more experienced drivers, drivers vs other road users, or lay persons vs safety experts), the test was used with 144 respondents, including students and adults, certified road safety auditors or Traffic Police officers. In total 9 hypotheses were formulated and statistically tested: some of the identified relationships provided expected results, consistent with previous studies: for example high risk perception of females compared to males or lack of differences between students (non-professionals) and experts (professionals); other findings were less expected, for example lack of relationships of risk perceptions to age and experience. Nevertheless in order to reduce potential consequences of subjective assessments, based on risk perception, the identified differences should be considered in future road safety auditors' or traffic conflict observers' training procedures.

Keywords: road safety, traffic risk, risk perception, driver behaviour.

1. Introduction

It is recognized that majority of road traffic accidents may be attributed to human error (Treat et al., 1979; Hendricks et al., 2001; Andres et al., 2012). In order to propose appropriate safety countermeasures, it is thus necessary to investigate road users' characteristics and behaviour. One of determinants is traffic risk perception (also referred to as hazard perception or situation awareness), i.e. a subjective interpretation of the risk involved in traffic situations (Deery, 1999). It is also closely related to subjective safety, which refers to anxiety regarding being unsafe in traffic for oneself and/or others (Vlakveld et al., 2008). Since road users modify their behaviour according to the risk they perceive, the concept is fundamental for traffic safety – knowing risk perception may enable prediction of safety. Past studies found links of risk perception to safety in various traffic environments (e.g. Watts and Quimby, 1980; Kanellaidis and Dimitropoulos, 1994; Kowtanapanich et al., 2006; Lipovac et al., 2016). Numerous studies also described risk perception as a skill that is highly correlated with traffic crashes: experienced drivers perceive potential risk situations better and more quickly than novice drivers, while drivers who can detect hazards faster are less involved in traffic crashes than those who detect hazards slower. In contrast, inexperienced drivers with less developed risk perception skills, were found more likely to be involved in a crash (Peltz and Krupat, 1974; Armsby et al., 1989; McKenna and Crick, 1997).
Several factors were found associated to risk perception and subjective safety, including:

- Traffic features, such as road geometry, speed, traffic volume or traffic separation (Żakowska, 1995; Cho et al., 2009; Sørensen and Mosslemi, 2009),
- Biological, psychometric, cultural and societal characteristics (af Wåhlberg, 2001; Nordfjærn et al., 2011; Lim et al., 2013).

In addition, subjective safety in traffic can lead to road users limiting their mobility and social activities, which is one of the reasons it warrants policy-related attention; understanding risk perception is also important for traffic enforcement and traffic education, or for design of appropriate safety campaigns. Another interesting application is local safety assessment – i.e. using perceived (or *subjective*) risk in order to determine safety level of specific location (e.g. an intersection) or the events, which take place on such location. Traditionally *objective* safety measures have been used for this purpose, based on frequency of accumulated accidents; however accident-based measures enable reactive (retrospective) approach only. In contrast, alternative (proactive) measures, which are valuable in cases of accident non-existence, rarity or underreporting, are so called safety performance indicators or surrogate safety measures, e.g. traffic conflicts (Ambros et al., 2014). The proactive measures, utilizing principles of risk perception, may complement process of road safety inspections (Ambros et al., 2016), which are mostly based on expert judgment. These assessments are usually done off-road (outside-of-vehicle) as opposed to typical hazard perception studies being conducted from the driver perspective (on-road or in driving simulators).

[1] Corresponding author: jiri.ambros@cdv.cz

Given the interesting concept of traffic risk and its applications, it is worth investigating the factors which determine how we perceive risk. With this focus we prepared an on-line test, consisting of general questionnaire (gender, age, driving experience), risk perception assessment (rating level of risk in video clips of traffic situations), personality questionnaire, and Driver Behaviour Questionnaire. We used the test with several groups of students and adults, including certified road safety auditors or Traffic Police officers. The objective was to study the link between subjective risk assessment and personality traits, as well as differences across several dimensions, such as male vs female drivers, less/more experienced drivers, drivers vs other road users (cyclists, pedestrians), or lay persons vs traffic safety experts. The paper presents data and methods, hypotheses testing and results, followed by discussion, summary and conclusions with focus on practical implications.

2. Method

2.1. Test

An on-line test was prepared (http://riziko.cdvinfo.cz/), consisting of four parts:

1. General questionnaire (gender, age, driving experience, etc.)
2. Risk perception assessment (rating level of risk in video clips of traffic situations)
3. Personality questionnaire TVP (129 items)
4. Driver Behaviour Questionnaire (50 items)

The general questionnaire aimed at collecting basic demographic information in 30 items (gender, age, educational and marital status, occupation – including type of school and year of study in case of students, population of the city of residence, etc.) as well as information pertaining to driver experience (type and year of obtaining a driving licence, average monthly/yearly/accumulated mileage, driving offences and accidents, etc.). A five-point Likert scale was used for self-assessment of the respondents' driving skills (1 – excellent, …, 5 – very poor) and the participants were also asked to identify themselves with one group of the road users: drivers, cyclists or pedestrians.
Following the initial set of questions, a risk perception assessment was carried out using 35 video clips, i.e. short (approx. 10 seconds) records of traffic situations, displaying various situations in mostly urban environments. In terms of Czech traffic conflict technique (Ambros et al., 2014) severity grades, the interactions ranged from "none" to "severe". They displayed different interaction types between vehicles (crossing, turning, overtaking, rear-end) or between vehicles and pedestrians. The application text instructions informed the respondents that on a picture (prior to running the video) they can see the location of a traffic interaction. After running and watching the video (with one possible repetition) they were instructed to assess the perceived severity (not based on traffic rules compliance or non-compliance) on a drop-down menu (Fig. 1) using four-point Likert scale: 0 (none), 1 (slight), 2 (medium) or 3 (severe).

Fig. 1.
Interface of video clips in the on-line application, with perceived risk severity assessment on the right

The second half of the test comprised two questionnaires. First of them was the Personality questionnaire TVP ("Test zur Erfassung verkehrsrelevanter Persönlichkeitsmerkmale", Spicher and Hänsgen, 2003; Czech version by Černochová and Rudá, 2016), which is used for personality diagnostics within the scope of traffic psychology and consists of 129 four-point Likert-type items (1 – strongly disagree, …, 4 – strongly agree). There are 13 scales in total, with 7 to 12 items loading on each scale. The scales follow the Five Factor Model of personality (Neuroticism, Extraversion, Openness to experience, Agreeableness, Conscientiousness), with each factor being measured as "traffic-specific" and

"generic" (10 scales in total). Besides the five factors, "disparagement" (generic and traffic-specific) as a measure of socially desirable answers is assessed, and a reactance scale is added. The higher the score on each scale, the more noticeable the trait is for the participant.
The second was the Manchester driver behaviour questionnaire (DBQ, Reason et al., 1990; Czech version by Šucha et al., 2014), used to survey aberrant driving behaviour. It consists of 3 factors (Dangerous Violations, Dangerous Errors, Straying and Loss of Orientation) and 50 items in total. A six-point rating scale is used to measure the frequency of a particular behaviour (0 – never, …, 5 – nearly all the time): the higher the score on each factor, the more often the participant displays the aberrant driving behaviour.

2.2. Respondents

The selection of respondents followed the idea of sampling the driver population (i.e. only the holders of a driving licence) across age groups; additional idea was to use university students from several different backgrounds. Respondents were asked mostly through e-mail to participate in a survey, with no financial incentives. In the e-mail they were directed to the on-line application website, where they were to register, sign in and fill in all four mentioned parts of the test.
Following groups were targeted:

1. University students
    a. psychology students at Palacký University Olomouc (Czech abbreviation "UPOL")
    b. students of College of Logistics in Přerov ("VŠLG")
    c. transportation students of Czech Technical University in Prague ("ČVUT")
2. Traffic police officers, attending courses at Police College of the Ministry of the Interior in Prague ("VPŠ")
3. Road safety auditors, certified by the Ministry of Transport
4. Adults (i.e. non-students)

Participation of university students was arranged within their current classes; other groups participated in their free time. In total 263 respondents filled in the test; 144 (55%) of them, who completed all 4 parts, were used for the analysis. Due to small sub-samples, auditors and Traffic Police officers (VPŠ) were combined into Experts; Adults were renamed to Seniors in order to be distinguished from *adult* Experts. Selected characteristics of the subgroups are summarized in Table 1 in terms of their frequencies (counts and percents), age (minimum, maximum, mean, standard deviation) and gender structure.

Table 1
Selected descriptive characteristics of the respondents' sub-samples

	Frequency		**Age**				**Gender**	
	N	**%**	**Min.**	**Max.**	**Mean**	***SD***	**Male**	**Female**
VŠLG	55	38.2	20	25	21.8	1.12	32	23
ČVUT	24	16.7	20	32	22.4	2.18	17	7
UPOL	19	13.2	19	38	23.5	4.13	3	16
Seniors	22	15.3	30	79	53.1	13.71	16	6
Experts	24	16.7	28	67	41.3	9.94	20	4
Total	**144**	**100.0**	**19**	**79**	**30.2**	**13.83**	**88**	**56**

Respondents were mostly single (69%) or married (26%). In total, 65% and 35% identified themselves as drivers and "other users" (pedestrians or cyclists), respectively. They mostly used their traffic mode in order to get to their work or study location (40%), or short trips for shopping, socializing, sport, etc. (38%). They reported average monthly mileage 1080 km (range 0 – 10,000; SD = 1507.46). Škoda was reported as a typical vehicle brand (41%). Roughly one third confessed to having been fined for a traffic offence, such as speeding or wrong parking. Six respondents (4%) reported having their driving licenses withdrawn; seven respondents (5%) obtained penalty points. In total 22% caused an accident and 26% participated in accident, both mostly with slight injuries. Due to the differences in further demographic and driver experience-related characteristics, the 5 groups presented in Table 1 were retained in the study.

2.3. Data analysis and hypotheses testing

Individual respondents' data, which were obtained from on-line application, were treated as:

– Independent variables (demographic data and variables related to driver experience)
– Dependent variables (average of perceived risk from 35 video clips, 13 TVP scores and 3 DBQ factors)

We formulated following 9 hypotheses:

– H1: The average risk perception of traffic situations is lower for males than for females.
– H2: The average risk perception of traffic situations is lower for road users, who identify themselves as drivers, than for those identifying themselves as "other users".

- H3a: There is a positive association between perceived risk and age (the older the respondents, the higher their average risk perception).
- H3b: There is a negative association between perceived risk and years of holding a driving licence (the more years, the lower the average risk perception).
- H4a: There is a negative association between perceived risk and average monthly mileage (the higher the monthly mileage, the lower the average risk perception).
- H4b: There is a negative association between perceived risk and total accumulated mileage (the higher the total mileage, the lower the average risk perception).
- H5: There is a negative association between perceived risk and self-assessment of driving skills (the better the grade for the driving skills, the higher the average risk perception).
- H6: There is a negative association between perceived risk and population of city of residence (the higher the population, the lower the average risk perception).
- H7: There is a difference in average risk perception between the student groups UPOL, VŠLG, ČVUT, the expert group and the group of seniors.

Hypotheses were tested in IBM SPSS according to the following steps:

1. For each hypothesis containing an association measure, the level of each variable was determined based on the scale used (e.g., ordinal scale for self-assessment of driving skills, continual scales for age, mileages, years of holding a driving license and average risk perception).
2. For each hypothesis containing a group comparison, the normality assumption of the dependent variable was tested for each group using Shapiro-Wilk test with $\alpha = 0.05$.
3. For each hypothesis containing a group comparison, the homogeneity of variances assumption was tested using Levene's test with $\alpha = 0.05$.
4. Based on the results of the assumption testing, following methods were chosen to test the individual hypotheses:
   a. for H1 and H2, an independent-samples t-test (one-tailed, $\alpha = 0.05$) and Cohen's d as a measure of effect size;
   b. for H3a, H3b, H4a, H4b and H6, Pearson correlation coefficient (one-tailed, $\alpha = 0.05$);
   c. for H5, Spearman correlation coefficient (one-tailed, $\alpha = 0.05$);
   d. for H7, one-way analysis of variance ($\alpha = 0.05$).

Besides the hypotheses, between-group differences (UPOL, VŠLG, ČVUT, experts, and seniors) were also tested for TVP scales and DBQ factors. Shapiro-Wilk test was firstly used to investigate normality assumption of all dependent variables for each group. Normality held ($p > 0.05$) for most TVP scores, with exception of generic extraversion for VŠLG students ($p = 0.037$), traffic-specific extraversion for UPOL students ($p = 0.004$), traffic-specific agreeableness for UPOL students ($p < 0.001$) and reactance scale for all student groups ($p < 0.05$). Each DBQ factor showed non-normal distribution of the scores for at least 2 of the groups ($p < 0.01$), which could be expected due to the nature of the variables (aberrant behaviour). Differences between groups in terms of all TVP scores, with the exception of reactance scale, were then analysed using one-way analysis of variance ($\alpha = 0.05$) and post-hoc tests with Bonferroni correction where necessary. Kruskal-Wallis test was used to test for group differences for the reactance scale and DBQ factors ($\alpha = 0.05$; post-hoc tests with adjusted p-value were also carried out where necessary).

3. Results

Overall differences between groups in the TVP scale scores are summarized in Table 2.

Table 2
Differences between groups in generic (g) and traffic-specific (t) TVP scales, using one-way analysis of variance (ANOVA, df1 = 4, df2 = 139)

Post-hoc tests with Bonferroni correction were carried out in case of significant ANOVA results. Based on these, a difference between VŠLG students and all other groups except for ČVUT students was found in traffic-specific extraversion (p < 0.01 for each VŠLG-group comparison, except ČVUT, p = 0.104). In generic neuroticism, a difference exists between ČVUT students and seniors as well as experts (p < 0.05 each), and between UPOL students and seniors as well as experts (p < 0.01 each). In traffic-specific neuroticism, a difference was found between UPOL students and VŠLG students (p < 0.05), UPOL students and seniors and experts (p < 0.01 each). Further, a difference between VŠLG students and all other groups except for ČVUT students was found in generic openness (p < 0.05 for each VŠLG-group comparison, except ČVUT, p = 0.146). In traffic-specific openness, a difference exists between UPOL students and VŠLG and ČVUT students (p < 0.01 each). In generic agreeableness, a difference was found between VŠLG students and seniors as well as experts (p < 0.05 each), and a possible difference might exist between VŠLG and UPOL students (p = 0.051). Finally, a difference between VŠLG students and all other groups except for ČVUT students (p = 0.052) was found in traffic-specific agreeableness (p < 0.01 each), and there was a difference between ČVUT and UPOL students in this trait as well (p = 0.035).
Group differences in the reactance scale were examined using Kruskal-Wallis test (K-W = 41.220; df = 4; p < 0.001), with a difference found between VŠLG and UPOL students (p < 0.001), ČVUT students (p = 0.012) as well as experts (p < 0.001). Using Kruskal-Wallis test, no group differences were found in DBQ factor 2 (Dangerous Errors; K-W = 5.197; df = 4; p = 0.268) or factor 3 (Straying and Loss of Orientation; K-W = 1.592; df = 4; p = 0.810). The only difference between the groups was found in factor 1 (Dangerous Violations; K-W = 10.881; df = 4; p = 0.028), probably due to the difference between VŠLG and UPOL students (unadjusted p = 0.018) as well as experts (unadjusted p = 0.009); the adjusted p-values were, however, not significant in the post-hoc tests (p = 0.178 and p = 0.089 respectively). In the following paragraphs, individual hypothesis tests are reported.

3.1. H1: The average risk perception of traffic situations is lower for males than for females

Descriptive characteristics are reported in Table 3. Normality assumption of average risk perception was retained (Shapiro-Wilk test, p > 0.05 for both groups), as well as the assumption of homogeneity of variances of both groups (Levene's test, F = 0.553, p = 0.458). Using the independent samples t-test, at the significance level of 0.05, a difference was found between males and females in their average risk perception (one-tailed t_{142} = –2.766, p = 0.003). On average, females perceive the risk of traffic situations as higher than males. Therefore, hypothesis H1 is accepted. In terms of practical significance (statistical power), the effect size is medium (Cohen's d = 0.473).

Table 3
Descriptive characteristics for testing of hypothesis H1, using Shapiro-Wilk (S-W) test

	N	**Mean**	*SD*	*SE*	**S-W test**	**Sig.**
Males	88	1.59	0.46	0.05	0.991	0.787
Females	56	1.81	0.47	0.06	0.984	0.647

3.2. H2: The average risk perception of traffic situations is lower for road users, who identify themselves as drivers, than for those identifying themselves as "other users"

Descriptive characteristics are reported in Table 4. Normality assumption of average risk perception was retained (Shapiro-Wilk test, p > 0.05 for both groups), as well as the assumption of homogeneity of variances of both groups (Levene's test, F = 0.938, p = 0.334). Using the independent samples t-test, at the significance level of 0.05, no difference was found between drivers and "other users" in their average risk perception (one-tailed t_{141} = –0.053, p = 0.479; Cohen's d = 0.008). Therefore, hypothesis H2 is rejected.

Table 4
Descriptive characteristics for testing of hypothesis H2, using Shapiro-Wilk (S-W) test

	N	**Mean**	*SD*	*SE*	**S-W test**	**Sig.**
Other users (pedestrians/cyclists)	50	1.67	0.42	0.06	0.978	0.457
Drivers	93	1.68	0.51	0.05	0.989	0.600

3.3. H3a: There is a positive association between perceived risk and age (the older the respondents, the higher their average risk perception)

Based on Pearson correlation coefficient, no association between perceived risk and age was found at α = 0.05 level (one-tailed r_{144} = –0.033, p = 0.348). Therefore, hypothesis H3a is rejected.

3.4. H3b: There is a negative association between perceived risk and years of holding a driving licence (the more years, the lower the average risk perception)

Based on Pearson correlation coefficient, no association between perceived risk and years of holding a driving licence was found at $\alpha = 0.05$ level (one-tailed $r_{144} = 0.003$, $p = 0.486$). Therefore, hypothesis H3b is rejected.

3.5. H4a: There is a negative association between perceived risk and average monthly mileage (the higher the monthly mileage, the lower the average risk perception)

Graphs in Fig. 2 display the average perceived risk plotted against average monthly mileage (in kilometres). Based on Pearson correlation coefficient, initially, no significant association between perceived risk and average monthly mileage was found at $\alpha = 0.05$ level (one-tailed $r_{144} = -0.120$, $p = 0.076$). Upon closer inspection, there are 4 outliers in the sample (full dots in the left graph) – the drivers who reported driving 5800 km per month or more. After discarding these respondents, the correlation increases and becomes statistically significant (one-tailed $r_{140} = -0.157$, $p = 0.032$; restricting the hypothesis to drivers with an average monthly mileage < 5800 km). However, the association is still very weak (R^2 close to zero in both cases) and there are no further reasons for discarding the outliers (except that they have unusually high average monthly mileage in comparison with the rest of the sample). We therefore conclude, in compliance with the initial results, that there is no significant association between perceived risk and average monthly mileage and reject the hypothesis H4a.

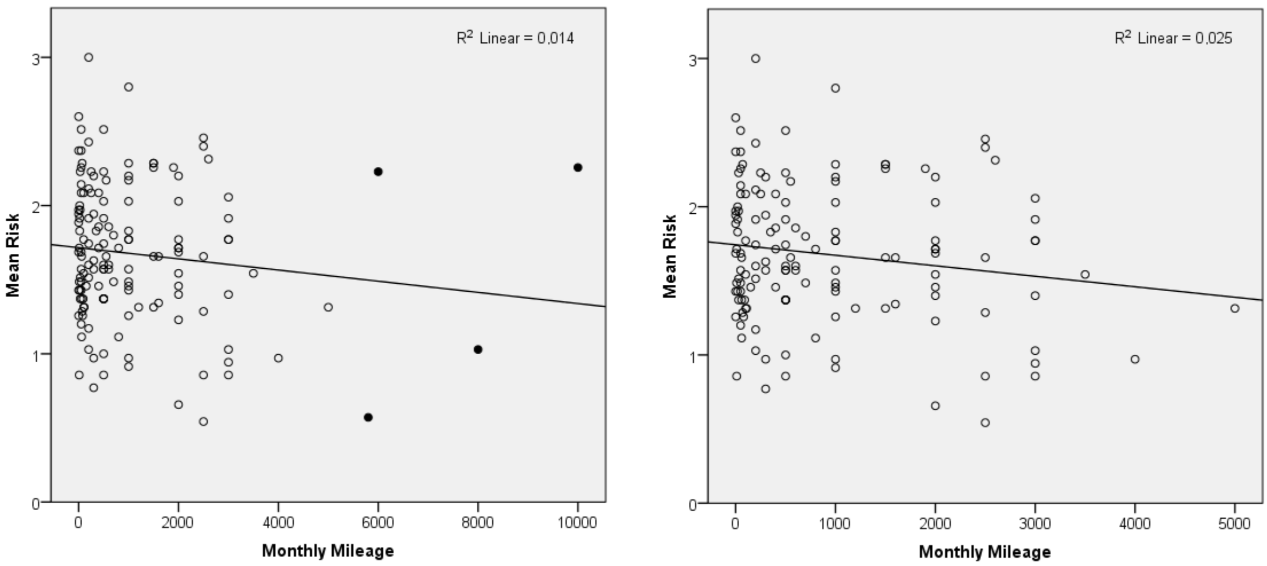

Fig. 2.
Relationship between average perceived risk and monthly mileage, with and without outliers (full dots)

3.6. H4b: There is a negative association between perceived risk and total accumulated mileage (the higher the total mileage, the lower the average risk perception)

Graphs in Fig. 3 display average perceived risk plotted against total accumulated mileage (in kilometres). Based on Pearson correlation coefficient, initially, a weak negative association between perceived risk and total accumulated mileage was found at $\alpha = 0.05$ level (one-tailed $r_{144} = -0.185$, $p = 0.013$). However, the R^2 is close to zero, and upon further inspection, there are 2 outliers in the sample (full dots in the left graph) – the drivers who reported having driven 1.4 and 1.5 million km. After discarding these respondents, the correlation decreases and becomes statistically insignificant (one-tailed $r_{142} = -0.123$, $p = 0.073$). Because the association between the two inspected variables is weak in both cases (R^2 close to zero), and probably influenced by the two respondents with unusually high total monthly mileage, we conclude that there is no association between perceived risk and total accumulated mileage and reject hypothesis H4b.

3.7. H5: There is a negative association between perceived risk and self-assessment of driving skills (the better the grade for the driving skills, the higher the average risk perception).

Based on Spearman correlation coefficient, no association between perceived risk and self-assessment of driving skills was found (one-tailed $\rho_{144} = 0.130$, $p = 0.060$). Therefore, hypothesis H5 is rejected.

3.8. H6: There is a negative association between perceived risk and population of city of residence (the higher the population, the lower the average risk perception)

Based on Pearson correlation coefficient, a significant weak negative association was found between perceived risk and population of city of residence (one-tailed $r_{144} = -0.233$, $p = 0.003$). Solely on these results, hypothesis H6 is accepted. No apparent outliers were identified in the data, however, the association is still low ($R^2 = 0.05$).

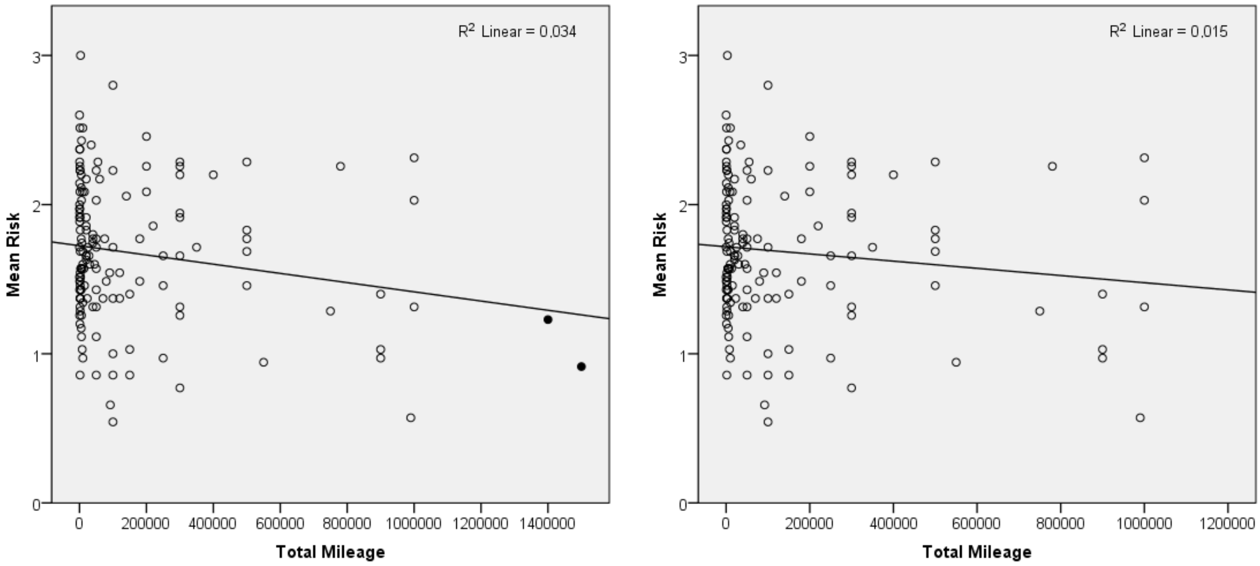

Fig. 3.
Relationship between average perceived risk and total mileage, with and without outliers (full dots)

3.9. H7: There is a difference in average risk perception between the student groups UPOL, VŠLG, ČVUT, the expert group and the group of seniors

Descriptive characteristics are reported in Table 5. Normality assumption of average risk perception was retained for all groups (Shapiro-Wilk test, $p > 0.05$ each), as well as the assumption of homogeneity of variances (Levene's test, $F_{4,\ 139} = 1.429$, $p = 0.228$). Using the one-way analysis of variance, at the significance level of 0.05, no difference was found between the student groups UPOL, VŠLG, ČVUT, the expert group and the group of seniors ($F_{4,\ 139} = 1.765$, $p = 0.139$; see Fig. 4). Therefore, hypothesis H7 is rejected.

Table 5
Descriptive characteristics for testing of hypothesis H7, using Shapiro-Wilk (S-W) test

	N	**Mean**	***SD***	**S-W test**	**Sig.**
VŠLG	55	1.79	0.50	0.986	0.754
ČVUT	24	1.56	0.38	0.976	0.819
UPOL	19	1.51	0.39	0.960	0.572
Seniors	22	1.64	0.57	0.975	0.831
Experts	24	1.70	0.43	0.946	0.219

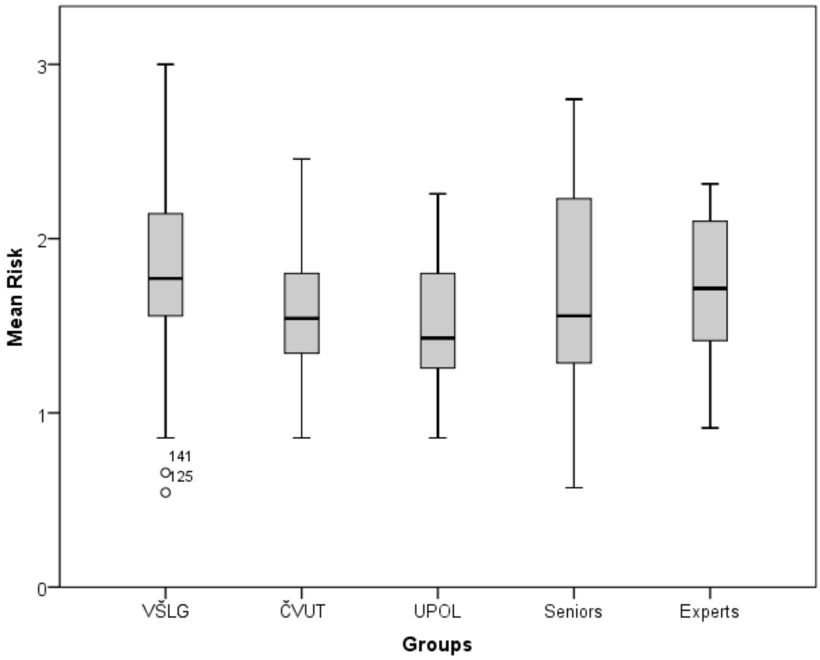

Fig. 4.
Average perceived risk of traffic situations for individual respondent groups

4. Discussion

The results of previous hypotheses testing are summarized and discussed in the following paragraphs:

- *(H1) On average, females perceive the risk of traffic situations as higher than males*. This finding is consistent with earlier studies, which indicated that males tend to be more optimistic regarding their driving skills and perceive the behaviours as less serious and less likely to result in accidents (DeJoy, 1992; Farrand and McKenna, 2001; De Craen et al., 2011).

- *(H2) No difference was found between drivers and "other road users" (pedestrians/cyclists) in their average risk perception.* While it appears as surprising, this may be caused by the fact that most of video clips displayed interactions between vehicles. It means that the respondents, who identified themselves as primarily pedestrians or cyclists, may perceive the risk as related to vehicle drivers rather than to themselves. Nevertheless this is not supported by theory, since neither cyclists' risk perception nor comparisons to drivers' risk perceptions have been sufficiently studied so far, as indicated e.g. by Chaurand and Delhomme (2013) or Lehtonen et al. (2016).

- *(H3a) No association was found between perceived risk and age* and *(H3b) No association was found between perceived risk and years of holding a driving licence*. These findings are not consistent with general knowledge that hazard perception is related to age and experience (Finn and Bragg, 1986; Sagberg and Bjørnskau, 2006; Borowsky et al., 2009), which both contribute to over-involvement of young drivers in accidents. This might be caused by research sample bias, as the sample is rather small and consists mainly of students (younger participants) and traffic experts (older participants). Hypothesis then might be, that both groups perceive traffic risk at the same or similar level, but due to different reasons: young people because of their age (they are known to rather underestimate risk) and traffic experts (older drivers) because of their experience (belief that they can handle such a situation).

- *(H4a) There is no association between perceived risk and average monthly mileage* and *(H4b) There is no association between perceived risk and total accumulated mileage*. Similarly to hypotheses H3a and H3b, we did not find sufficient evidence for the association of driving experience and risk perception in traffic situations in our sample. This could be the result of the aforementioned sample bias – most participants (85%) in our sample reported driving 2000 km or less on average per month and having driven 35000 km or less in total. A less restricted sample in terms of driving experience (i.e., including more professional drivers) might yield different results and become more consistent with existing literature.

- *(H5) No association between perceived risk and self-assessment of driving skills was found.* This finding is not surprising, since literature is mixed on this topic: some studies reported positive correlations, some negative, some none (e.g. Hattaka et al., 1997; Lund and Rundmo, 2009). We expected negative correlation between self-assessment of driving skills and level of risk perception: the better the grade drivers give themselves (with "1" meaning "excellent"), the higher the average risk perception (i.e. the more aware the drivers are of the traffic risk). One of the reasons why this relationship is so unclear might be the fact that most of the studies (including ours) did not distinguish between risk perception ("if I can identify risk, I can see the risk") and ability to handle the risk ("I perceive risk, but I believe I know how to handle it and so I don't consider this situation as risky").

– *(H6) A negative association between perceived risk and population of city of residence was found.* This finding may relate to possible differences in traffic performance and patterns in less vs more inhabited areas. Previous analyses, based on place of residence (as opposed to place of accident) shown that the risk is lower for city population compared to suburban and rural population (Blatt and Furman, 1998; Scheiner and Holz-Rau, 2011). These differences may have been translated to driving behaviour and skills, and in turn to hazard perceptions of users living in cities. However, we should keep in mind that the association in our sample was still rather weak.

– *(H7) No difference was found between the student groups UPOL, VŠLG, ČVUT, the expert group and the group of seniors in terms of average risk perception.* This hypothesis was originally formulated with the idea of checking the anticipated value of expert judgment, which is applied by certified auditors during road safety inspections. Lack of difference may be surprising; however there were previous studies aiming in the same direction. For example Sivak et al. (1989) did not find any differences in risk ratings of professional vs non-professional drivers; also Kouabenan (2002) found similar hazard perception patterns across various occupation and experience groups. In another study (Kruysse and Wijlhuizen, 1992), experts and lay persons were found equally reliable in judging hazardous traffic situations. These features may influence the expert judgments, in addition to already known biases, such as reliability between experts, confirmation of expectancies or skewed descriptive analyses, which are all important elements in road safety inspections and investigations. Although solutions were proposed (Melcher et al., 2001; Cafiso et al., 2006; Elvik, 2006; Washington et al., 2009; Brenac et al., 2012; Park and Sahaji, 2013; Classen et al., 2015), they have not yet become a standard practice.

It should also be noted that the presented study had limitations, which may influence the results and their interpretation:

– Sample size was low, which limited possibility of validation; in addition distribution was skewed towards students. In three of five groups males were overrepresented compared to females.
– The questionnaires were not designed to distinguish between risk perception and ability to handle the risk.
– Video clips of traffic scenes were taken "off-road", which may reduce comparability with previous studies that were typically from the driver perspective. In other words: in the present study, respondents assessed the risk to others, while most studies dealt with risk to respondents themselves. Perceived risks in these perspectives may differ, as noted for example by Sjöberg (2000).
– Pearson correlation coefficients for H3, H4 and H6 were rather low.

5. Summary and conclusions

The study objective was to reveal the links between subjective risk assessment and personality traits – the authors wanted to find an answer to the question *How do we perceive traffic risk?* To this end an on-line test was prepared, consisting of general questionnaire, risk perception assessment, personality questionnaire, and Driver Behaviour Questionnaire. Several groups of respondents filled in the test and their data were analysed.

Some of the identified relationships provided expected results, consistent with previous studies: for example high risk perception of females compared to males or lack of differences between students (non-professionals) and experts (professionals). Other findings were less expected, for example lack of relationships of risk perceptions to age and experience. These could have been influenced by small size of respondent sample or the fact that video clips, used for risk perception assessment were "off-road", as opposed to typical "on-road" design, which could limit comparability to past research.

Nevertheless the idea of the "off-road" video clips was to mimic the view of traffic experts, who conduct road safety inspections, i.e. "ordinary periodical verifications of the characteristics and defects that require maintenance work for reasons of safety" (European Directive 2008/96/EC). The inspections involve survey and reporting with use of check lists, optionally including traffic conflict observations, speed measurements or accident analyses. All these task are to some extent subjective, i.e. possibly influenced by risk perceptions. In this regards the identified differences, based for example on gender or city population, should be considered. Future improved studies may lead to implementation of these aspects in order to improve road safety auditors' or traffic conflict observers' training procedures.

Acknowledgements

We thank Tomáš Režňák (CDV) for developing on-line test interface, and the respondents for participation in data collection. We acknowledge help of the following persons with arrangement of respondents: Michal Turek (VŠLG), Karel Kocián and Tomáš Padělek (ČVUT), Jaroslav Konečný (VPŠ), Ilona Prausová (ČVUT alumni association), Eva Blažková (UPOL Alumni Club). The study benefited from using research infrastructure of Transport R&D Centre (CZ.1.05/2.1.00/03.0064).

UE GUIDELINES: RISK ASSESSMENT AND RISK MANAGEMENT FOR RAILWAY TRANSPORT

Giovanni Battista Ravera[1], Daniele Muschietti[2], Matteo Ravera[3]
[1,2] *ANSF – Agenzia Nazionale per la Sicurezza delle Ferrovie (National Railway Agency), 50100, Firenze, Italy*
[3] *Freelance, Risk Analysis for Business Expert, 50100, Firenze, Italy*

Abstract: UE guidelines prescribe the harmonization of the safety rules for the infrastructure manager and railway undertakings which must take the full responsibility of the safety, even by implementing measures for the risk control. The Member States do a clear distinction between the safety responsibility and the task of safety authorities to elaborate a national regulatory framework and to monitor the operators performances. Manufacturers, maintenance services suppliers, maintenance of wagons operators, services suppliers and contractor agencies are involved in the safety responsibility of the infrastructure manager and railway undertakings. Infrastructure manager and Railway undertakings work out their own safety management systems to fulfill the CST (Common Security Target), that it is in compliance with the national safety rules as per the directive 2004/49 (now directive 2016/798), as well as the TSI safety standards, that the points relevant to the CSM have been applied (Regulations UE 1169/2010 and 1158/2010).

Keywords: risk analysis, safety indicators, cost-benefit analysis.

1. Introduction

Let's start with some definitions, someone are listed in ISO 31000:

RISK	Effect of uncertainty on objectives; the uncertainty is the state, even partial, of the absence of information concerning the understanding and knowledge of an event, of its consequences and their likelihood. It is a probabilistic concept.
RISK MANAGEMENT	it is an coordinated activity to direct and control an organization about the risk management.
POLICY FOR RISK MANAGEMENT	it is a declaration of the guidelines and operational policies of an organization about the risk management.
RISK MANAGEMENT PLAN	it is a schema (plan) that specifies the approach, the management components and resources to be used for risk management.
RISK MANAGEMENT PROCESS	it is a systematic application of policies, procedures and management processes of communication , consultation, definition of context and identification, analysis, weighting, treatment, monitoring and risk review.
MONITORING OF RISK	it is a constant checking, supervision, critical observation and continuous determination of the state to changes compared to the level of performance required and expected .
RISK REVIEW	it is an activity carried out to detect the suitability, adequacy and effectiveness of something and achieve their objectives.

The infrastructure managers and railway companies shall implement their own safety management systems to fulfill CST (Common Safety Targets), in accordance with the national safety standards according to the Directive 49/2004, as well as the safety regulations TSI, for which are applied the relevant points for the CSM (EU regulations 1169/2010 and 1158/2010). Between these points, the following criteria are listed:

A The control measures for the risks linked to the activity of the operator rail;
B The control risk related to the supply of material and maintenance;
C The control of risk related to the use of contractors and suppliers;
D The risks coming from activities of other parties external to the railway system;
M Procedures and methods to perform risk assessment and risk control for every change in operating conditions or changes of railway systems.

2. Ue guidelines

An organization that subscribes a policy for risk management, coherent with its cultural principles, must determine the performance indicators in line with other strategic indicators and align the objectives of risk management with the business plan already identified, ensuring the respect of requirements.
The EU Directive 2004/49 (now EU 2016/798) regulates the safety of the railways in European Union. The same Directive introduces the indicators, methods and common safety targets (CSI, CSM, CST) to allow to develop and manage the railway safety in a harmonized way. In particular, the common safety targets (CST) are expressed in terms of risk acceptability or levels of safety objectives, and they are valued by the common safety indicators (CSI) considering the INDIVIDUAL RISKS and the RISKS FOR THE COMMUNITY.
About the SGS, the Directive attributes to the GI to IF responsibilities regarding risk control, internal and external, or induced by contractors.

Table 1
The risk management by directives EU

UE GUIDELINES
Common Safety Indicator CSI
Common Safety Method CSM
Common Safety Target CST

Risk control is a chore that competes also to all actors that have an impact on the safe operation of the EU rail system, including: manufacturers, maintenance service providers, owners, contracting authorities, etc.
Moreover, for the latter it is necessary to ensure the compliance with the requirements and conditions of use required for all exercises, materials and supplied services.
In the case of safety risks due to defects, construction non-conformities, or malfunctions of technical equipment, also of structural subsystems, the infrastructure managers (IM) and Railway Companies (RU) need to put in place the necessary corrective measures to cover the risk of security identified and reported this risk to stakeholders to allow to take the necessary additional corrective measures.
All this to ensure the safe operation of the rail system and facilitate the exchange of information between relevant actors.
As mentioned, the control of risk is expressed in terms of the safety target levels or risk acceptability, through the CST, regulated by appropriate CSM to be taken to ensure the objectives of safety, and CSI to evaluate the realization of the same goals .
The CSMs shall describe the evaluation of the levels and the achievement of safety goals through the development and adoption of methods for risk assessment, evaluation of compliance with the safety certification requirements, supervision and monitoring , applied by the national authorities security, performance assessments of rail operators, the evaluation of the realization of safety targets and all other relevant methods SGS to be authorized at EU level.
The CSM are prepared by ERA, on the basis of user opinions, by NSA and stakeholders, possibly including the social partners on consultative mandate of the EC.
The document drafted by ERA on the CSM represent a EC recommendation and consists of a report on the consultation results and a report on the impact assessment of new or modified CSM to be taken.
The CSM are subject to periodic reviews subsequent to experiences gained from their application or the global evolution of railway safety. The content of the CSM and any amendments may be adopted by the EC to issue its delegated acts.
The CST establish minimum safety levels that must be expressed by the rail system as a whole and from different parts of the rail system of each Member State of the EU.
The CST can be defined in terms of risk acceptance criteria or objective level for the security considering the individual risks they are exposed to all stakeholders and the risks for the company.
Even the CST are processed by ERA by mandate of the EC.
The recommendations ERA in approving SCST can be transposed from the EC by implementing acts. For this reason, the EC shall be assisted by an advisory committee that gives advice on ERA's recommendations.
Even the CST are subject to periodic reviews like the CSM.
All national regulations on safety must comply with the CST and CSM.
The NSA must verify that the IFs and GIs, including all concerned stakeholders, acquire a strict liability on the definition of a functional to a SGS project.
The SGS objectives should aim to identify associating dangers to control activities of all their components, engines and the risk that each individual can represent danger to the safety and operation.
Based on these assessments must develop strategies to reduce the probability and frequency of occurrence of each risk, to bring them to an acceptable level.

This is achieved, as already mentioned, by means of a correlation between the CSI and the CST, applying the CSM whose synthesis represents the SGS manual.

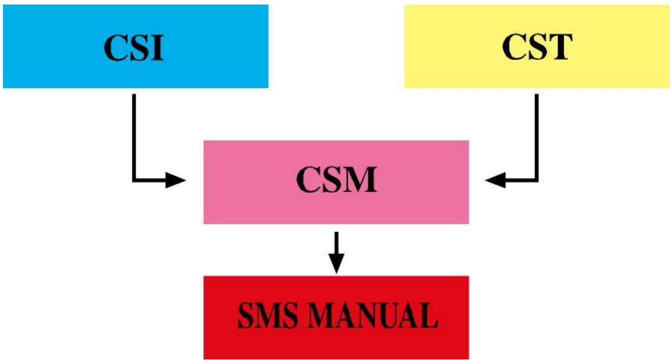

Fig. 1.
Correlation between CSI & CST

Therefore it needs to be developed a program of activities that will ensure that all security requirements are identified and implemented.

3. Factors causing the risk

DANGER: probability that it is reached the potential level of damage.
The danger is constituted by three basic components:

1. Hazard Element (HE) = it is the main source of danger, one that can generate the unexpected event;
2. Initianing Mechanism (IM) = it is the mechanism that causes the transformation from dormant state to the active state;
3. Target and Threat (T / T) = it is the damage /hurt that can suffer one thing / person exposed to the incident.

Fig. 2.
The danger triangle

Therefore a dangerous event can have harmful consequences only when it activates all the three components, or with other words in the moment when there is the simultaneous presence of the three components is the concrete risk of a dangerous occurrence.
In complement, the mere absence of one of the components makes it unlikely that the dangerous event activation. It follows that inhibition of one of the three components has an effect relieved / preventive on the risk of occurrence.

Table 2
Same risk examples. The free components HE, IM, T/T may be considerated as the triangle segmentes: if anyone there is not, the danger disappeared

HE	IM	T/T
- Track geometry defect;	- Prud'Homne limit Override; - Sidling limit Override;	- Railway vehicle Derailment, - Infrastructure Damage; - vehicles ehicles Damage; - Personal injury; - Environmental damage; - etc……..
- CCS subsystem	- Unreliability security	- Convoy clash;

degradation on less restrictive levels of ordinary ones; - Fail safe out of service;	apparatus; - Human error by staff responsable;	- Damage to third parties; - Personal injury; - Infrastructural Damage; - etc…..

The status of a danger remains latent until it gets a trigger that activates the transition from danger in an accident.
Two factors that influence the transition:

- The overall level of risk;
- The risk rate of each individual component.

It follows that the danger of components are the elements of definition of the same hazard and the risk of accident is the probability that a danger cause an event of a certain severity.

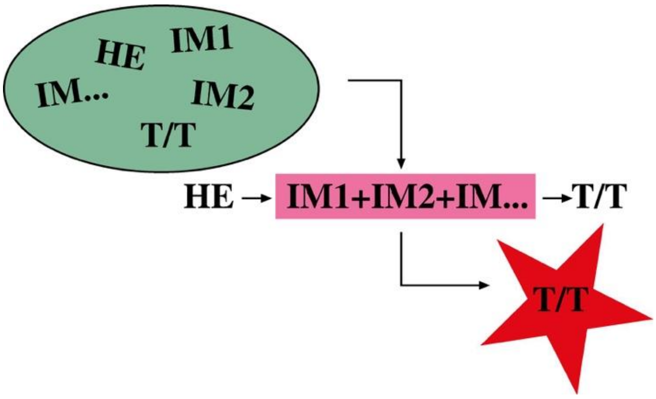

Fig. 3.
The incident birth

To summarise, the accident can happen only if the three components of the danger, consisting of one or more elements are aligned on a specific configuration at the same time.
This means that all the causality of the danger components will not cause the accident until the interaction will not assume a predefined sequence.
The three components can be all causes of accidents independently of the order with which they appear.

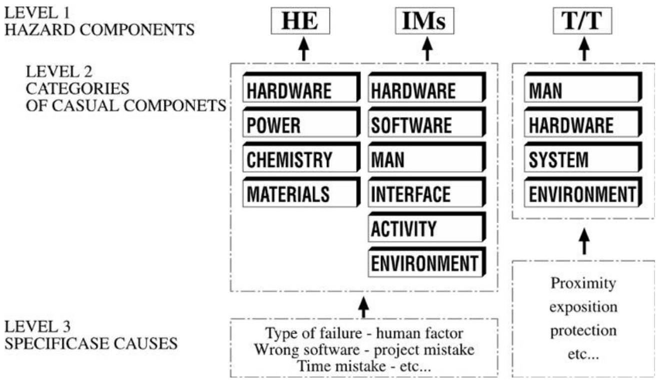

Fig. 4.
Factors causing the danger. The level 1 is the top level and includes the components of danger (HE + IM + T/T). 2 level is the intermediate containing the categories of factors causing the danger (HCF). The level 3 represents the lower level where all detail items of specific causes of danger are placed.

The hazard causal factors (HCF) may be present in a system, because they are inevitably used by the system and / or because the conceptual assumptions of the project was inadequate, or because induced by an exogenous source to the system.
The analysis of the cause of the danger factors is the basic principle of the theory DANGER-STEP, which can be summarized as follows:
The danger due the accident; a hazard is a condition that defines a possible future event (accident);
A danger and an accident are two different states of some phenomena (before and after);
Each hazard / accident has its own and unique risk (probability and frequency);
A danger is an entity identified by three components (HE + IM + T / T);

HE and IM are the factors of the causes of danger and define the probability factor of the risk of accident;
T / T with parts of HE and IM define the severity factor of the risk of accident;
HCF (hazard causal factors) can be characterized by three different levels;
h. the probability that a hazard exists is "1" or "0"; However, the probability that happen an accident is linked to the specificity of the HCF.

4. Risk management

Risk management explicitly addresses uncertainty, its nature and its treatment.
The basic principles to allow for effective risk management does not transcend the value of the organization and management processes, are part of the decision-making process by helping managers to make informed choices, through priority stairs, about possible alternative actions.

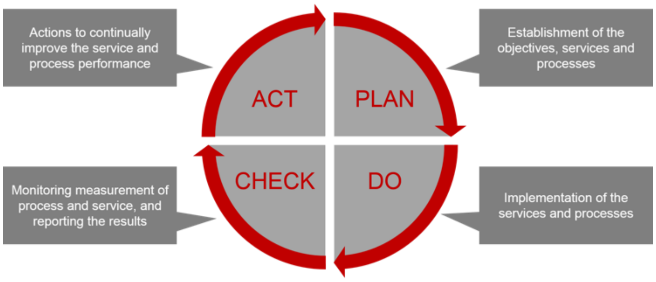

Fig. 5
The risk management is an activity in "perpetuo motu"

The approach to the risk management must be structured, systematic and timely; this allows to make efficient the action through the consistency of the results to be comparable and reliable.
An effective risk management is based on reliable information, clear and, as far as possible repeatable.
The historical data, the experience feedback, the comments, the specialist studies are Input elements for the analysts.
The risk management must be always contextualized to internal and external events of the organization, according to a predefined risk profile, and must consider the human and cultural factors that can facilitate or impede the achievement of the objectives.
All stakeholders must be involved in risk management so as to make it transparent and inclusive more as possible.
An effective risk management caused a continuous improvement of the organization or the company, responding to the stress of change in a dynamic, iterative and responsive way; whenever the external and internal events change the context and knowledge, it should be implemented to monitor and review, to detect new risks or the changing and the disappearance of some other risks.

5. Instruments for risk management

The creation of appropriate safety case provides a means to demonstrate that the planned activities were implemented successfully, achieving the risk reduction objectives.
For a certification / authorization, the NSA should verify the consistency of the processes implemented by the IF and GI, that requiring the certification, in particular they should delay on the implementation and on the consistency of the following activities:

a. Preliminary Hazard Analysis (PHA);
b. SGS Manual: must detail the strategies for reducing risks to an acceptable level established by applying the CIS and the CST;
c. Hazards Analysis (HA and Hazard log): Check on starting a hazard analysis and creating and maintaining the register of the dangers;
d. Plan of monitoring: preparation of audits / inspections / Process Security checks to verify compliance of security activities with SGS and any other required standard;
e. Specification of security requirements (organizational procedures, operational procedures): specific safety requirements derived from the risk reduction strategies must be fully available for the audit work / inspections / checks by setting up appropriate procedures;
f. Validation of security requirements: he appropriate testing procedures must be developed to validate the safety requirements;
g. Safety case: is a documentary process that tests the security processes to capture information on the effectiveness of control and risk management.

In the following, we delay the attention on the first three activities.
The Hazard Analysis (PHA and HA) has as its objective the identification of hazards and hazardous events, for all reasonably foreseeable circumstances, including the misuse and fault conditions, and the definition of the causes for

analyzing the sequence of events in appropriate combinations. This must lead to the determination of the risks associated with dangers.
The Hazard Analysis is therefore an iterative process that continues throughout the life of the system, designed to identify and mitigate hazards that may be induced by the relevant activity of design, development, testing, functional testing, maintenance and disposal (sale) of a system. A fundamental document, result of the Hazard Analysis, is the Hazard Log (Register of dangers). In this, for every danger, are recorded the results of a Hazard Analysis process development steps, including specific mitigation or prevention actions.

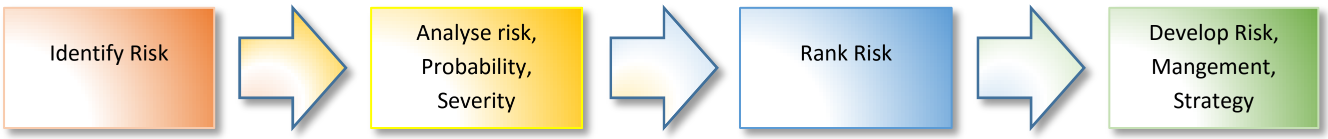

Fig. 6.
Hazard analysis block flow

The procedural flow of the Hazard Analysis can be simplified into the following macro-actions:
i. identify,
ii. then analyze,
iii. then classify
iv. and, at the end, advancing!

The first step identifies the scenarios and the dangers qualifications and corresponds to the block "Identify Risk". The steps 2 and 3 analyze the dangers and define its connotation in terms of scenarios (Si), the probability of occurrence (Lj) and harmful consequences (Xk); the risk of occurrence is represented by this set of three vectors:

$$\text{Risk} = \{< S_i, L_i, X_i >\} \quad (1)$$

The steps 2 and 3 are identified in the block "Risk Analyse, Probability, Severity," while the step 4 is represented by the block "Rank Risk". Step 5 is the block generator "Develop Risk, Mangement, Strategy" and conception of the Risk Planning.

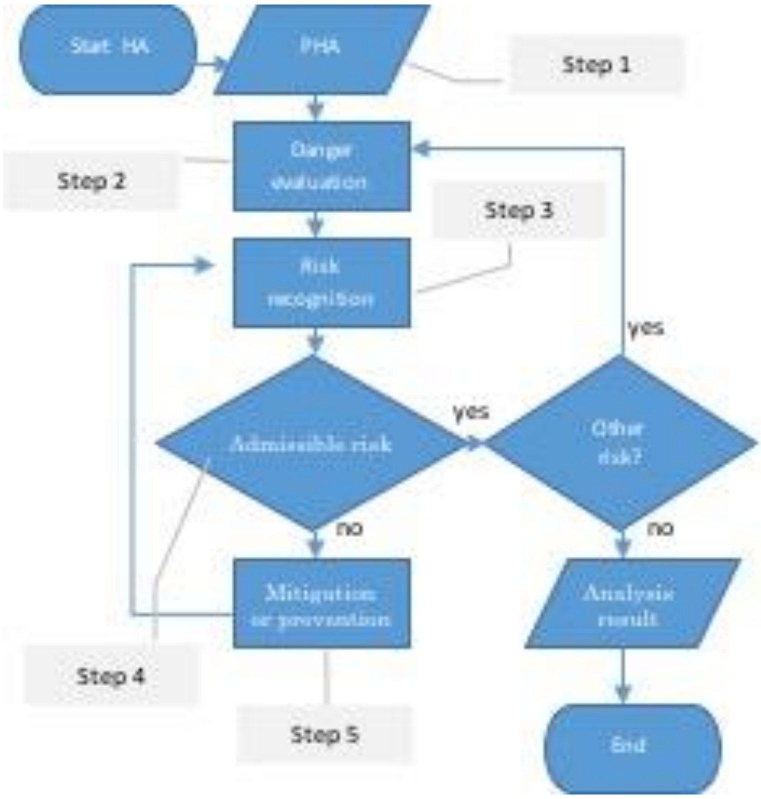

Fig. 7.
Develop of analysis process/risk assessment

Any operating environment directly in engineering of industrial organizational systems is characterized by the presence of real risks. Many can relate the organizational area, other corporate strategies, and of course, many others are relevant to the productive functioning; and in the transport this operation should be safe.

Some scenarios are listed below:
The collapse of an organizational system or part of it (the organizational failures are often the main sources of risk).
Risk of extreme or rare events can be distorted by the only assessments based on the expected value measure (the measure of the expected value of risk for rare but catastrophic events of low probability with other less high probability of adverse events can distort or result in the management of pain catastrophic risk).
The risk of exceeding the project costs and delays of the program (the design of engineering systems is often characterized by the cost overruns and program delays and, therefore, the management process and the risk assessment can be a necessary requirement to prevent ' inability to meet performance criteria).
Risk management is an integration requirement for engineering systems (all aspects, components and functions of the system must rely on an assessment of the associated risks, this ensures a second approximation also an understanding of the functional aspects that emerge as a subprocesses of integration).
The restructuring and maintenance of structural subsystems (the accurate assessment of risk of failure and functional degradation of the structural subsystems is a requirement for the effective allocamento resource).
The overall extent of the failure modes and reliability of engineering systems (there are different types of faults and interpret the consequences is a priority for management and risk assessment).
The risk on the development of intellectual activities in the field of engineering systems (can not be developed the research and yhe technological innovation when the system is beset by problems of cost overruns and production delays).
The risk of unexpected and critical to the security of the system (the assessment and management of risk is not sufficient without the construction of safety-related systems, including ensuring the most remote probability of failure a safe stop without catastrophic consequences).
Engineering system characterized by interdisciplinarity (the engineered systems serve the welfare of the population and the integration of basic knowledge of other disciplines is essential; the risk of bankruptcies on the rise, increasing throughout this interdisciplinary).
Risk management: a requirement for a sustainable development (sustainable development and guarantee secure protection of the environment and ecology, and this can not be achieved without a systemic process of assessment and risk management).
Risk assessment based on evidence (data-base and limited information often characterize systems, especially during the phases of conception, design and implementation; the reliability of the evidence, including those produced by the experts, it is essential for the practical risk management these systems).
impact analysis (a good methodology necessarily incorporates a best practice risk management, in particular the decision implemented today has impact on future decisions and opinions).
The application of hazard-accident theory to some of the risks listed and bringing it to the reality of railway subsystems, can give rise to the examples given in the following table:

Table 3
Application of danger-incident theory about system railway scenarios

HE	IM	T/T
- Evaluation based limitate about expected risk	- Presumption of own infallibily for many experiences; - Statistical elements up or low overestimate; - - etc. …	- Disorientation of corporate strategy and policy; - Bed management of corporate balance sheet; - Wiste production; - etc. …
- Overflow of budget cost; - Delay of manufactoring	- Unsatisfied performances; - Absence of re-examination assessment; - - etc. …	- Bank index redetermination; - Finance charge unknowledge; - Job cost increse; - Productivity decrese; - etc. … -
- Risk management approach not oriented to system and process	- Not available WBS process definition; - - incomplete assessment of process risk	- Total cost unknowledge; - Incident; - Wiste production; - etc. … -

HE	IM	T/T
- Indeterminated functional degeneration; - Indeterminated funzional reset; - Deteriorated operation	- Inadequate policy manufacturing needs; - Mistake application of mantenance engeenering; - Inadequate supply of material and mantenance; - Operative inability; - etc. …	- Lost of manifacturing; - Total cost unknowledge; - Incident; - Damage of materiali and plant; - Injuries; - - etc. …
- Unavailability of manufactoring; - Indetermineted failure; - Technical crash; - Deteriorate operation	- Failures and malfunctionigs; - Operational incompetence; - Human mistake; - - etc. …	- Incident; - Lost of manifacturing; - Unespected repair costs; - Plant damage; - Injuries; - -etc. …

The danger-accident theory tries to give a methodical approach to the application of analysis and evaluation of a set of data, to express in terms of probability of achieving a potential level of damage. Although deterministic, the measurement problem of a risk is linked to statistical concepts and type of decision variables, for which can be a suitable configuration that optimizes the choice of appropriate decisions, in terms of safe operation and secure maintenance.

Fig. 8.
The risk management must be measured

In these cases the math always provides the best opportunity to solution through the application of one of its disciplines. The use of a suitable mathematical model can represent a real system.
Therefore, a mathematical model is a set of equations that describe and represent the real system. This type of equations analyses the various aspects of the problem, it identifies the functional relationships between all the components of the system and the elements of its environment, it lays down measures of effectiveness and constraint, indicating what data should be collected to address the problem qualitatively.
Often mathematical models optimize or solve the problems encountered in real life, through the techniques of optimization or simulation appropriate. For example: the definition of a scenario of optimal decisions, $\{x_1^*, \dots, x_n^*\}$, could result from the maximization (or minimization) of an objective function, $f = f(x_1, \dots, x_n)$

$$\max = f(x_1, \dots, x_n) \tag{2}$$

subject to predetermined constraints,

$$\begin{cases} g_1(x_1, \dots, x_n) \leq b_1 \\ \dots \dots \dots \dots \dots \dots \dots \dots \\ g_n(x_1, \dots, x_n) \leq b_m \end{cases} \tag{3}$$

to summarise: $f(x_1, \dots, x_n)$ is the objective function, $\{x_1, \dots, x_n\} = \vec{X}$ are the decision variables, $g_1(\vec{X}), \dots, g_n(\vec{X})$ are the constraints and $\{b_1, \dots, b_m\} = \vec{B}$ are known as resources.
In the case of linearity of the binding functions, the system of equations can be represented in matrix form:

$$G\vec{X}^T \leq \vec{B}^T \tag{4}$$

and the problem can be solved with the principles of linear programming.
An example of scenario where the implementation of optimized decisions is the functional subsystem maintaining railway infrastructure and rolling stock (locomotives and cars).
The European regulations and national legislation obliging operators to equip themselves with a GSE that contains the provisions and procedures to meet the requirements for the maintenance in a safe condition.
Assuming that these conditions are governed by the decision variables $\{x_1, \ldots, x_n\} = \vec{X}$, you can assume the following system functions:

$$\begin{cases} R = R(\vec{X}, \vec{E}) \\ A = A(\vec{X}, \vec{E}) \\ M = M(\vec{X}, \vec{E}) \end{cases} \tag{5}$$

where $\vec{E}$ is the any exogenous event or stochastic.
Consider then the maintenance system of the structural subsystems Infrastructure (INF) and command / control / signalling (CCS), bound by a number of restrictions:

$$\begin{aligned} &g_1 = g_1(R, A, M, C) \leq K_1, \text{costo funzionamento sicuro;} \\ &g_2 = g_2(R, A) \leq F, \text{rischio avaria;} \\ &g_3 = g_3(R, A, M) \leq T, \text{rischio degrado funzionale;} \\ &g_4 = g_4(M, C) \leq K_2, \text{costo ripristino sicuro.} \end{aligned} \tag{6}$$

Assuming that the objective function is represented by a linear combination of the system functions, the definition of the optimal decisions can be obtained from the minimization of the objective function:

$$\min\{f(R, A, M)\} \Longrightarrow \overrightarrow{X^*} = \{x_1^*, \ldots, x_n^*\} \tag{7}$$

Since the entire analysis is based on the possession of variables and resources derived from concepts and safety rules, it follows that the decisions optimized characterize the safety of maintenance and operation.

6. Cost of risk

In addition to what indicated in Annex I paragraph 5 of the Directive 798/2016, the calculation of the economic impact of accidents, must be considered among the direct and indirect costs also failures.
Damage can always be traced to a mathematical expression, f (faults, failures, accidents), even in the first approximation. In fact there are unexpected costs for both the GI IF when the train does not respect the hours of service, that is late.
What are the causes that may cause a delay when traveling?
Essentially:

- weather;
- damage
- accidents (including those not caused by railway vehicles);
- strikes.

All these unwelcome phenomena involve Additional Costs for both business in general but also for the community.
The basic safety guidelines consider only costs incurred by the GI and IF.
In fact, there are costs to be borne by the EU, individual states, local public administration, And Also for the passengers.
So to optimize the interventions, in addition to requiring the safety rules, it is very important to analyze in a comprehensive and exhaustive manner the risk phenomenon.
How to proceed?

- indicative of potential;
- determine all the possible levels;
- give each level a cost equivalent Ceq, for its elimination;
- at each level of risk of degradation associate hypothetical scenarios;
- to every degradation, quantifying a relapse in economic terms Cd;
- compare Ceq / Cd;
- draw the considerations in terms of corporate image ... it is a choice of enterprise policy.

7. Conclusions

The following is a set of 13 logical steps with which to address problems:

a. Define and generalize the client's needs. Consider the total problem environment. Clearly identify the problem.
b. Help the client determine his or her objectives, goals, performance criteria, and purpose. Similar to step 1; consider the total problem's environment. Evaluate the situation, the constraints, the problem's limitations, and all available resources.
c. Study and understand the interactions among the environment, the technology, the system, and the people involved.
d. Incorporate multiple models and synthesize. Evaluate the effectiveness, and check the validity of the models.
e. Solve the models through simulation and/or optimization.
f. Evaluate various feasible solutions, options, and policies. How does the solution fulfill the client's needs? What are the costs, benefits, and risk trade-offs for each solution (policy option)?
g. Evaluate the proposed solution for the long term as well as the short term. In other words, what is the sustainability of the solution?
h. Communicate the proposed solution to the client in a convincing manner.
i. Evaluate the impact of current decisions on future options.
j. Once the client has accepted the solution, work on its implementation. If the solution is rejected, return to any of the above steps to correct it so that the client's desires are fulfilled.
k. Postaudit your study.
l. Iterate at all times.

ESTIMATING THE NUMBER OF TRAFFIC ACCIDENTS, INJURIES AND FATALITIES IN TURKEY USING ADAPTIVE NEURO-FUZZY INFERENCE SYSTEM

Ali Payıdar Akgüngör[1], Ersin Korkmaz[2], Erdem Doğan [3]
[1,2,3] *Civil Engineering Dept., Engineering Faculty, Kırıkkale University, Kırıkkale, Turkey*

Abstract: This study proposes Adaptive Neuro-Fuzzy Inference System (ANFIS) models to estimate the number of accidents, injuries and fatalities in Turkey. In the model development, population (P) and the number of vehicles (N) are selected as model parameters. Three different ANFIS structure models are developed using the data covering from 2000 to 2014. Developed models' results are statistically compared to observed values for training and test data in terms of root mean square errors (RMSE), mean absolute percentage errors (MAPE) and coefficient of determination (R^2). The results of the ANFIS models showed that they was suitable to estimate the number of accidents, injuries and fatalities. To investigate the performance of ANFIS models for future estimations, a ten-year period from 2015 to 2024 is considered. Thus, future values of population was obtained from the projection of Turkish Statistical Institute (TSI) and the vehicle ownership rate is expected to reach 0.4 by 2024. Therefore, population and the number of vehicles are considered to reach approximately 85 and 34 million, respectively. The results obtained from future estimations reveal the suitability of ANFIS approach for road safety applications.

Keywords: traffic accidents, injuries, fatalities, Adaptive Neuro-Fuzzy Inference System (ANFIS), Turkey.

1. Introduction

Deaths and injuries in traffic accidents are serious problems for all countries. The World Health Organization (WHO) reports that worldwide over 3 400 people die and around 120 thousand people are injured or disabled each year because of traffic accidents . The number of deaths and injuries in traffic accidents of a country are directly proportional the level of development of the country. WHO expresses that 90 % of deaths resulted from traffic accidents occur in low and middle income countries, although these countries less than 50% of motor vehicles in the world (WHO, 2011). The poor road conditions, traffic infrastructure, inappropriate mixing of vehicle types, inadequate traffic law enforcement and behavior of road users cause to increase the number of fatalities and injuries in these countries. The roughly estimated cost related to traffic accidents is 1%, 1.5% and 2% of Gross National Product in low, middle and high income countries respectively.

Turkey is a developed country with growing population and economy. Today, the population and income of the country has reached 79 million people and 718.22 billion US dollars. However, the country has a significant burden of road traffic injuries and fatalities. For instance, according to the data of Turkey Statistical Institute (TSI) over 1.3 million traffic accidents happened in the whole country in 2015. 7.5 thousand people lost their lives and almost half of them lost their lives in 30 days after the traffic accidents. Additionally, nearly 305 thousand people injured or disabled in these accidents in 2015 (TSI, 2015). When these numbers are compared with some other Europe countries it is seen that traffic accidents are a serious problem for Turkey. The main reasons of traffic accidents in the country are the lack of awareness, driver and passenger related factors, over speed, cell phone usage during driving, dense freight and passenger traffic on highways, vehicle related factors, inadequate traffic law enforcement etc.

Accident prediction models are widely used decision makers and engineers to predict accident trends and develop new strategies for traffic safety. In the literature, various accident prediction models have been developed by using different assumptions. One of the oldest accident models was developed by Smeed in 1949. He investigated the relationship among death, number of vehicles and population while developing his model. He gathered one year data from 20 different countries to develop the accident model (Smeed, 1949). However, Andreassen deeply criticized Smeed's model. According to Andreassen, one year data was not enough to develop a model and the developed model by Smeed could not be used for 20 countries since each country has different traffic, economic and social parameters. Therefore Andreassen proposed an accident model for each country by using same model parameters (Andreassen, 1985). Jacobs and Hards (1978) studies Smeed's model, and they interestingly found that Smeed's model remained unchanged when the analysis was repeated for the same 20 countries using the 1950, 1960 and 1970 data. Valli (2005) for India and Akgüngör and Doğan (2008) for Turkey adapted the Smeed and Andreassen models to estimate the number of accidents, deaths and injuries. Zegeer and Deacon (1987) developed an accident prediction model by using both traffic, road geometry and terrain condition data. Abdel-Aty and Radwan (2000) used negative binomial distribution to estimate crash frequency by employing traffic and road geometry data. Different accident models for various countries have been proposed by researchers such as Al-Matawah and Jadaan (2009) for the United Arab Emirates, Jordan and Katar, Akgüngör and Doğan (2008) for Turkey, Ackaah and Salifu for Ghana (2011), and Chakrobort and Roy (2005) for India. Russo *et al.* (2014) investigated road safety from the perspective of driver gender and age as related to the injury crash frequency and road scenario. They developed safety performance functions (SPFs) to predict the number of injury crashes using a study on the influence of the human factors and road scenario on effects of a crash by varying the dynamic. It was understood that the age and gender of drivers considered together further refines how those factors contribute to crashes. Russo *et al.* (2016) studied to calibrate Safety Performance Functions (SPFs) that can predict the

[1] Corresponding author: akgungor@kku.edu.tr

frequency per year of injuries and fatalities on homogeneous road segments. A negative binomial regression model was used in this study and results of study confirmed the effectiveness of the SPFs.
In addition to mathematical models, artificial intelligence techniques have lately been utilized to developed accident models in road safety studies. Mussone *et al.* (1999) used artificial neural network (ANN) model to analyze accidents in Milan. ANN technique was also used by Abdelwahab and Abdel-Aty (2001) to predict driver injury severity and by Çodur and Tortum (2015) to estimate highway accidents. Chiou (2006) used ANN-based expert system for car crash accidents. Akgüngör and Doğan (2009) developed ANN and genetic algorithm models to estimate the traffic accidents in Ankara. Korkmaz and Akgüngör (2016) used differential evolution algorithm which is one of the artificial intelligence techniques to develop accident prediction models.
Zaho et al. (2014) used ANFIS to establish a vehicle crash model. Hosseinpour et al. (2013) also proposed an ANFIS technique for modelling traffic accidents as a function of road and roadside characteristics. The candidate set of explanatory variables included the mean horizontal curvature, shoulder width, road width, land use, access points, longitudinal grade, and horizontal curve density. The results showed that shoulder width, road width, land use and access points significantly affected accident frequencies. They found that proposed ANFIS model could be used as a robust approach to transportation safety studies. Hosseinlou and Sohrabi (2009) applied neuro fuzzy systems to predict and identify traffic hot spots on rural roads. They concluded that the stated system could predict 96.85 % of accident frequencies in the studied blocks.
In this study, three accident prediction models (for accident, fatality and injury) for Turkey were proposed based on population (P) and the number of vehicle (N) by using ANFIS. The performance of ANFIS models was evaluated by means of the root mean square error (RMSE), the mean absolute error (MAE) and the coefficient of determination. R^2 for both test and train data. Analysis results showed that all proposed accident models could be used for traffic safety studies.

2. Details Experimental

2.1. Adaptive Neuro-Fuzzy Inference System

ANFIS emerged as a practical application of artificial intelligent approaches for many fields. It was developed by Jang in the early 90's. Basically, it runs as a combination of Fuzzy Logic and Neural Network. In other words, it is a system, which incorporates Sugeno-type fuzzy into adaptive neuro network structure. ANFIS combines the advantages and benefits of fuzzy and neural network to reach optimum solution. To achieve this, the principles of Fuzzy Logic and Neural Network are used together in ANFIS. Rules, fuzzification, inference and neural network structure create the basic steps and structure of ANFIS. The schematic form of fuzzy system is shown in Fig.1.

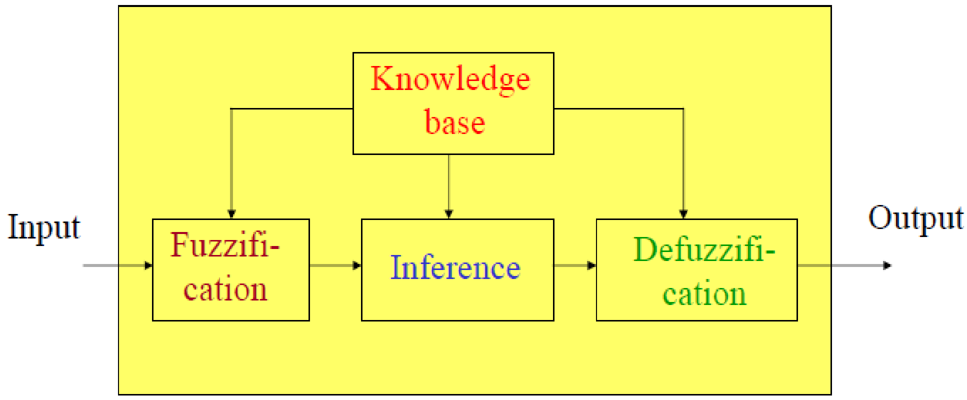

Fig. 1.
Fuzzy System

The output of neural network is determined according to fuzzy system or in other words, rules base. The neural network of fuzzy rule base is illustrated in Fig.2.

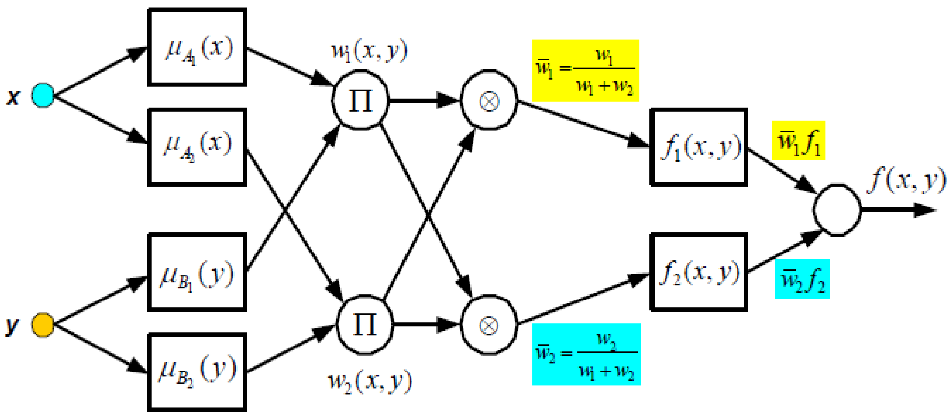

Fig. 2.
Neural Network Structure

2.2. Development of ANFIS model

In order to apply ANFIS for estimating of accidents, injuries and fatalities, determination of input data is a significant step. In the light of previous studies in the literature, ANFIS models for each event were developed depending on two input parameters, which are P and N. These necessary data were obtained from Turkish Statistical Institute (TSI, 2015). Fifteen-year data between 2000 and 2014 were randomly separated into training and test. For this purpose, 11 data were used for training remaining data were utilized for test. According to training data, ANFIS structure were created and run to determine coefficients of network. The structure of ANFIS is illustrated in Fig.3.

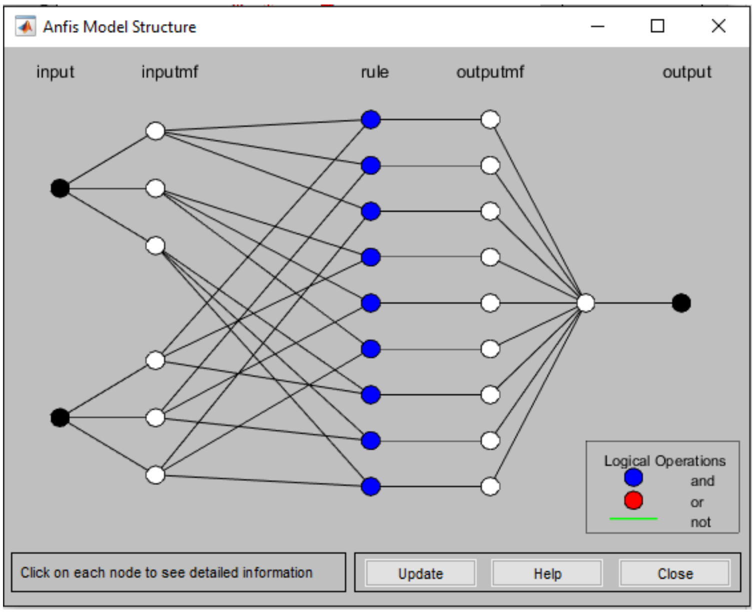

Fig. 3.
The Structure of ANFIS

ANFIS models for accidents, injuries and fatalities were created separately according to training data of each situation. 9 rules base were generated by ANFIS according to input and output data. The rules base is showed in Fig.4-6 respectively. In Fig.3 and Fig.7, input 1 is population and input 2 is the number of vehicles respectively. The distributions of training data are shown in Fig.7.

After training of ANFIS, it was tested with test data and obtained estimated values to illustrate the performance of models.

3. Results and Discussion

The performances of models were evaluated in terms of error criteria which are RMSE, MAPE and R^2 defined in Eqs. 1-3.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(D_{Observed} - D_{estimated})^2} \quad (1)$$

$$MAPE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{Co_{Observed} - Co_{estimated}}{Co_{Observed}}\right| * 100 \quad (2)$$

$$R^2 = 1 - \left[\frac{\sum_{i=1}^{n}(Co_{Observed} - Co_{estimated})^2}{\sum_{i=1}^{n}(Co_{Observed} - Co_{mean})}\right] \quad (3)$$

The comparison results are illustrated in Table 1.

Table 1
The Statistic of Training and Test Data for Comparison

	Accidents		Fatalities		Injuries	
	Training	**Test**	**Training**	**Test**	**Training**	**Test**
RMSE	6595	32825	272	373	4617	8187
MAPE	0.93	4.46	4.24	6.23	2.58	5.23
$\mathbf{R^2}$	0.9996	0.9856	0.8978	0.7428	0.9935	0.9878

Table 2
The Estimated Values of Test Data

Year	Accidents		Injuries		Fatalities	
	Observed	**Estimated**	**Observed**	**Estimated**	**Observed**	**Estimated**
1997	387533	393172	106246	118580	5125	5627
2002	439777	463360	116412	118942	4093	4343
2007	825561	875183	189057	179071	5007	4548
2010	1106201	1141691	211496	214631	4045	3865
2012	1296634	1215584	268079	252994	3750	3811

As seen from Table 1, the R^2 values of all models for training and test are close to each other. Especially, R^2 values of accidents and injuries are better than fatalities. On the other hand, MAPE and RMSE results show that ANFIS performs better for fatalities than the others. Some samples of test data are shown in Table 2. Estimated values of Accidents, Injuries and Fatalities are closer to statistical values. Therefore, in light of these statistical results it could be understood that ANFIS has enough performance and can be used estimation of future values of Accidents, Injuries and Fatalities.

4. Future Estimates of Traffic Accidents, Injuries And Fatalities for Turkey

With the help of developed models, the number of the traffic accidents in the future is estimated, and some measures can be taken to reduce the number of injuries and fatalities by developing new strategies. In this section of the study, a scenario is considered to estimate the number of accidents until 2024. According to the projection of TSI, the population of the country will be around 85 million in 2024. The vehicle ownership rate in Turkey is 0.25 now and it is expected to reach 0.4 by 2024. In this case, the number of the motor vehicles will reach to approximately 34 million.

This rate is consistent with the average vehicle ownership rate in European countries. The reader is referred to Table 3 for data on population and motor vehicle data used in this scenario. ANFIS model estimates are tabulated in Table 4. The study results show that the number of the accident and injuries steadily will increase in Turkey and will reach 2 229 392 and 450 000 respectively. On the other hand, according to the ANFIS model estimate the number of fatalities gradually decrease and will be nearly 2 800.

5. Conclusion

This study presents an application of the ANFIS to estimate the number of traffic accidents, ınjuries and fatalities in Turkey for the next decade. ANFIS Traffic accident prediction models are developed by using a fifteen-year historical data covering the years between 2000 and 2014. In the model development, the population and number of motor vehicles are considered as model parameters. A comparative study is performed among developed accident models and observed data. The all ANFIS model results have a good agreement with observed data. Moreover while accident and injury ANFIS models catch the increasing trend of traffic accident and injury, the fatality ANFIS model is coherent with decline trend as usual. Therefore, all developed models can be used for future estimates.

All developed models are statistically compared in terms of error criteria, such as RMSE, MAPE and R^2 for both training and test stage. When test statistics are considered the performance of fatality model is relatively better than that of others in terms of RMSE. However, R^2 values of accident and injurie models are better than the coefficient of determination of the fatality model. MAPE values of all developed models are lower than 10%. It means that all models have high accuracy (Lewis, 1982; Lawrence at al. 2009).

In order to evaluate the future performance of the developed ANFIS models, a scenario is considered. This scenario covers a ten year period from 2015 to 2024. According to the scenario, the population and number of vehicles in Turkey will reach nearly 85 and 34 million in 2024, respectively. During the same period the number of accident and injury will steadily increase. While the number of the accident go up from 1 349 725 to 2 229 392, number of the injury raise up from 297 288 to 446 766 if necessary preventions for traffic safety are not taken. On the other hand, fatality ANFIS model results show that the number of fatalities will decrease from 3 794 to 2 841 in the same period.

The performance of a model may increase with increasing the number of the model parameters. However, in this study two common parameters (such as, the number of vehicle and population) are selected for simplicity and practical usage. For further studies, other parameters which are effected on traffic accidents could be employed to improve the performance of the models.

SAVE GUIDING OF VISUALLY IMPAIRED PEOPLE - ARTIFICIAL GUIDING LINES ARRANGEMENTS IN THE INFRASTRUCTURE

Jana Košťálová[1], Jaroslav Matuška[2]
[1,2] *University of Pardubice, Jan Perner Transport Faculty, Pardubice, 532 10 Czech Republic*

Abstract: The paper presents arrangements that ensure safe mobility of visually impaired people in public places and sites intended for transport. An analysis of the current situation points to the fact that there is a real problem in using artificial guiding lines as for their parameter differentiation in interior and exterior. Some countries do not use artificial guiding lines at all while others overuse them; moreover, they use different parameters and surface. The article shows how logic is applied in the creation of barrier free environment, where artificial guiding lines are an integral part. Further, the article defines fundamental features and parameters of the artificial guiding lines in the Czech Republic. The aim of the paper is to propose a gradual convergence of tactile arrangement systems, especially for the guiding lines, which are one of the most fundamental requirements for safe mobility of visually impaired people.

Keywords: accessibility, barrier free environment, Design for All, guiding lines, safety, visually impaired people.

1. Introduction

Safety of all pedestrians, not only of the passengers with reduced mobility (PRM), is an important aspect taken into account when assessing the quality of the public environment (Lazou et al., 2015, Susnienė, 2012). Visually impaired people (the blind, the partially sighted) belong among those PRM who need very specific adjustments for their movement. The accessibility of the urban environment, public transport, and other environments is conditioned by specific adjustments that allow the visually impaired to move freely and safely. Independent movement and safety play an important role in the life of the blind and the partially sighted. It is not possible to treat these aspects separately (Matuška, 2009).

To enable the blind to move independently, various technical devices utilising new technologies have been worked on in the last few years. For example Suzuki et al. (2010) conducted an experiment on pedestrian crossings with traffic lights using the assisting technology VLC (visible light communication). He assessed the ability of the blind to maintain straight direction when crossing the road, and their speed. These two parameters affecting the safety of the blind on pedestrian crossings are conditioned by the age of the pedestrians, the time and way of losing their sight (from birth, later in life, suddenly, gradually). Peraković, Periša, and Remenar (2015) showed the possibilities of how to increase mobility and safety of the visually impaired with the help of information and communication technologies. Further, they presented a dynamic model of guiding the blind on an example from the city Zagreb. Periša et al. (2015) investigated the utilisation of the RFID (Radio Frequency Identification) technology for guiding the blind in the urban environment (pedestrian crossings). Zhou et al. (2012) focused on the utilisation of the information & communication technologies enabling easier access of the visually and physically impaired to public transport. Further, Brian et al. (2012) studied the utilisation of modern technologies in the process of guiding the blind in the urban environment. In addition, Kurian and Pillai (2009) conducted research on the system of guiding the blind inside and outside buildings with the help of ultraviolet rays and digital technologies transmitting the information into acoustics.

The blind in the Czech Republic (CR) can make use of a navigation centre, whose staff can monitor the blind via the GPS technology, and when needed the staff can inform him about his position, and tell him the right direction. A research team at the Faculty of Electrical Engineering has been working on the navigation system NaviTerier, designed for mobile phones, which should help the visually impaired in the CR move freely in exterior and interior (Balata et al. (2014).

Despite all the newest devices and assisting technologies, the blind agree that the white cane remains their primary and most easily accessible device for acquiring necessary (tactile) information (Brian et al., 2012; Matuška, 2009). That is why correctly conducted tactile adjustments for the blind are of vital importance. Training of independent movement and spatial orientation with a mobility instructor is a prerequisite for an effective utilisation of the tactile adjustments.

The article aims to explain the logic of the tactile elements (TEs) in the CR and draw attention to the critical points which should be solved consistently and meaningfully.

2. Legal environment

The tactile contrast elements for safe guiding of the blind appeared, for the first time, in the late 70s of the 20th century, in Japan, and from there they spread to Europe (Aoki, Mitani, 2012). The tactile adjustments for the blind are different in each country in terms of law, design, and utilisation. There are states with a large variability of the used tactile surfaces for the same situation, or ambiguously defined requirements for products prevailingly used by the visually impaired (e.g. visual contrasts and slip resistance).

[2] Corresponding author: jaroslav.matuska@upce.cz

2.1. Public transport accessibility

The general terms of the air, rail, bus, and water transport accessibility for the PRM are determined, in the EU, by the relevant regulations. The PRM are guaranteed the right to travel under specified conditions. For example transports or assistance needs requested are subject to advance warning of usually 36-48 hours. This mainly concerns the wheelchair users. The blind people, who do not need any assistance, do not have to report their trip in advance. However, it is impossible to guarantee the given rights throughout the EU as some countries have taken the possibility of exceptions e.g. access to bus terminals.
The general requirements for using the TEs for safe movement and orientation of the visually impaired in transport facilities, in the EU railway system, are a part of the Technical Specifications for Interoperability (TSI PRM, 2014). Unlike the ISO standard, the regulation TSI PRM is applicable only in the EEA[3] countries. Tactile contrast marking must be used for example on platforms and their access paths/roads, on roads leading to check-in halls, or at other places where it is appropriate. The TSI PRM defines the general requirement for using the tactile signs; it does not distinguish between the artificial and natural guiding lines, or other elements.
The railway platform tactile adjustments are, in principal, almost identical throughout the EU. The safety strip at the platform edge (usually 800 mm wide) is separated by tactile and colour contrast adjustments. In some countries (not only in Europe) both surfaces with grooves and blisters are used.
In Great Britain, Loo-Morrey (2005) states six different surfaces with different functions (5 with the warning function and 1 with the guiding function); what more each surface has a precisely defined utilisation (railway platforms, public transport stops, stairs, pavement/ pedestrian crossings, etc.).
In Germany, the basic adjustments for the PRM are conditioned by the standard DIN 18040-3: 2014 or DIN 32984. In Switzerland, the adjustments are conditioned by the regulation SIA 500 or SN 640075. In Slovakia, this issue is addressed in the directive Ondrovič (2011) and Decree No. 532/2002 Coll. The most important decree in the CR is the Decree No. 398/2009 Coll. The Czech Technical Standards (CSN), which deal with specific measures such as at pedestrian crossings, cycle tracks, railway platforms, crossings, and others, build on this decree.

2.2. Accessibility of the built environment

The international standards ISO 23599:2012 and ISO 21542:2011deal with the tactile and visually contrastive adjustments for the blind at building constructions. Both the standards distinguish the attention and guiding patterns. These two patterns are similar to the tactile elements found in European countries. In other TWSIs[4] installation requirements, the adjustments do not fully correspond to the logic of spatial orientation of the visually impaired. The currently set standards for the CR are only provisional as they do not comply with the law and relevant implementing regulations, and technical standards.

3. The logic of tactile adjustments for the visually impaired in the Czech Republic

In a very simple way, visually impaired people can be divided into two groups. The first group comprises the moderate and severely sight impaired people. The second group includes the blind. The ratio of the two groups is, according to WHO[5], 10:1. Each 120th person in the CR is severely visually impaired.
To ensure their independent movement, it is important to transfer the visual information to a combination of TEs. The moderate and severely sight impaired people have different priorities for the combinations. “A sufficient number of easily identifiable points, whose connectors create guiding lines (GLs), forms the basis of safe movement of the blind or partially-sighted” (Dudr, Lněnička, 2002, p. 5). The term ‘*guiding line*’ is prevailingly used when designing barrier-free adjustments for the visually impaired at public facilities, public spaces, and transport environment. The adjustments are those who prevent injuries and loss of spatial orientation, while simultaneously support the targeted transport in exterior and interior. The users of such adjustments are not only temporary and permanently visually impaired people but also people who move through large areas such as transport terminals, or passages of civic facilities because it is difficult to orientate in such places. The fuzzy logic has proved that artificial guiding lines (AGLs) can be intuitively used by people without any visual impairment (Košťálová, 2016). For example, if a user is in a given space for the first time or does not understand the local language or pictograms, his eyes perceive the surroundings more intensively and he intuitively uses the GLs. Therefore, it can be said that GLs are used by a wider range of people than those whom they were originally designed for.
“When walking along a guiding line, it is necessary to keep a 300 - 400 mm safety distance in interior and 800 mm in exterior in order to minimise the risk of crashing into obstacles at the waist level and above” (Slouka et al., 2013, p. 189). A blind person follows the GLs and therefore it is important to maintain a free passage area, which is min. 800 mm wide and 2100 mm high in interior, and 2200 mm in exterior, without any obstacles. This is a fundamental problem of all TWSIs. Not knowing the characteristics of the movement of severely visually impaired people results in placing obstacles in the unobstructed width. The most common examples of such obstacles are promotional items, racks with

[3] European Environment Area
[4] tactile walking surface indicators
[5] World Health Organization

displayed goods, tables and chairs placed freely around the refreshment shops, unsecured scaffolding and excavations, including technical equipment.

3.1. Natural tactile elements forming guiding lines

Natural tactile elements (NTEs) forming guiding lines are created during common construction work or by thoughtful arrangements of the sites; they can assist the blind in terms of orientation and wayfinding. Examples of these NTEs are fence retaining walls, walls of buildings, underpasses, railings with lower guiding bars, garden kerbstones increased by 60 mm above the walking surface. Further, while maintaining the safety principles of guiding the blind, it is possible to use garden adjustments which are increased above the walking surface, palisades, outdoor planter flower pots, and bases of information or ornamental elements, see Fig. 4. Yet, they have to be easily found and identified by a white cane, and must be constant. The legislation of the CR defines these elements as 400 mm wide, 300 mm high, 1500 mm (new buildings) or 1000 mm (reconstructions) long.

3.2. Artificial tactile elements forming guiding lines

An artificial tactile element (ATE) forming a guiding line guides a visually impaired person with a white cane safely at places where another guiding is missing. It is a specially created part of a facility helping the visually impaired to orientate and move independently. After training, a visually impaired person is capable of keeping a straight walking line up to the distance of 8 m, within an acceptable deviation, that is why this distance is incorporated in the Czech standards as a maximal possible interruption of a guiding line.
The basic requirements for TEs in the CR are: min. width 300 mm in interior and 400 mm in exterior, a min. length necessary for directing the visually impaired is 1500 mm at new buildings and 1000 mm at reconstructions, guiding in straight direction, artificial lines cannot be bent, a change in direction is allowed only in necessary situations and preferably at a right angle (90°), crossing of an AGL is done by a flat surface (a paving block without TEs) in the width of the line.
The installation of an artificial guiding line must be logical and simple. The artificial tactile elements forming a GL must be, at both its ends, linked to a natural guiding line or an acoustic guiding device (e.g. an acoustic guiding beacon). Ensuring this continuity is a necessary prerequisite for independent movement of the visually impaired. A continuous line can be formed by visual and TEs or their combination.

3.3. Basic visual elements

A visually contrasting strip, min.150 mm wide, marks the edge of the safety distance at the bus, trolley, and tram stops (500 mm from the edge), is defined by the CSN 73 6425-1:2007. A 150 mm wide yellow strip forms a warning strip and is a part of a GL on level crossing railway platforms. The strip is situated 800 mm from the platform edge, and is defined by the CSN 73 4959:2009, and the Specification of Railway Infrastructure Administration in Ž 8.7, change 2.

3.4. Basic tactile elements

The system of tactile adjustments comprises a combination of basic elements differing in dimensions (effective width) and surface (see Table 1). The products forming the TEs cannot be used for any other purposes. These elements are, in the CR, precisely defined in terms of material, shape and dimensions (see Fig. 4), and must be '*the products*', which comply with the detailed technical and user characteristics defined by the Technical Centre TN TZUS 12.03.04-07. Each element must have a product verification complying with the Government Decree No.163/2002 Coll. The material used, in the CR, is not innovative; mostly, it is concrete or stone paving blocks, or stone blocks forming a mosaic. Paving blocks from artificial stone, polymer concrete slabs or plastic belts (rubber, recycled material, PVC) are used to a limited extent.

Table 1
Basic Tactile Elements

SURFACE	**WIDTH** [mm]	**FUNCTION**
BLISTERS *according to the material used walking areas: truncated cones or hemispherical pins, irregular stumps*	150	warning
	400	warning
	800 - 1000	directing, orientation important point
LONGITUDINAL GROOVES *cross sections of grooves: a sinusoidal rib, a triangle, a rectangle, or a trapezoid*	300 inter. / 400 ext.	guiding – walking area for pedestrians
	550	guiding – vehicular way

Source: Decree No. 398/2009 Coll.

Important visual information for the blind has to be transferred to tactile or acoustic information. The requirement is also applied to road signs, where the combination of basic elements signals a change in the traffic mode and differentiation of the function groups on the roads; e.g. the differentiation between a pavement and a cycle track or the differentiation between pedestrian and residential areas and the roads (see Fig. 4).
The sequence of adjustments in parts of buildings, roads and public places for the visually impaired:

- the priority is to organise the disposition of a sufficient number of appropriate (and clear) orientation points and NTEs forming GLs,
- it is important to utilise the acoustic guiding and visual contrasts to improve the orientation situation, (see Fig. 1)
- an AGL is used only as a complementing element (interior and exterior) for ensuring independent movement.

All the elements must be perceptible by a white cane and sole while maintaining the visual and tactile contrast.
The surface area, at a minimal distance of 250 mm from the elements, must be flat and in compliance with the slip resistance requirement. To ensure the tactile requirement, it is necessary to design the paving without any skews, and with a straight edge, which does not create any gaps noticeable by a white cane (see Fig. 2, 3).

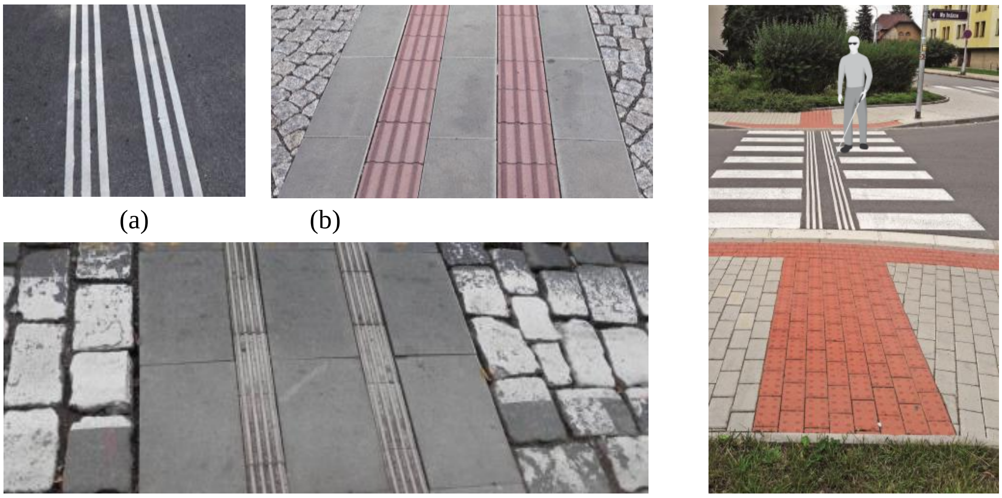
4. Differences between the Czech Republic and other countries

The analysis of the current situation in safe guiding of the blind indicates that:

- The majority of European countries currently use AGL and TE made of a wide range of **material**. Stone or concrete tactile paving is the most widely used but ceramic tiles and PVC belts, products from polymer concrete, and stainless steel are also used; e.g. in Slovakia (Ondrovič, 2011), and in Poland (Poliński, 2013).
- The standard ISO 21542, similarly to some other transnational regulations (e.g. the TSI PRM), defines the **colour contrast of the elements**; this is not included in the Czech legislation. The standard describes a simple method of light reflectance value difference, and, for a comparison, other three methods widely used in the world (Michelson, Weber, Sapolinski). When defining the necessary colour contrast, it is important to take into account the character of the displayed information (orientation or safety).
- A rarely used TE in Europe is the **crossing directional strip** in a vehicular way, which helps to shorten the time in dangerous places, see Fig. 5 (d). In the CR, it is only installed at pedestrian crossings, where it is difficult to keep the direction: the signal strip is not long enough (< 1 m), the axis of the crossing is not perpendicular to the axis of the road and its length is longer than 8 m, or the crossing comes from the rounded curbs of *r* > 12 m in diameter. It is necessary to maintain the colour contrast depending on the material used, see Fig. 5(a) – (c).



(a) (b)

(c) (d)

Fig. 5.
Crossing Directional Strip
Source: J. Košťálová

- **Surface structures** are unfamiliar with the negative relief (groove in the surface), which is commonly used in the CR. Such structure is used for guiding the blind on platforms, or inside terminals.
- Research in V4 countries has proved that **acoustic information** is important for the visually impaired, yet insufficiently used (Matuška et al., 2015).
- A wide variety of **guiding patterns** is used for the same situations, which are difficult for the blind to remember (one bar, two bars, two triples of bars, paving with 5-7 grooves, a combination of a negative relief[6] and steel guiding riband).[7]
- **Tactile elements** with an attention pattern are not used in the CR in front of sloping barrier-free ramps and stairs as the visually impaired are guided by the AGL, from the side, to the railing. No tactile element should create an obstacle for other users (people in wheelchairs, people with physical disabilities and small children) when entering and leaving the ramps, see Fig. 6. According to the Czech Statistical Office, there are, in the CR, six times more people with severe physical disabilities than visual.
- In the subways, malls, corridors, the TEs are often situated in the centre of the walking area and they do not respect the usable lines of the walls. Should the load increase, the elements rising above the surface have reduced durability and create obstacles, see Fig. 7.

5. Conclusions and recommendation

The function of individual elements (different according to the national standards) must not be confusing, as the user safety is the priority. The legislation of most European countries addresses these requirements, yet the reality shows the more the information and details have to be solved additionally, the more incorrect and life-threating the situations. Instead of a simple functional solution, the result is incomprehensible for severely visually impaired people and causes restrictions for other users.

NTEs used in interior or on roads are advantageous for:

- **the blind -** as they get permanent information, which is more recognisable by the white cane and is less dependent on the weather and pollution,
- **investors** – NTEs save financial means spent on adjustments for safe guiding of the blind, allow easier cleaning and maintenance of the walking areas,
- **other users** of the environment – NTEs do not create any obstacles (for small children, people in wheelchairs, people with rollators, crutches, or sticks, etc.).

The process of creating a barrier - free environment (user-friendly) has to take into account not only the legislation (design and planning) but also the finances. Long-term sustainability can only take place in the cities with smart municipal politics, with cost-effective and accessible public transport and the modification of its conception; further, with the education of the experts forming the public environment (transport and building civil engineers, architects, representatives of governments and legislators).
Some good examples are not only seen in some European cities, Japan, the USA and Canada, but also in some cities in South America. Therefore, it is necessary to pay attention to all the TEs forming tactile GLs, which are and will be a necessary part of Design for All.
Experts including the members of the European Blind Union should discuss the following topics: effects of the increased use of NGLs in interior and exterior; materials suitable for guiding the blind in interior and exterior; the unification of basic adjustments for the blind across Europe; the use of acoustic information for the blind.

Abstract: The Study analyses the conduct of several drivers while driving over three different type of pedestrian crossings by night. The monitored vehicle drives over horizontally and vertically marked pedestrian crossings in a town. These pedestrian crossing have different structural arrangements and different location. The first and the second of them are standard type of pedestrian crossing and the third is modern type with the traffic island. Abilities of driver's perception have been influenced by the not quite suitable crosswalk arrangements as well as by unnoticed surroundings near the crosswalks. The results of the analysis have been compared to the results of extensive driving tests conducted in real road traffic, in the year of 2014. Optical reactions of drivers have been measured by using eyetracking method. Changes in the driver's perspective have been measured by using a special eyetracking device called Viewpointsystem®, GmbH from Austria. The driver's conduct in definite traffic scenarios, driver's reaction to crossing pedestrians, driver's watching duration of crossing pedestrians, controlling of the situation behind the vehicle by the driver using the rear-view and outside mirrors (i.e. total necessary time for the driver to assess the situation behind the vehicle as well as individual parts of entire time) as well as driver's reaction to another significant stimulus have been evaluated. The vehicle operating by the driver has been monitored using sensors in the vehicle.

Keywords: road traffic safety, traffic accidents involving pedestrians, driver's optical reaction, controlling of the situation behind the vehicle, collision prevention option, eye movement monitoring.

1. Introduction

Pedestrians belong among the most vulnerable road traffic participants. In the Czech Republic alone 131 pedestrians died as a result of traffic pedestrian-vehicle accidents in 2015 (which is around 19 more than in 2014). 128 pedestrians were mortally wounded in vehicle collisions, while the remaining three were secondary accident participants. The majority (more than 56 %) of pedestrians, who died as a result of collision with vehicles, were mortally wounded at night (72 of 128 people, which is about seven more than in 2014) (CSPSD, 2015).
Light conditions have a significant impact on the increased danger at night. These light conditions significantly affect not only the ability of a driver to recognize a pedestrian in time, but also the ability of a pedestrian to identify the vehicle's position and speed. The ability of a driver to recognize a pedestrian is further affected by the complexity of a driving situation. The more and more stimuli, the higher the probability that a driver will not notice one of the important ones. The number of stimuli also increases when vehicles drive consecutively. In such a case a driver has to pay more attention to traffic behind the vehicle with the help of rear view mirrors. One of the important factors is therefore the time needed for the investigation of the situation behind the vehicle. Pedestrian crossings are frequent sites of traffic accidents. According to Czech Police statistics, accidents most often occur as a result of inattentive or unexpected entry of a pedestrian into the road. It is necessary to pay a constant attention to the safety of pedestrians and strive for the extension of knowledge about driver's perceptional viewing of the driving situation and his behaviour in areas with increased danger, because pedestrians are very vulnerable participants of road traffic.

2. Analysis of the contemporary situation

The contemporary development of measurement methods based on so-called eyetracking (measurement of the change in the angle of driver's view) enables the extension of knowledge about a driver's behaviour during the driving process. Viewpointsystem® instruments, besides other things, achieve highly accurate measurements. Some of them even enable measurement at night under ordinary road traffic conditions. By this method it is possible thereafter to acquire new knowledge about a driver's perception of the driving situation, a driver's response to various stimuli, a driver's behaviour during the driving process, and also about his ability to distinguish important driving stimuli at an adequate distance, and subsequently investigate the influence of a driver's surroundings at this distance. In his works (Pfleger, 2012; Pfleger, 2009; Pfleger, 2010; Pfleger, 2013), Pfleger – the author of Viewpointsystem® method – deals with the investigation of a driver's behaviour, in particular driving situations and his complex analysis, on a long-term basis. Many research works deal with, thereafter, an analysis of drivers' response time to various stimuli and the influence on its length by light conditions and other factors. Some aspects of modern methods and procedures in research of perceptual recognition of pedestrians are introduced by Weyde (Weyde, 2010). Habibovic et al. (Habibovic, 2013) analyses, on the basis of videos recorded from the vehicle, different driving situations, during which a pedestrian crosses the road from various directions. He adjusts the DREAM method (The Driving Reliability and Error Analysis Method) for the identification of the factors affecting a driver's attention, direction of his view, and a pedestrian's

[1] Corresponding author: pavelmaxera@gmail.com

behaviour while crossing. The ways leading to the creation of a safe and user-friendly environment on different types of roads are introduced by Mackie (Mackie, 2013) in his work. On the basis of the implementation of a proposal of changes he points to the ways that favourably influence the conduct of road traffic participants. Bella and Silvestri (Bella, 2015) dealt with possibilities of increasing safety at pedestrian crossings situated on two-lane urban roads. They carried out measurements using a modern driving simulator, where they simulated various driving situations and examined the influence of safety features (extension of kerbs, restriction of parking near a pedestrian crossing, deceleration retardants) on a driver's behaviour. Ni et al. (Ni, 2016) dealt with an analysis of the movement of vehicles and pedestrians at pedestrian crossings and the detection of critical situations from camera records. They evaluated the mutual movement of vehicles turning right and pedestrians passing over a pedestrian crossing in relation to the time and speed of individual traffic participants. Sullivan (Sullivan, 2011) points out, proceeding from the evaluation of police investigation reports about traffic accidents with pedestrians, differences in the course of these accidents at daytime and at night. He calls attention to the influence of symmetrical and asymmetrical headlights on the ability to see a pedestrian. Jurecki and Stańczyk (Jurecki, 2014) dealt with the time of a driver's response to a pedestrian entering the road from its right and left side. In simulated driving situations they analysed the movement of a vehicle from the moment of optical stimulus creation to the vehicle stop. They situated screens on both sides of the road, subsequently placed figures behind them and at a certain moment exposed them to the drivers. The task of the drivers was to respond to the change of the driving situation by means of activation of the vehicle braking system and stopping the vehicle by braking. The driver's response time was measured. Even the authors of this publication dealt with the issue of a driver's behaviour during the driving process in reduced visibility by darkness in an area of pedestrian crossings. In the work (Kledus, 2013) they examined the driver's behaviour at a pedestrian crossing designed in a modern way. In the work (Maxera, 2015) they dealt with the driver's behaviour when passing through a common pedestrian crossing in an area with many stimuli caused by the nearness of other crossings and a number of road signs. The time that a driver needs to evaluate the situation behind a vehicle was analysed in the article (Belák, 2016). This article follows the authors' previous works and those works further develops this.

3. Aims of the work

The aim of the work is to compare behaviour of 20 drivers in an area of three pedestrian crossings designed in various ways. It attempts to verify, proceeding from the comparison, the appropriateness of the K coefficient in quantification of danger in the area of a pedestrian crossing under various conditions. It further aims to compare the values of characteristic quantities describing the behaviour of the driver and pedestrian in different driving situations laid down by the different ways in which the pedestrian crossings are designed. It mainly attempts to evaluate the time of driver's response in relation to hazardousness of the situation and also the degree of attention the driver pays to the pedestrian from the moment of noticing the stimulus by eye retina (or from the moment of the first optical reaction, hereinafter FOR) to the moment at which a vehicle passes over the crossing. Attention is also paid to the time that the driver devotes to observation of the situation behind the vehicle while passing over the crossing.

4. Methods of solution

4.1. The method of performance of driving tests

The performed evaluations proceed from extensive driving tests carried out in 2014. Measurements were made within a solution of TAČR TD 02239 project – Strengthening of legal certainty in technical evaluation of traffic accidents with pedestrians in reduced visibility. The tests were performed under ordinary road traffic conditions. Drivers' behaviour in reaction to analogous driving situations was monitored during testing. Experienced drivers passed through a given trajectory at a distance of ca. 23 km in an ordinary way. There were figures placed on the route that simulated the same driving situations. The presented evaluations show the results achieved at three pedestrian crossings, where the figures simulated passing pedestrians.

4.2. Measurement technology and vehicles

For measurement two comparable vehicles of Škoda Yeti, Czech made brand have been used. The first vehicle was equipped with headlights containing halogen bulbs, while the second one was equipped with headlights containing xenon discharge tubes. Because of the fact that all presented measurements were carried out on stretches of a road with public illumination, the differences in headlight properties are not crucial for evaluation of the tests as they do not become significantly evident when the road illumination is sufficient. The vehicles were equipped with measurement technology according to Table 1. Viewpointsystem® measuring device was used for the measurement of a vision angle direction. Its main part is formed by rims in the shape of glasses with two cameras. The first part scans the driver's eye lens, while the second part scans the situation in direction of the driver's view. The view direction is evaluated from a comparison of records of both cameras using specialized software. The position of the vehicle and movement of its bodywork during testing were measured with the help of an accurate, differential GPS. The way of the driver's vehicle control was further evaluated with the help of data acquired from sensors used for the vehicle drive unit (OBD diagnostics) and from a sensor of the brake pedal position.

Table 1
Survey of used measuring devices and measured quantities

Measuring device	Measured quantities
Eyetracker (Viewpointsystem®)	Direction of a vision angle of the driver
GPS device	Vehicle trajectory, angles of pitch, incline, bodywork turn
OBD Diagnostics (On-Board Diagnostics)	Engine speed, vehicle speed, rate of accelerator press
Infra LED diode connected with the braking pedal position sensor	Braking pedal activation moment

4.3. Measurement areas and figures

For measurement three pedestrian crossings designed in various ways were chosen. All of them were marked with horizontal and vertical traffic signs and illuminated by means of public illumination lamps situated in the driving direction of the vehicle on the right side. The first crossing (CW1) was situated on a straight road stretch near a car park exit. On the sides in the area of side guide lines and in the middle in the area of a central dividing line circular decelerating retardants were situated. However, these retardants do not limit significantly the passing of smaller vehicles. The second crossing (CW2) was situated nearby a left turn on a clear stretch of main road. The crossing was designed in a modern way, with a central dividing traffic island and yellow retroreflective framing of signs highlighting the crossing sign. The third crossing (CW3) was situated at the end of a straight, relatively indented stretch of road with three more crossings and numerous traffic signs. In the right direction of the driving vehicle there was a park with full-grown trees in the area of the crossing. The trees limited the view of the areas adjacent to the road in the area of measurement. A comparison of monitored crossings is performed in Fig. 1.

Fig. 1.
Areas of measurement – CW1 crossing (on the left), CW2 crossing (in the middle), CW3 crossing (on the right)
Source: (Google Maps, 2016)

All three figurants had darker clothes of various colours. At the crossings CW1 and CW3 both figurants wore a black jacket, dark denim trousers and black shoes. Figurant at the CW2 crossing had a black jacket, red trousers and dark shoes. The figurants' clothes was compared in Fig. 2. The figurants were waiting near the crossing in the right direction of the vehicle pass during driving tests. At the moment of arrival of the testing vehicle they were supposed to cross the road in the ordinary way before the passing vehicle in order not to endanger themselves.

Fig. 2.
Figurants at posts before entrance to the road - CW1 crossing (on the left), CW2 crossing (in the middle), CW3 crossing (on the right)

4.4. Result processing method

A driver's eyes respond to visually significant stimuli, which are also pedestrians moving on the road and in its proximity, by instant involuntary change in the direction of a vision angle in such a way that the stimulus can be observed in the area of sharp vision of an eye and subsequently analysed in the central nervous system, see Fig. 3. In the case where this change in the vision angle is evident, it is possible to evaluate with high credibility the beginning of FOR to a given stimulus. On the basis of an analysis of saccadic and smooth monitoring movement of eyes it is thereafter possible to evaluate not only the moments of FOR to individual stimuli, but also a time that the driver pays attention to the pedestrian passing over the crossing or even to other important stimuli including those observed by the driver using rear view mirrors.

Fig. 3.
Example of the first optical response of the driver to the pedestrian (drive P12 crossing CW2; on the left – the beginning of the optical reaction (8.56 sec and 66.4 m prior to the crossing), the driver's eye when looking in a straight direction peripherally notices the figurant; on the right side – figurant in the area of sharp vision (8.52 sec and 65.9 m prior to the crossing), the driver's eye after change in view direction fixes on the figurant.

4.5. Result processing procedure

The way of driving of 20 drivers was evaluated at each of the monitored pedestrian crossings. The characteristics listed below describing a driver's behaviour and the mutual movement of the vehicle and passing figurant were discovered for each driving process:

1. The point of intersection of a vehicle trajectory and a figurant trajectory was determined in the area of the crossing. This place was chosen as the beginning of the coordinate system for measurement of distances s between the vehicle and the crossing. The direction against the vehicle driving direction was chosen as positive. In the point of intersection it is therefore true $s_{CRW} = s = 0$.
2. The moment of vehicle pass over the pedestrian crossing was determined t_{CRW} and instant vehicle speed v_{CRW} when passing the crossing. For further result processing the time t_{crw} was chosen as the moment equal to time 0 ($t_{CRW} = t = 0$). In the case that the driving situation required the driver to stop the vehicle prior to the crossing, the moment of vehicle stop was determined. This moment was subsequently chosen as the moment equal to the time 0.
3. The moment of the first optical response (FOR) of the driver to the passing figurant was chosen t_{FOR} and vehicle distance from the crossing equal to this moment s_{FOR} and instant vehicle speed v_{FOR}.
4. The moment of acceleration pedal release by the driver was determined t_{RAP}, or also the moment of breaking pedal activation by the driver t_{ABP}. At the same time the response times from the FOR moment were calculated according to relationships $\Delta t_{RAP} = t_{FOR} - t_{RAP}$ and $\Delta t_{ABP} = t_{FOR} - t_{ABP}$.
5. The substantial moments related to the movement of the figurant around the road and on the road were determined. It was always the moment of entrance of the figurant to the road t_1 and the moment, when the figurant left the traffic lane, in which the monitored vehicle was moving t_2. The quantities characterizing the vehicle movement in these moments, i.e. a distance between the vehicle and the crossing s_1, s_2 and instant vehicle speed v_1, v_2, were subsequently determined.
6. The degree of attention *Att* that the driver paid to the figurant from the FOR moment to the pass of the vehicle over the crossing was evaluated. The relative value was expressed as a percentage according to relationship $Att = \sum \Delta t_{att} \cdot 100 / t_{FOR}$,where $\sum \Delta t_{att}$ is the sum of the time intervals, in which the driver watches the figurant in the area of sharp view of the eye and t_{FOR} determines the time interval from the FOR moment to the moment of vehicle pass over the crossing.
7. The time Δt_{PR} that the driver after noticing the figurant controlled the situation behind the vehicle by means of the rear view mirror, or the time Δt_{PO} that he devoted to control of the situation behind the vehicle after passing over the crossing, was evaluated.

8. On the basis of the evaluation of vehicle speed v_{FOR} in the FOR moment the minimum value s_{BRK}, necessary for stopping the vehicle from v_{FOR} speed, was subsequently calculated[2]. On the basis of comparison of distances s_{FOR} and s_{BRK} the value of dimensionless coefficient **K** was subsequently stated for each drive according to relationship $K = s_{FOR}/s_{BRK}$, which characterizes in an appropriate way the hazardousness of the emerged driving situation. The K coefficient values lower than 1 mean that in case the figurant started the crossing process during a given test, the driver would not probably stop prior to the crossing and the collision of the vehicle with figurant would possibly take place.

The drives were divided into four basic categories according to the K coefficient values:

1. Entirely safe drives ($K > 2.5$) – during these drives the drivers optically responded to the figurant at a sufficient distance and the driving situation thus did not require immediate action of the driver, such as immediate accelerating pedal release or even the activation of the brake pedal. The driver thus only decelerated vehicle speed in the ordinary way and the figurant crossed the road without any problems (the drives are depicted by green colour on the charts on the Fig. 4 – 6).
2. Drives with increased danger ($2.5 \geq K > 1$) **-** during these drives the drivers optically responded to the figurant later than in category 1, often immediately after FOR adjusted the vehicle drive, decelerated intensively, but did not need to stop the vehicle prior the crossing (the drives are depicted by red colour on the charts on the Fig. 4 – 6).
3. Dangerous drives ($2.5 \geq K > 1$) – during these drives the drivers optically responded to the figurant later than in category 1, immediately after FOR adjusted the vehicle drive and had to apply the brakes until the vehicle stopped so the figurant could cross the road (the drives are depicted by red colour on the charts on the Fig. 4 – 6)
4. Critical drives (usually $K \leq 1$) – during these drives the drivers optically responded to the figurant too late, or not at all and the figurant evaluated the situation as very dangerous and did not even initiate the process of crossing the road (the drives are depicted by grey colour on the charts on the Fig. 4 – 6).

5. Presentation of results

5.1. Evaluation of measurement on the CW1 crossing

The results of measurement on the CW1 crossing and the performed evaluations are graphically compared on the Fig. 4. Individual drives are distinguished by colours according to the above mentioned categories (entirely safe drives, drives with increased danger, dangerous drives and critical drives). They are sorted by the determined values of K coefficient. From the charts in Fig. 4 it is clear that 14 out of the 20 drivers managed to respond to figurant at a sufficient distance and in many cases did not even need to activate the brake pedal ($K > 2.5$), five drivers had to brake intensively, although they did not need to stop the vehicle prior to the crossing. None of the drivers had to apply the brakes until a stop. Only one driver reacted too late ($K = 0.88$). In this case the figurant evaluated in the right way the possible danger and did not even enter the road. The moments of the first optical reactions of the drivers, the moments of acceleration pedal release, brake pedal activation and the corresponding distances between the vehicle and the crossing can be subtracted from the charts in Fig. 4.

The average values of characteristic quantities including the lengths of reaction times and proportional observation times of the figurant by the drivers are stated in Table 2. From observation of the test, during which the figurant was crossing the road, it is clear that the average time from the FOR moment until the moment of vehicle pass over the crossing was 8.0 s. During this time the drivers directly observed the figurant for an average time of 4.9 s, which is 61 % of the time they had at their disposal. They paid him the most attention at the time before the entrance to the road and during the movement in the right traffic lane. The average time of observation of the figurant before the entrance to the road was 2.3 s, which is 86 % of the time 2.7 s that the drivers had at their disposal. In the right traffic lane, the figurant was moving for on average 2.5 s. During this time the drivers were directly watching him for on average 1.9 s, which is 76 % of the time they had at their disposal.

In the monitored stretch only seven drivers controlled continuously the situation behind the vehicle, while ten drivers did not use rear view mirrors. Only one driver controlled the situation behind the vehicle during deceleration process, four drivers controlled the situation behind the vehicle immediately after passing over the crossing. The determined times needed for control of the situation behind a vehicle with the differentiation of the time of the actual scene fixation in the rear view mirror are stated in Table 3.

[2] A reaction time of the driver of 1 sec and achievable deceleration of the vehicle 5.8 m/s^2 are taken in account in the calculation.

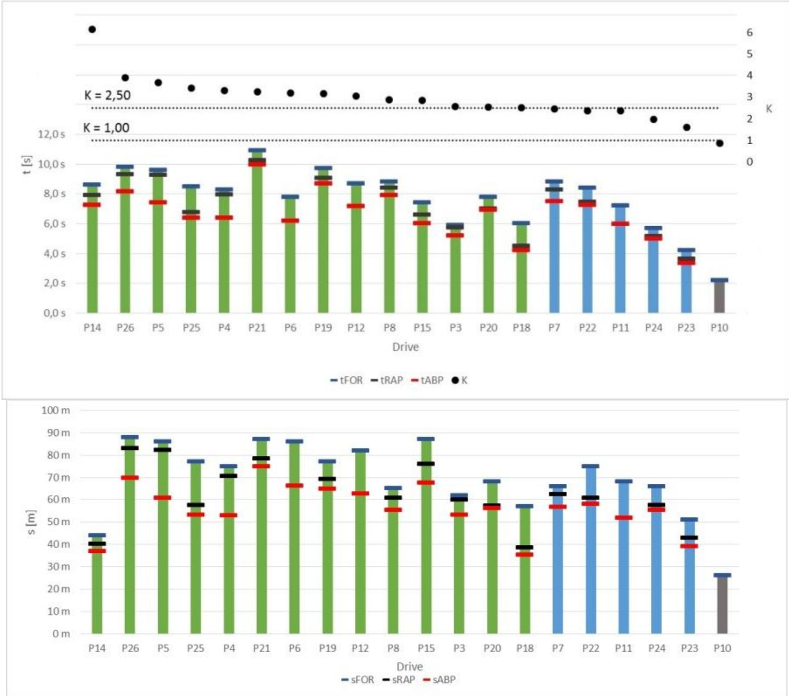

Fig. 4.

5.2. Evaluation of measurements on the CW2 crossing

The results of measurements on the CW2 crossing designed in a modern way and the performed evaluations are graphically compared in Fig. 5. Individual drives are, like those mentioned above, distinguished by colours according to the specified categories for the drive safety. They are sorted by the determined values of K coefficient. From the charts in Fig. 5 it is clear that nine out of twenty drivers managed to respond to figurant at a sufficient distance and also in many cases did not activate the braking pedal (K > 2.5), seven drivers had to brake heavily, although they did not need to stop the vehicle prior to the crossing. Three drivers had to brake to a stop. Only one driver reacted too late (K = 1.08). In this case the figurant realized the possible danger and did not even enter the road. The moments of the first optical reactions of the drivers, the moments of acceleration pedal release, brake pedal activation and corresponding distances between the vehicle and the crossing can be subtracted from the charts in Fig. 5.

The average values of characteristic quantities including length of reaction times and proportional times of observation of the figurant by the drivers are stated in Table 4. From observation of measurement, during which the figurant was crossing the road, it is clear that the average time from the FOR moment to the moment of vehicle pass over the crossing was 7.8 s. During this time the drivers directly observed the figurant for an average time of 5.0 s, which is 64 % of the time they had at their disposal. As in the case mentioned above, they paid him the most attention at a time of his movement on the right edge of the road and in the right traffic lane. The average time of observation of the figurant before the entrance to the road was 3.4 s, which is 81 % of the time 4.1 s that the drivers had at their disposal. In the right traffic lane, the figurant was moving for on average 1.9 s. During this time the drivers were directly watching him for on average 1.4 s, which is 71 % of the time they had at their disposal.

In the monitored stretch only seven drivers of twenty continuously controlled the situation behind the vehicle. Three drivers controlled the situation behind the vehicle during deceleration process, five drivers controlled the situation behind the vehicle immediately after passing over the crossing. The determined times needed for control of the situation behind the vehicle are stated in Table 5. A time of the actual scene fixation in the rear view mirror is stated separately.

5.3. Evaluation of measurements on the CW3 crossing

The results of measurement on the CW3 crossing and the performed evaluations are graphically compared in Fig. 6. Individual drives are, like those mentioned above, distinguished by colours according to the classification in categories for the drive safety. They are sorted by the determined values of K coefficient. From the charts in Fig. 6 it is clear that while six of the twenty drivers managed to respond to the figurant at a sufficient distance (K > 2.5), nine drivers had to brake intensively, although they did not need to stop the vehicle prior to the crossing. Three drivers had to brake to a stop. Two drivers reacted too late (K = 1.2). In this case the figurant realized the possible danger and did not even enter the road. The moments of the first optical reactions of the drivers, the moments of accelerator pedal release, brake pedal activation and corresponding distances between the vehicle and the crossing can be subtracted from the charts in Fig. 6.

The average values of characteristic quantities including length of the reaction times and proportional times of observation of the figurant by the drivers are stated in Table 6. From observation of measurements, during which the figurant was crossing the road, it is clear that an average time from the FOR moment to the moment of vehicle pass over the crossing was 6.9 s. During this time the drivers directly observed the figurant for an average time of 4.3 s, which is 63 % of the time they had at their disposal. They paid him the most attention at the time of his movement on the right edge of the road and in the right traffic lane. The average time of observation of the figurant before the entrance to the road was 2.6 s, which is 80 % of the time 3.2 s that the drivers had at their disposal. In the right traffic lane, the figurant was moving for on average 2.1 s. During this time the drivers were directly watching him for on average 1.5 s, which is 71 % of the time they had at their disposal.

In the monitored stretch only three out of the twenty drivers continuously controlled the situation behind the vehicle. Only one driver controlled the situation behind the vehicle during the deceleration process, while three drivers controlled the situation behind the vehicle immediately after passing over the crossing. The determined times needed for control of the situation behind the vehicle with the differentiation of a time of the actual scene fixation in the rear view mirror are stated in Table 7.

6. Conclusion

The article demonstrates the possibilities of the investigation of driver's conduct under various road traffic conditions. It points to new possibilities of danger quantification in the areas of pedestrian crossings using K coefficient that enables the quantification of the frequency of dangerous situation occurrence and consideration of the influence of a given traffic solution on road traffic safety. Twenty measurements were compared on three pedestrian crossings designed in various ways. The evaluation results show significant differences in the frequency of the occurrence of dangerous situations. While on the CW1 crossing one critical situation occurred and not even once did the drivers need to brake heavily until a stop, on the CW3 crossing, designed in a modern way, one critical situation occurred as well, but also three situations in which the drivers had to brake until a stop took place. Proper illumination of the area of the figurant's entrance to the road turns out to be an important element in increasing safety level on the CW1 crossing. It is not, however, a complex solution as the area of pedestrians' entrance from the left side in the driving direction of the testing vehicle is illuminated only insufficiently. The well-marked central traffic island, which is a significant visual stimulus for the drivers and draws their attention to a potential danger, turns out to be an important element increasing safety level on the CW2 crossing. The most dangerous situations occurred on the CW3 crossing as two critical situations and three situations requiring braking until a stop took place there. The view limitation in the area of figurant's entrance to the road turns out to be significant by the CW3 crossing.
The $K = 1$ coefficient value, characterizing critical situations, turns out to be characteristic in all cases. All three figurants, under different conditions and independently of each other, evaluated the dangerous situations characterized by the K value close to one as highly dangerous and did not enter the road. At the same time, it turns out that the $K > 2.5$ value properly characterizes expected situations as under these conditions the time from the FOR (of the driver) moment to moment, when the driver starts to adjust the way of driving, extends significantly. The possibility of using records from the driving tests for the identification of risk factors limiting the possibilities of the driver to respond to important stimuli is also the advantage of the eye tracking method.
From the comparison of the reaction time needed for brake pedal activation (see Fig. 7) it is clear that increasing hazardousness of the driving situation arouses the need of its immediate solution and leads to the reaction time reduction. The lower border is, however, naturally limited by human capabilities. It turns out, nevertheless, that in visibility reduced by darkness a reaction time not exceeding one is achievable in a critical situation. On the contrary, the rate of driver's attention (see Fig. 8) grows with increasing hazardousness of the driving situation. The shorter time a driver has to find a solution to the driving situation, the larger part of the time at his disposal he devotes to direct observation of the dangerous object. The most attention was paid to the figurant (by the drivers) before his entrance to the road and during his movement in the right traffic lane and mainly in the time of his movement in the corridor of vehicle pass.

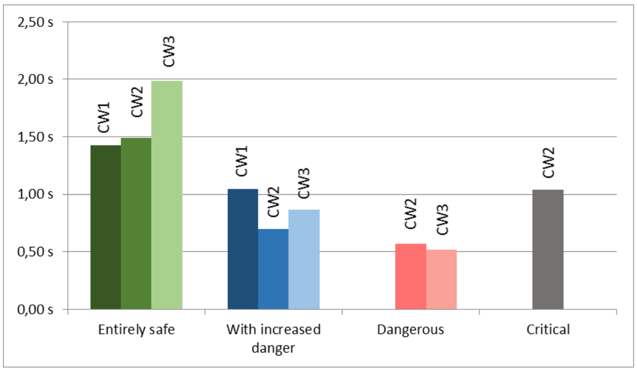

Fig. 7.
All measurements – an average time from the FOR moment to the braking pedal activation moment (or reacting time)

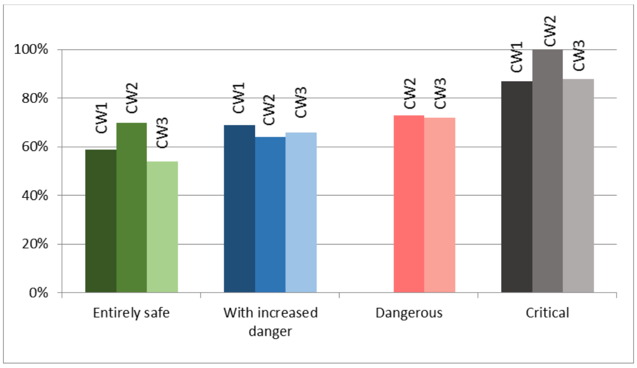

Fig. 8.
All measurements – an average rate of attention that the driver paid to the figurant from the FOR moment to the moment of vehicle pass over the crossing – Att

It turns out that a cause of dangerous situation occurrence can even be an inappropriately chosen moment for control of the situation behind the vehicle using rear view mirrors. During a critical drive on the CW2 crossing (P19 measurement) the driver controlled, by looking into the rear view mirror, the situation behind the vehicle without any evident external stimulus at a distance of ca. 45 m prior to the crossing. This operation lasted for about 1.3 s and the driver noticed the figurant only at a distance of 29 m prior to the crossing. If the figurant entered the road, a very dangerous situation would undoubtedly take place. In the case of other drivers controlling the situation behind the vehicle in the area of the crossing, three drivers have done so after stopping the vehicle and four drivers have done so after significant speed reduction before the crossing. Four drivers observed the figurant in the rear view mirror after they passed over the crossing. An average time needed to look in the rear view mirror, fixation of the scene in the rear view mirror and change of a look back was on average 0.88 s.

APPLICATION OF WATERBORNE ROAD MARKING PAINT IN CROATIA: TWO YEARS OF ROAD EXPOSURE

Tomasz E. Burghardt[1], Darko Babić[2], Dario Babić[3]
[1] M. Swarovski GmbH, Industriestrasse 10, 3300 Amstetten, Austria
[2,3] University of Zagreb, Faculty of Transport and Traffic Sciences, Vukelićeva 4, 10000 Zagreb, Croatia

Abstract: Waterborne road marking paints with various glass beads were applied two years ago at a test field in Croatia, on a road with Averaged Daily Traffic (ADT) of 8469 vehicles. Retroreflectivity (R_L) was measured periodically using a dynamic test method and the results are provided herein. Performance of the evaluated systems depended mostly on the utilised glass beads, with high-performance glass beads of exceptional roundness and surface quality clearly furnishing the highest R_L after the two seasons; indeed, the systems consisting of waterborne paints and those high-performance glass beads appear to be suitable as three-year marking material. With other evaluated glass beads, all systems were also clearly passing after two years. For the systems durability, the role of road marking paint was secondary, which is expected in the cases where the glass beads are of high quality and appropriately matched. High-performance waterborne paint was somewhat better than the standard fast-dry material. Overall, waterborne paints were found to be an excellent choice, somewhat outperforming simultaneously applied solventborne paints. Their lesser environmental impact is an additional benefit that should be considered.

Keywords: horizontal road markings, waterborne road marking, glass beads, retroreflection, road safety.

1. Introduction

Improvement of road safety is one of the priorities for the European Union (EU). In 2010, an ambitious plan to lower accident rates on EU roads by 50% within the decade has been undertaken. So far, the results seem promising, but the target may still be difficult to reach: In 2014 on EU roads there were reported 1 079 800 vehicular accidents, in which 26 009 people lost their lives and 1 419 800 were injured. That is a meaningful drop since 2010, when in 1 130 484 accidents died 31 490 people (European Road Statistics, 2016).
Horizontal road markings, which guide the drivers, play a meaningful role in accidents reduction. Miller (1992) reported a 20% drop in accidents on roads marked with both edge and centre lines. Subsequent findings not only confirm it, but also pinpoint that their effectiveness is particularly prominent during poor visibility conditions (Migletz et al., 1994), which can be possible because of their retroreflection.

2. Horizontal road markings systems

Horizontal road markings are systems consisting of a pigmented layer and reflective elements. The pigmented materials are usually paints, either water- or solvent-borne. The use of thick-layer durable systems like coldplastics and thermoplastic materials is also frequent, particularly on roads exposed to heavy traffic. There are also several less commonly used marking materials like tapes, epoxy paints, urethane-based systems, or solvent-less acrylic-modified products. Road marking materials were recently reviewed by us (Babić and colleagues, 2015).
The second inalienable part of the road marking systems are glass beads (alternatives to glass beads do exist, but are generally not used because of economic reasons), which furnish retroreflectivity and also protect the paint from abrasive action of traffic. The most commonly used standard glass beads of diameters between 100 and 800 µm are prepared by flame attenuation of ground recycled float glass. Preparation of larger beads, reaching even 2000 µm in diameter, is possible by atomization of virgin glass melt. All prepared glass beads ought to have surface free of defects, be devoid of air bubbles, and be at least 80% round.
Refractive index (RI) is a property related to glass composition: Standard glass beads have RI of 1.5, high-index beads are defined as those with RI above 1.9. Glass beads with high RI are capable of providing significantly larger R_L, exceeding even 2000 mcd/m²/lx, whereas standard glass beads furnish typically about 400 mcd/m²/lx. However, glass beads with high RI are rather costly due to the production process and raw materials and their surface is quite prone to scratching. Therefore, they are seldom used for road marking.
Swarco-proprietary SOLIDPLUS technology permits for preparation of glass beads with low RI, but with retroreflectivity enhanced to reach even 1000 mcd/m²/lx under laboratory conditions. Furthermore, SOLIDPLUS glass beads have high resistance to scratching, as can be seen in Fig. **1**: For the test, the glass beads were embedded in a standard road marking material, subjected to abrasion, and evaluated under a microscope: high-index glass beads failed due to numerous scratches (Fig. **1** centre), standard glass beads passed as only a few scratches were observed (Fig. **1** left), and SOLIDPLUS glass beads were superior with almost no scratches (Fig. **1** right). Such abrasion resistance translates to higher retroreflectivity in the field after exposure to numerous vehicles passing.

[1] Corresponding author: Tomasz.Burghardt@swarco.com

Fig. 1.
Glass beads after abrasive testing: Visible scratching in standard glass beads (left), severe scratching in high-index beads (centre), and almost absence of scratches in SOLIDPLUS product (right)

To provide highest retroreflection, glass beads must be embedded in the pigmented layer at about 50%, as has been shown, based on theoretical calculations, by Grosges (2008). Our proprietary observations confirm the findings. Only with **appropriate application technique** and **correct selection of glass beads** one can achieve the optimum embedment, which is shown in Fig. **2** below. In addition to embedment, appropriate coating of glass beads to furnish chemical adhesion to the road marking materials is critical.

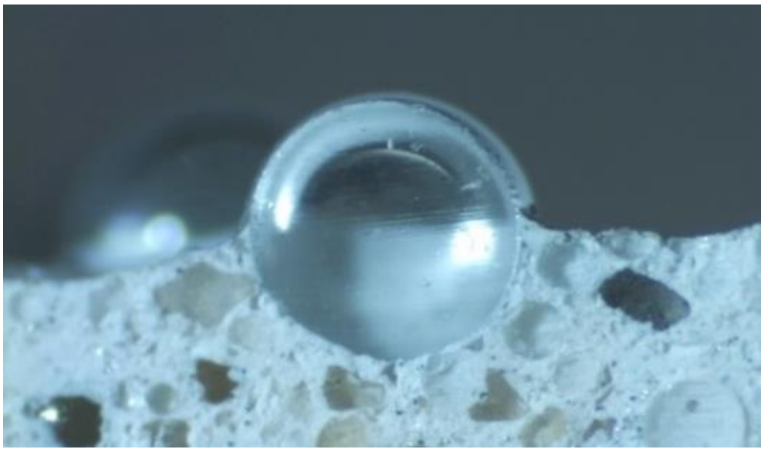

Fig. 2.
Cross-section of a road marking material with a properly embedded glass bead

Despite the fact that the SOLIDPLUS technology is more costly than preparation of standard glass beads, the additional R_L and improved scratch resistance are affordable benefits. SOLIDPLUS beads can be freely blended with standard materials to provide affordable solutions to benefit the applicators seeking fulfilment of the minimum R_L requirement for performance contracts.

3. Road test in Croatia

We have reported the successful application of two waterborne road marking paints and two standard solventborne paints in Croatia (Babić and colleagues, 2015). For the evaluation, various combinations of paints, paint thicknesses, and glass beads were applied as edge lines and single centre line (either solid or intermittent where passing is permitted). Coating of glass beads was matched to the used paints to maximise their adhesion and the beads contained 20% of anti-skid additives to assure appropriate skid resistance and safety under wet conditions. Each of the test areas were 500-m long (in two reported cases 250 m and in one only 100 m). The initial results were meeting the expectations. At present, we can report results after 21 months of normal road usage. The selected road near Zagreb, Croatia, has ADT of 8469 vehicles; hence, the systems were subjected to traffic of 5.3 million vehicles. In addition, there was a snow plough activity during the two winters.
Measurements of R_L were done with a dynamic method, recently described by Babić and co-workers (2014). The readings were done with retroreflectometer ZDR 6020 (Zehntner; of Sissach, Switzerland) mounted on a side of a vehicle, as shown in Fig. **3**. Data collection was done during normal driving, at speeds up to 90 km/h permitted on the test site. This convenient method allows for collecting data every few milliseconds, which is then averaged by the software for 25-m intervals. Additional measurements done with static method are not provided here; however, we can disclose that the results were sufficiently similar. Data collected two weeks after the application was assumed as initial, as is customary in road marking industry.

Areas where the markings were visibly dirty from farming or construction activities, damaged due to road work, or in places that were somehow obscured were marked during data collection; hence, such areas were removed from the results reported herein.

Fig. 3.
Vehicle with side-mounted retroreflectometer

4. Results and discussion

The results achieved with selected road marking systems are provided in Table 1. Averages of results given by the software are reported. In most of the cases, standard deviations were quite low – they are given in Table 1 in parentheses.

The two systems with solventborne paints, toluene-containing (system 1) and aromatic solvents-free (system 2), applied at the edge line on a straight road stretch, furnished good results, meeting the retroreflectivity requirements throughout the test. The systems lost 40-45% of the initial R_L, which is quite a good result. The system without aromatic solvents performed worse than the toluene-based system – not only the initial R_L was lower, but also at the end of exposure lowest R_L amongst all of the systems was measured. Such performance may be expected, because of the use of toluene, which is a good choice for paint, but a very poor choice for environmental reasons (Burghardt et al., 2016). In particular, the ozone-formation capability of toluene is a concern in high-insolation areas, as is being reported separately during this Conference (Burghardt et al., 2016b).

Performance with fast-dry waterborne paint W13 depended on the used glass beads. Systems where SOLIDPLUS glass beads were used performed admirably, either as an edge line (SOLIDPLUS30, containing 30% of SOLIDPLUS glass beads, system 3) or as a short 100 m stretch centre line with passing permitted (SOLIDPLUS100, containing exclusively SOLIDPLUS glass beads, system 4). The loss of R_L was only 12-36%, which is a proof of excellent glass beads adhesion and also resistance of SOLIDPLUS beads to scratching. Paint W13 also performed well at centre line with large glass beads SWARCOLUX50 (glass beads targeting Type II road markings, system 5).

High-performance waterborne paint W15 consistently outperformed the other evaluated systems. The highest retroreflectivity was expectedly obtained with SOLIDPLUS glass beads (system 7 and system 8). It should be noted that system 8, even though it was applied as solid centre line, was located at a road curve, which put more stress on the markings. R_L loss of 36-43% seemed quite high, but still – because of very high initial R_L – these systems could last for another two seasons before the drop below 150 mcd/m²/lx would occur. We assume here the validity and importance of the recently proposed 150 × 150 formula as a standard for horizontal road marking performance (Mosböck, 2016).

The performance of paint W15 with large glass beads SWARCOLUX50 was equally good at edge line with 400-µm and 600-µm wet film applications and at the centre line with 600 µm wet film build (corresponding systems 6, 9, and 10). R_L loss at edge line was lesser than at the centre line (24-36% loss of R_L at edge line, as compared to 52% at the centre), which was according to the expectations.

The use of very large MEGALUX-BEADS® (suitable for Type II markings, systems 11 and 12) also gave surprisingly good results. This is quite important, because with such large glass beads the embedment had to be significantly less than optimal – obviously, chemical interaction between the glass beads coating and the paint permitted for retention of the beads for two seasons and maintaining the required retroreflectivity. R_L loss throughout the exposure period was expectedly high, over 50%. The use of a drying accelerator for the paint did not meaningfully affect the performance. The drying accelerator, intermixed with glass beads, is capable of significant accelerating of drying and development of washout resistance of quick-set waterborne paints (Babić and colleagues, 2015), which is particularly important during marginal application conditions of low temperature and high relative humidity.

Glass beads adhesion to solventborne paints was worse than measured with waterborne paints, which becomes obvious only after considering that for waterborne paints larger glass beads were used (i.e. there was more stress on them). The R_L loss serves as confirmation. The large glass beads are generally not suitable for solventborne paints, because of the paints' poor film formation at thicknesses over 400 µm.

Table 1

Road testing results: Retroreflectivity

System, location	**Paint (applied wet film build) + glass beads type and size range [µm][(a)]**	**—— Retroreflectivity [mcd/m²/lx][(b)] ——**			
		Initial	**10 months**	**21 months**	**Loss**
1, edge line	Solventborne toluene-containing (400 µm) + SWARCOLUX50 200-800	425 (50)	317 (25)	233 (30)	-45%
2, edge line	Solventborne aromatic-free (400 µm) + SWARCOLUX50 200-800	385 (51)	234 (44)	183 (32)	-40%
3, edge line	Waterborne W13 (400 µm) + SOLIDPLUS30 300-1000	516 (81)	527 (60)	329 (57)	-36%
4, centre line, passing[(c)]	Waterborne W13 (400 µm) + SOLIDPLUS100 212-850	623 (84)	679 (57)	476 (156)	-24%
5, centre line, passing	Waterborne W13 (400 µm) + SWARCOLUX50 212-1400	265 (35)	180 (12)	233 (8)	-12%
6, edge line	Waterborne W15 (400 µm) + SWARCOLUX50 212-1400	343 (87)	365 (54)	261 (62)	-24%
7, edge line	Waterborne W15 (400 µm) + SOLIDPLUS30 300-1000	455 (52)	370 (37)	291 (24)	-36%
8, centre line, no passing[(d)]	Waterborne W15 (400 µm) + SOLIDPLUS100 212-850	697 (46)	543 (36)	396 (25)	-43%
9, edge line	Waterborne W15 (600 µm) + SWARCOLUX50 212-1400	338 (53)	290 (52)	231 (40)	-32%
10, centre line, passing	Waterborne W15 (600 µm) + SWARCOLUX50 212-1400	358 (21)	297 (28)	215 (36)	-52%
11, centre line, no passing	Waterborne W15 (600 µm) + MEGALUX-BEADS® 600-2000	422 (22)	276 (42)	204 (47)	-58%
12, centre line, no passing[(d)]	Waterborne W15 accelerated (600 µm) + MEGALUX-BEADS® 600-2000	455 (22)	280 (54)	192 (33)	-52%
(a) In all of the cases, glass beads were applied at 400-450 g/m². (b) Average of the collected measurements, less areas of visible dirt and other unrelated imperfections. Standard deviations are given in parentheses. (c) Stretch only 100 m. (d) Stretch only 250 m.					

In summary, the performance of road marking systems depended more on the glass beads than on the pigmented layer. It is expected in all of the systems where there is an appropriate match between the glass beads, glass beads coating, and the paint. Chemical and physical interactions assure good adhesion of the reflective elements, which protect the paint and thus furnish long-lasting road marking systems. These results overall match those presented at Transportation Research Arena by Burghardt, Pashkevich, and Żakowska (2016a) from a different test field and different arrangement of the markings.

5. Conclusions

Road marking systems consisting of waterborne paints reflectorised with high quality glass beads were shown to be a viable alternative to the currently used solventborne paints. The best performance was measured with SOLIDPLUS glass beads, which due to their exceptional finish and roundness provided systems that after two years had retroreflectivity exceeding 400 mcd/m²/lx. Since the retroreflectivity loss over two seasons was less than 50%, it might be possible that such systems are capable of providing three or even four-season durability. The use of other glass beads provided excellent results as well – in none of the cases retroreflectivity drop below 150 mcd/m²/lx was recorded.

Environmental advantages of the use of waterborne road marking systems are obvious in light of the high system durabilities reported herein.

THE COMPARISON OF THE ACCIDENT RATES IN HEAVY TRANSPORT SECTORS OF EUROPE AND USA

Jonas Matijošius[1], Kristina Čižiūnienė[2], Artūras Petraška[3], Edgar Sokolovskij[4]
[1,2,3,4] *Vilnius Gediminas Technical University, Vilnius, Lithuania*

Abstract: Heavy transport vehicles are the main units in the supply chain system. In one hand, it is very important to vouch the efficient system work, to prevent the accidents, on another hand to minimize the system costs. This is very important in the two biggest world economics – Europe and USA. The comparison of the accident rates - the distribution of traffic events that cause deaths according to types of event sites, traffic event situations (collisions against motorcyclists and bicyclists, cars) were presented at this article.

Keywords: accident rates, Europe, USA, transport sectors.

1. Introduction

In Europe, a collision of a car with a truck often results serious injuries or even deaths of the drivers. Most frequently, the driver of the car is a causer of the traffic event. As it is emphasized in a majority of papers, a probability of coming into collision with a truck is much lower than with another vehicle (Dell’Acqua et al., 2016). A probability of causing a traffic accident by a truck is 3 times less, as compared to a car. A low number of such accidents may be explained by the circumstance that heavy trucks are usually used on highways or other roads where the relative accident rate is considerably lower; however, such accidents, as a rule, cause serious injuries or deaths.
As it is pointed out in the report of „Volvo Trucks“ on traffic safety and traffic events on European roads, nine of ten traffic events where load-carrying vehicles are involved are caused by human factors. According to Kleinauskas (2013), 90% of total number of traffic events where trucks are involved occur because of human factors (unduly estimation of the road trajectory, fatigue, inattention and so on). In majority of traffic events where drivers of load-carrying vehicles suffer, no vehicles of other types are involved. The most frequent cause of a traffic event is off-going of a truck.
The aim of article – to compare the accident rates in heavy transport sectors of Europe and United State of America.
The tasks of the article:

- To make overview of traffic event causes in USA and Europe;
- To identify causes of heavy transport traffic events.

2. The analysis on traffic event causers in USA and Europe

One of the topical problems of heavy transport sector is an ignorance of safety belts by the drivers: over a half of the total number of drivers involved in truck driving on European roads do not use the safety belts. On collisions of trucks with cars, 36% of car drivers violated at least two provisions of the traffic rules, whereas only 11% of truck drivers committed several offences simultaneously. The report of „VOLVO Trucks“ for the year 2013 that drink-driving was not one of the main causes of traffic events (where drivers of trucks were involved) (Kleinauskas, 2013). Only 0.5 % of truck drivers having caused a serious traffic event were intoxicated by alcohol or other psychotropic substances. However, 15–20% of car drivers having caused a serious traffic event were intoxicated by alcohol or other psychotropic substances. So, it is notable that this difference is considerable. The groundless public opinion on truck driver as alcohol users may be ignored (Detailed Star Rating, 2014; Zefreh and Török, 2016).
The diagrams of the most frequent causers of traffic events have been preliminary formed. Let’s compare the situation in Europe and USA. In all traffic events where at least one load-carrying vehicle was involved, the causers were distributed as follows:

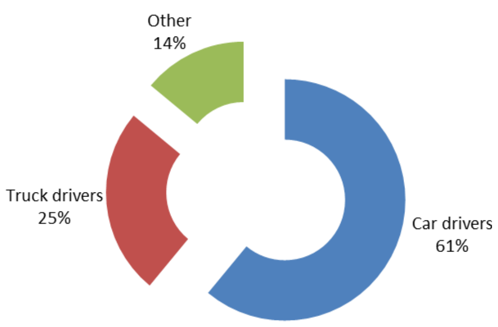

Fig. 1.
The analysis on traffic event causers in USA

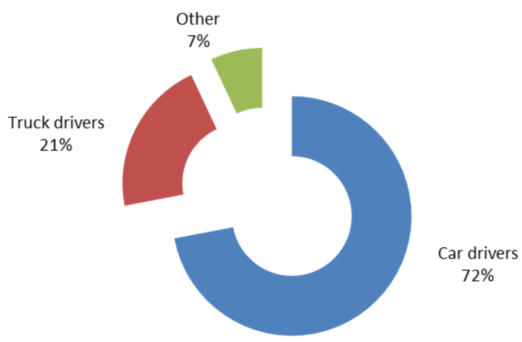

Fig. 2.
The analysis on traffic event causers in Europe

[1] Corresponding author: jonas.matijosius@vgtu.lt

Both in Europe and USA, the statistics show that car drivers cause from 61% to 72% of the total number of traffic events. The statistical data are very much alike. Drivers of trucks cause only 23% of the total number of traffic events. Other causes of traffic accidents include technical problems of the vehicles, weather conditions or the road surface defects.

3. The causes of traffic events

The statistics shows that a majority of traffic events world widely occur in towns; however, the events that cause deaths are distributed as follows:

Fig. 3.
The distribution of traffic events that cause deaths according to types of event sites

Both in Lithuania and other European Union Member States, most traffic deaths occur out of towns. Because velocities of vehicles are higher out of towns, the consequences of traffic events there are more serious. 64% of traffic deaths occur on roads out of towns and 36% – in towns. On comparing all traffic deaths, the following distribution is revealed.

Table 1
The distribution of traffic deaths

Traffic participants	USA	Europe
Car drivers and passengers	76%	54%
Bicyclists, motorcyclists and pedestrians	9%	40%
Truck drivers	15%	6%

Source: Detailed Star (2016)

In America, 76% traffic fatalities caused by a collision with a truck are deaths of car drivers and passengers. However, in Europe this indicator is lower – 54%. Within the territory of USA, deaths of bicyclists and motorcyclists are caused only by 9% of the total number traffic events. In Europe, this indicator is 40%. Why? We think the cause includes a number of aspects. First, highways are broader in USA; second, choppers are very popular there for a long time, so people got used to meet them. The last aspect is related to truck drivers: within the territory of USA they die in 15% of the total number of traffic accidents caused by a collision with the truck, whereas in Europe – in 6% of total number of traffic accidents. The said indicators may appear to be unexact, because sometimes only one driver survived after an accident and his history could be incorrect (Ministry of Transport and Communication, 2014).
According to data from Michigan University, after analysis of 8’309 traffics events where trucks were involved, it was found that car drivers caused 89% of front collisions and 88% of lateral collisions against an oncoming heavy vehicle; in addition, they caused 80% rear-end collisions and 72% lateral collisions on movement of both vehicles in the same direction (Godoy et al., 2015).
American National Highway Traffic Safety Administration has analyzed 10’092 traffic accidents and provided similar figures. According to its data, 91% of front or lateral collisions against oncoming vehicles were caused by car drivers. In addition, they were responsible for 71% of front collision and 77% of lateral collisions on movement in the same direction (Godoy et al., 2015).
In addition, in course of the research, the most frequent causes of traffic events were established:

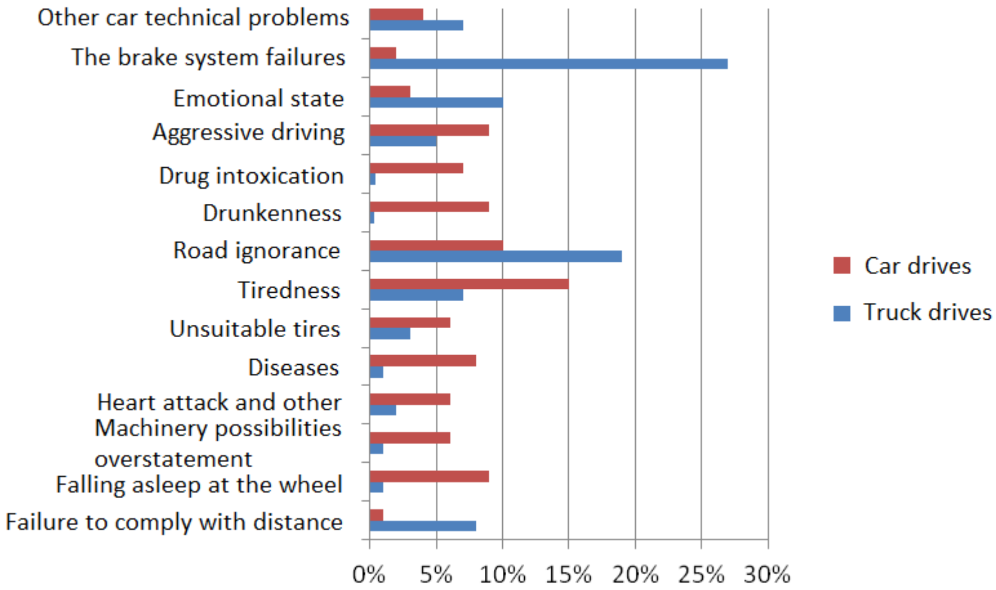

Fig. 4.
The causes of traffic events

The most frequent cause of a traffic event for a load-carrying vehicle is a fault of its braking system (27%). In our opinion, this indicator is too high. In course of the analysis of studies by other authors, no data supporting the statement that a majority of traffic events are caused by a fault of the brakes were obtained. Car drivers most commonly cause traffic events through their fatigue (15%). The concept of fatigue is hardly determinable, because each person may subjectively assess, whether he (she) is tired or not. Usually a driver perceives a lack of sleep or rest. The other aspect is poor awareness of the road (19%). This indicator is high both for cars and the heavy transport sector. Each driver ever experienced the stress caused by poor awareness of the road: at such a moment, the behavior of the driver becomes irresponsible and he may cause an accident situation with serious consequences. Other factors that may cause traffic events include sleep-driving, safe distance ignorance, unfit tires and so on (Novikovienė, 2009; Li and Fratrović, 2016).
A majority of studies confirm that usually traffic injuries or traffic deaths occurred in the following situations:

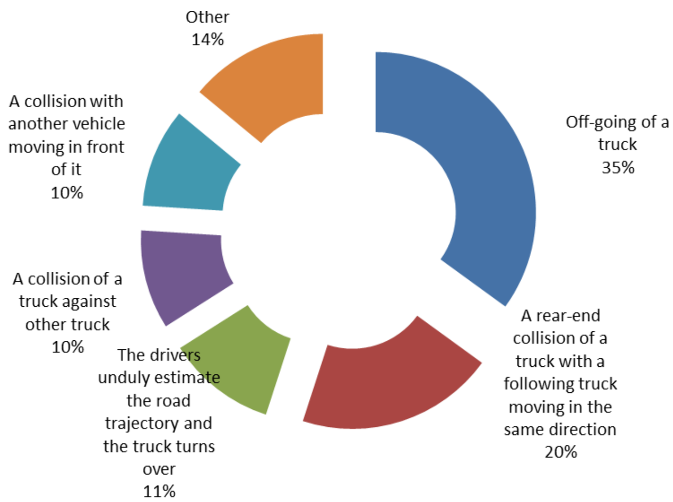

Fig. 5.
Traffic events

It was found that a majority of traffic event was caused by off-going of a truck (35%). The causes of this factor are abundant, including the slippery road surface or fatigue of the driver. They also may include road dimples that violate the uniform movement of the truck or other causes. Other very frequent situation is a rear-end collision of a truck with a following truck moving in the same direction (even 20% of cases). Many traffic events are caused when the drivers unduly estimate the road trajectory and the truck turns over (11%). 10% of traffic situations are formed separately by a collision of a truck against other truck or another vehicle moving in front of it. After all the above-mentioned situations, a survival of the driver is almost impossible (Kleinauskas, 2013).
The numbers of heavy injuries or deaths of drivers and passengers of cars after a collision against a truck in the totality of such traffic events:

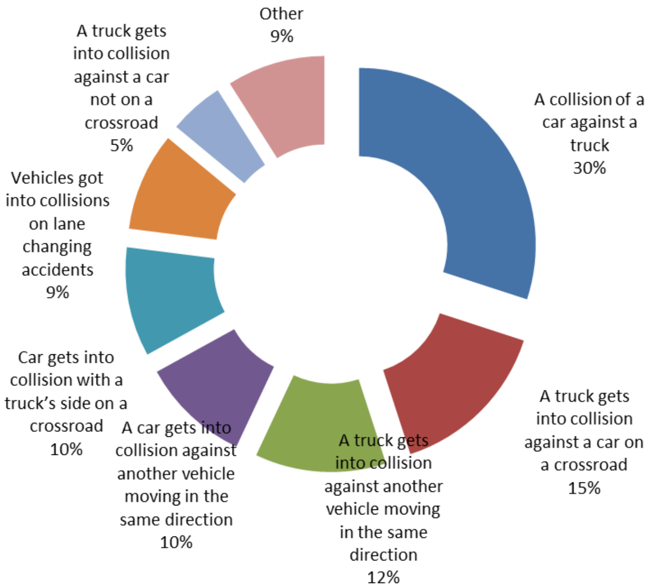

Fig. 6.
Traffic event situations (a collision against a car)

It was found that a probability of survival or avoidance of serious injuries on a collision of a car against a truck (the rate of such situations is up to 30%) is low. A higher probability of avoidance of a serious injury or death is typical for a situation, when a truck gets into collision against a car on a crossroad. Maybe, it is caused by considerably lower velocities at crossroads (Buzási and Csete, 2016). Very frequently, a truck gets into collision against another vehicle moving in the same direction or a car gets into collision with a truck's side on a crossroad. Drivers and passengers also suffered injuries when vehicles got into collisions on lane changing accidents (9%) (Kleinauskas, 2013).
The remained part of the injured and killed includes motorcyclists, bicyclists and pedestrians. When they are involved in traffic events, they suffer serious injuries, if:

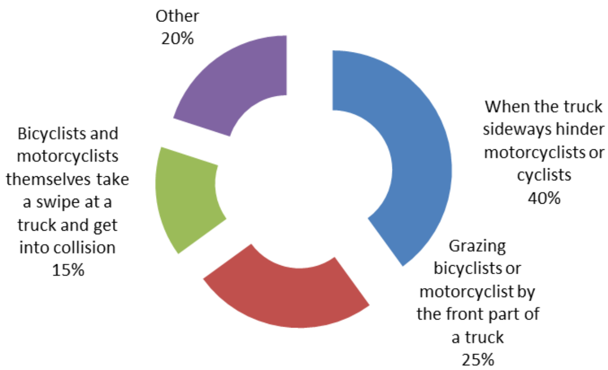

Fig. 7.
Traffic event situations (collisions against motorcyclists and bicyclists)

Usually, in case of a sideswipe by a truck, avoidance on injury of the motorcyclist or the bicyclist is almost impossible. Such traffic events form 40% of all traffic events. Many traffic events are caused by grazing bicyclists or pedestrians by the front part of a truck. It seems to be strange but bicyclists and motorcyclists themselves take a swipe at a truck and get into collision against it in 15% of situations. We have not found such high percentage in studies by other authors however, such situations when a motorcycle moving with a high velocity takes through a carelessness of its driver a swipe at a truck vehicle sometimes occur (Gaddam et al., 2016; Gaal et al., 2015).
In summary, it may be stated that a probability of causing a traffic event by a truck is considerably lower, as compared to other types of vehicles (for example, it is 3 times lower, as compared to a car). The groundless public opinion on heavy drinking of truck drivers should be denied. In course of various studies in was found that only in 0.5% of traffic events where at least one truck was involved the drivers were intoxicated by alcohol, whereas this indicator for car drivers amounts to 17.5%. Talking of the distribution of traffic events, it should be stated that the number of traffic deaths out of towns is higher, as compared to towns. This difference is caused by considerably higher velocities of vehicles out of towns. Most frequent causes of traffic events are various – they vary from a fault of the vehicle to poor awareness of the road. Frequently, traffic events are caused by sleep-driving or ignorance of a safe distance. However, a majority of traffic event are caused by off-going of a truck (35%). Very frequently, traffic events are caused by taking a swipe of a truck at another truck that moves in front of it and so on (Kleinauskas, 2013).

4. Conclussions

1. An analysis of the conception of accident rate in scientific literature shows that its key element is a vehicle. However, it should not be forgotten that a bicyclist or even a pedestrian may be involved in a traffic event. So, it is spoken about persons whose actions may be directly or indirectly important for a traffic event.
2. According to causes of their appearance, traffic events are classified to those occurred through a fault of humans, impact of natural forces or by a matter of chance. Errors of drivers while driving the vehicles are the principal cause of a majority of traffic events. Other causes of traffic accidents include technical problems of the vehicles, weather conditions or the road surface defects.
3. One of the main problems of heavy transport sector in Europe is an ignorance of safety bells by the drivers.
4. The main causes of heavy transport traffic events are: malfunction of brake system; unawareness the road; emotional conditions; failure to comply with the distance; fatigue.
5. The completed analysis of scientific literature showed the existing situation of accident rates in the heavy transport sector and disclosed its problems both in Europe and USA. It was concluded that most frequently traffic events occur through a fault of drivers. Talking of the situation of accident rates in the heavy transport sector, it should be stated that the situation is being improved, but this process is slow, in spite of increasingly growing number of traffic safety measures.
